In our recent report on using the ^{13}C cross-polarization (CP) NMR technique to characterize the organic matter in whole soils[1], we discussed the limitations of the technique in terms of resolution and the improvements possible using 'magic-angle' sample spinning (MAS). We now report experiments on a soil and a brown coal in which these techniques have been combined. The spectra provide information on the chemical structure of the materials and throw new light on the nature of the various types of carbon in coals and humic materials.

Although carbonaceous substances such as coals and humic materials are among the most widely distributed and important natural products on the Earth, there have been few techniques available by which their intimate chemical structure could be obtained. However, NMR techniques have allowed semi-quantitative estimations of aromatic carbon in coals[1-3] and whole soils[1] to be made. Recently, high power cross-polarization techniques coupled with magic-angle spinning[4] have improved quantification, through increased resolution, enabling better estimates of the aromaticity of coals[5] and humic substances[6]. High field techniques have also been used to obtain structural information on coals[7] and soils[8], but research here has had to be confined to soluble material.

We have combined the ^{13}C CP-MAS technique with the use of high fields to obtain spectra at 75 MHz for a New Zealand silt loam and an Australian brown coal xylite fraction. The spectra (Fig. 1) consist of many broad resonances, each of which gives information on the structural environments of the carbon atoms present.

A major problem with obtaining ^{13}C CP-MAS spectra is the need to spin at speeds sufficient to remove both the chemical shift anisotropy (CSA) of highly anisotropic carbons (that is, aromatic and carboxyl carbons) and the spinning sidebands from the chemical shift range. As the CSA is field dependent, the required spinning speed increases with increasing field strength and speeds of the order of the CSA are usually considered necessary. At 75 MHz, experiments would have to be performed at speeds in excess of 7 kHz, which are not technologically feasible at present. However, Stejskal *et al.*[9] have shown that an anisotropy of ~3 kHz is effectively removed at spinning speeds of ~1 kHz but at the expense of an increase in spinning sideband intensities. The spinning speeds we have used at 75 MHz (3.2–3.6 kHz) should be sufficient to remove large anisotropies effectively and hence reveal the expected resolution advantage of high fields. The increased problem of spinning sidebands is difficult to solve but, because their position depends on the spinning rate, their contribution can be reduced by multiplication of spectra obtained at significantly different spinning speeds.

Figure 1*a* shows the ^{13}C CP-MAS spectrum of Maungatua silt loam. We have previously obtained a 22.6 MHz ^{13}C CP spectrum[1] which indicated that the silt loam was largely aliphatic and highly oxygenated. The high field CP-MAS (3.2 kHz) spectrum confirms these conclusions and provides greater detail. However, as a consequence of the low carbon content of the soil (22% C) the spectrum is complicated by resonances from the rotor (perdeuterated polymethylmethacrylate[9]).

^{13}C resonances in the spectrum can be assigned if it is assumed that the isotropic chemical shifts (δ) in such solids are not significantly (±3 p.p.m.) different from those found in solution[10,11]. The spectrum can be divided into four regions: δ 10–50 p.p.m. (aliphatic carbon), δ 50–110 p.p.m. (oxygenated alkyl carbon), δ 100–160 p.p.m. (aromatic and alkenic carbon) and δ 160–220 p.p.m. (carbonyl carbon).

The strong group of resonances at ~δ 176 p.p.m. arises from carboxyl carbon in the soil and/or the rotor. Clearly carboxyl carbon is only a minor contributor to this soil. The O-alkyl region exhibits signal over the range δ 50–110 p.p.m. with the resolved resonance at δ 74 p.p.m. indicating oxygen-bonded carbons in ethers other than methoxy or ethoxy, or possibly ring carbons in polysaccharides. That the O-alkyl region extends to greater than 100 p.p.m. would be consistent with the presence of polysaccharides[12]. Unfortunately, the methoxy and methyl ester region is complicated by strong rotor resonances (δ 55–51 p.p.m.) and therefore we cannot comment on the presence of these groups.

The alkyl region contains clearly defined resonances at δ 29–32 and 15 p.p.m. The range of signals δ 29–32 p.p.m. presumably arises from methylene carbon β, γ, δ and ε from terminal methyl groups. The signal at δ 15 p.p.m. arises from terminal methyl carbon of alkyl chains. A small but probable contribution from rotor signals to this resonance, means the only

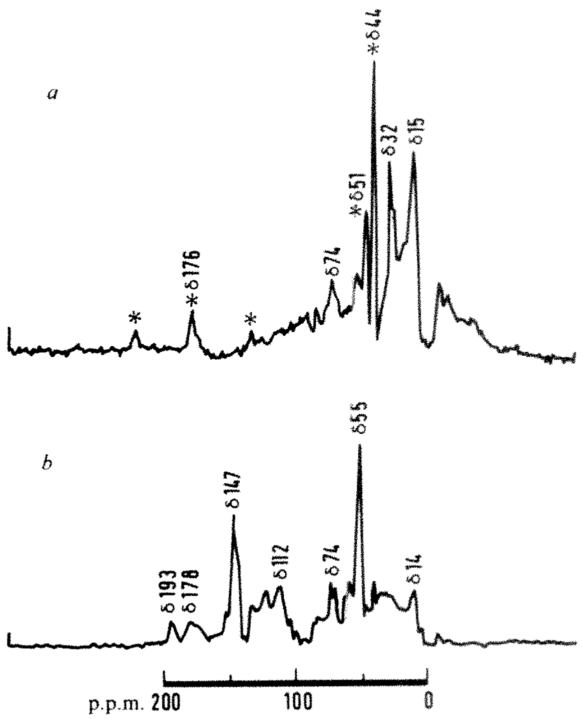

Fig. 1 75 MHz ^{13}C CP–MAS spectra obtained using H_1 fields of 19 and 76 G for ^1H and ^{13}C respectively, with a single contact of 1 ms, on a Bruker CXP-300 spectrometer and Z32 PE/MAS probe. The rotor was machined from perdeuterated polymethylmethacrylate. *a*, Maungatua silt loam. Obtained without block multiplication and using a spinning speed of 3.2 kHz. * Indicates rotor signals and sidebands. *b*, Yallourn brown coal xylite. Obtained by block multiplication of spectra using spinning speeds of 3.2 and 3.6 kHz to reduce spinning side bands. The resulting free induction decay was gaussian resolution enhanced. These materials have been described in detail elsewhere[1]. No special procedures were needed for sample preparation other than crushing. Assignments were made by comparison with known compounds[24,25]. Chemical shifts are relative to external tetramethylsilane and were initially determined relative to external adamantane and are considered accurate to ±3 p.p.m.

0028-0836/81/040275—02$01.00

comment we can make on alkyl chain length is that polymethylene is an important constituent of this soil. Our results clearly show, however, the potential of MAS in soil research. We are investigating the potential of other rotor materials for obtaining spectra of whole soils.

Numerous attempts have been made to devise structural formulae which represent the alkali soluble fractions of soil organic matter. These models[13–15] differ considerably in structure but all involve the idea that soil humic substances are highly aromatic materials.

It has recently been suggested that soil humic substances may not be as aromatic as previously thought. Anderson and Russell[16] suggested that polymaleic-acid-like polymers are important contributors to humic substances. Grant[17] has shown that polymethylene may constitute as much as 30% by weight of humic structures. Signals from aromatic carbons contribute only moderately to the ^{13}C NMR spectra of some soil humic materials in solution[18–20]. Although it may be argued[18] that nuclear Overhauser and relaxation effects prevent quantitative determination from ^{13}C NMR of the extract aromaticity, gated ^{1}H decoupling and significant pulse delays have little effect[20] on relative signal intensities of soil humics recorded so far. Our work on whole soils[1] has shown that the soil organic matter present can vary from highly aliphatic to at least moderately aromatic. The soil investigated in the present study is clearly highly aliphatic. Hence the structure models proposed by Fuchs[13], Felbeck[14], Dragunov[13] and Schnitzer[15] are not applicable to this soil, though they may adequately represent the organic matter in extracts from other soils.

Figure 1*b* is the spectrum obtained from a Yallourn brown coal xylite. Previous examination of this material[1] by the ^{13}C CP technique (without MAS) at the relatively low frequency of 22.6 MHz showed that the xylite contained considerable amounts of aromatic, O-alkyl and alkyl carbon. The presence of highly anisotropic aromatic carbon would be expected to lead to significant sideband problems. Hence, Fig. 1*b* is the result of the multiplication of spectra obtained at two spinning speeds to reduce this problem. The 75 MHz ^{13}C CP-MAS spectrum exhibits considerable detail and confirms the previous conclusions.

The broad strong resonances present in the spectrum are clearly not from spinning side bands. The resonance at δ147 arises from aromatic carbons bound to oxygen whereas that at δ112 is indicative of carbon *ortho* to C_{Ar}–O or of alkenic carbons. The major resonance at δ123 p.p.m. is due to C_{Ar}–H carbons.

The region δ50–100 p.p.m. can be assigned to the O-alkyl carbon of alcohols, ethers and esters. Resonance from δ70–90 p.p.m. can in general be assigned to carbon α to oxygen where the alkyl group contains more than two carbons. The spectrum exhibits signals over this whole range. Primary alcohols, ethoxy ethers and ethyl esters resonate over the range δ60–65 p.p.m. and small amounts of these materials may be present. The strong resonance at δ55 p.p.m. can be assigned to methoxy carbons. The presence of large amounts of methoxy groups has been confirmed by pyrolysis–gas chromatography and mass spectroscopy.

The alkyl region extending from δ10 to δ50 p.p.m. is not dominated by any alkyl types. There is no large polymethylene peak at δ29 p.p.m. Zilm *et al.*[5] obtained the 15.1 MHz ^{13}C CP–MAS spectrum of an American lignite and identified a major peak at δ29 p.p.m. which is readily assigned to polymethylene $(CH_2)n$. There is only a very minor peak at δ29 p.p.m. in the xylite spectrum. It follows that the alkyl chains in Yallourn brown coal xylite are short and branched whereas the alkyl chains in the American coal are much longer. Hence our results indicate the variability of alkyl structures in brown coal components.

Assigning resonances to carboxyl and carboxylic carbon is complicated by the uncertainty of the contribution of spinning side bands to the spectrum but brown coals are known to contain carboxylic carbon. Although the peak at 165–180 p.p.m. could be assigned to carboxylic carbon it may also arise from a residual spinning side band signal. The peak at δ193 p.p.m. possibly represents ketone carbon, although residual spinning side bands may contribute to this region. Ketone and carboxylic carbon were, however, also identified in pyrograms.

It is generally believed[21,22] that brown coals contain considerable amounts of carboxylic acid, ether and phenolic functional groups bound to aromatic structures of one or two rings. Our results show the important contribution of methoxy ethers in brown coal xylite. The very strong resonance at δ55 p.p.m. highlights the importance of methoxy ethers in this brown coal. The unequivocal assignments made here (to those signals which cannot arise from spinning side bands) are also those found in lignin[23]. This strongly suggests that Yallourn xylite is a modified lignin.

We are not aware of any reported NMR spectra of whole soils or solid coal which permit the detailed structural assignments achieved here. The present results show the potential and problems of high field high power NMR techniques in soil and coal chemistry.

We thank Drs D. Muller and H. Forster, and Bruker Analytische Messtechnik GMBH, Karlsruhe, FRG for obtaining the CP-MAS spectra. P.F.B. was supported under the National Energy Research, Development and Demonstration program administered by the Commonwealth Department of National Development.

Was the Laramide orogeny related to subduction of an oceanic plateau?

Richard F. Livaccari, Kevin Burke & A. M. C. Şengör

Department of Geological Sciences, State University of New York at Albany, Albany, New York 12222

Numerous models have been presented to explain the late Cretaceous/early Cenozoic Laramide orogeny, which affected the foreland region of the western cordillera within the US[1]. The most attractive models invoke low-angle subduction[2–4], which can develop for various reasons[5,6]. Evidence from South America indicates that one such reason may be the subduction of buoyant ocean floor. We here extend the low-angle subduction models by attributing the shallowing of the subduction angle during the Laramide orogeny to subduction of a large oceanic plateau of anomalously thick and buoyant oceanic crust. Pacific plate history indicates that a twin to the Hess Rise may represent the oceanic plateau that triggered Laramide events.

Large regions of anomalously shallow ocean floor, 100,000 km^2 or more in area, are found in the Pacific, Indian and Caribbean ocean basins. These regions were formed between the late Jurassic and the late Cretaceous and lie at depths several kilometres shallower than contemporaneous normal oceanic crust[7]. The plateaus have been interpreted as composed of abnormally thick and more buoyant oceanic crust[8].

Regions such as the Ontong Java and Manihiki plateaus, the Hess Rise and the eastern portion of mid-Pacific mountains seem to have formed by areally extensive, on ridge-axis, volcanic events between 120 and 90 Myr BP (Barremian to Turonian)[9–11]. Conversely, the western portion of the mid-Pacific mountains and the present oceanic crust of the Caribbean area seem to be a result of thickening of normal oceanic crust by voluminous off ridge-axis volcanic activity[9–11]. The shallowness of the Caribbean ocean floor is related to the late Cretaceous intrusion of large volumes of sills that thickened and made more buoyant the oceanic crust of this area[8]. Plateau regions that are generated by intense on ridge-axis volcanism may form symmetrical objects or 'twins' on two plates[12].

Regions of unusually buoyant ocean floor are difficult to subduct[8,13–15]. Therefore, the subduction or attempted subduction of oceanic plateaus or linear aseismic ridges can be expected to have a profound effect on the internal tectonics of the associated arc[8,13–15].

Because oceanic plateau regions are composed of crust that has a buoyancy between normal oceanic crust and continental crust, the subduction of such plateaus will cause the subducted lithospheric plate to ride higher in the asthenosphere, considerably lowering the angle of subduction[15]. For example, beneath the South American Cordillera the subducted oceanic plate has been segmented along strike, resulting in alternating sections of high- and low-angle subduction of the same plate[16]. Segments characterized by low-angle subduction correspond with portions of the cordilleran belt that lack arc-related Quaternary volcanism. Above the segments of high-angle subduction, Quaternary volcanism is abundant. An extremely important observation is that the segments of low-angle subduction beneath Peru and central Chile correspond with places where the eastern extensions of the Nazca and Juan Fernandez aseismic ridges have been subducted[16–19]. This suggests that the thickened and more buoyant oceanic crust of both the Nazca and Juan Fernandez aseismic ridges causes the descending oceanic plate to ride higher in the asthenosphere, resulting in a lower angle of subduction[17,19]. Enhanced seismic activity in the upper 50 km of the overriding South American plate[20] and extensive high- and low-angle thrust faulting in the foreland regions of Peru and Ecuador up to 700 km east of the South American trench[19,21,22] are associated with these sections of low-angle subduction.

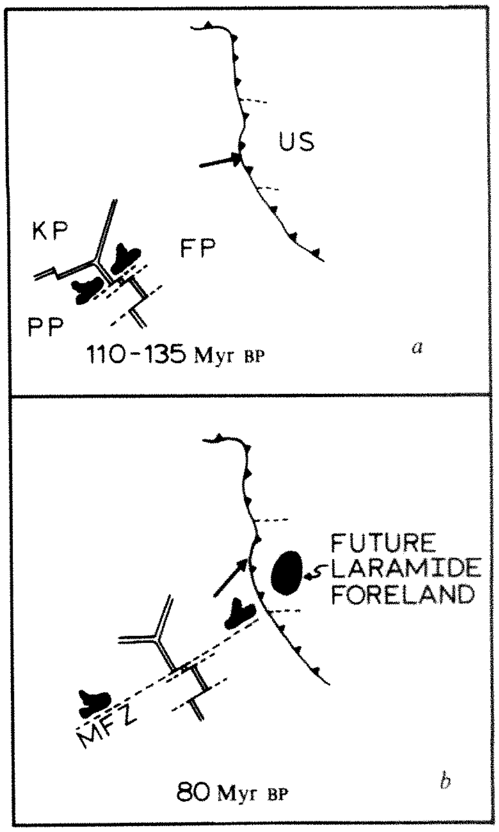

Fig. 2 Cretaceous reconstructions of the Kula, Farallon, Pacific and North American plates (modified from ref. 33): *a*, The formation of the Hess Rise and Hess Rise 'twin' by an unusually intense on axis volcanic event during the early Cretaceous; *b*, the movement of the Hess Rise 'twin' towards the future Laramide foreland during medial and late Cretaceous. Black arrows show the relative motion between the North American and Farallon plates[33] (KP, Kula Plate; FP, Farallon Plate; PP, Pacific Plate; MFZ, Mendicino Fracture Zone).

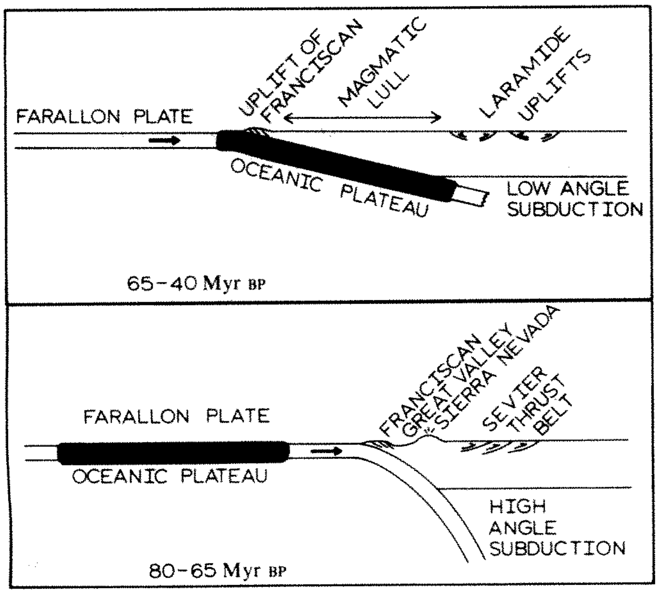

Fig. 1 Schematic cross-sections of the western US cordillera illustrating the progressive approach of an oceanic plateau towards the western US during the medial Cretaceous times and eventual subduction of the plateau during the Laramide orogeny.

The Laramide orogeny was characterized by the development of basement-cored overthrusts and adjacent synkinematic depositional basins in the foreland of the western US between northern Montana and northern New Mexico[23]. Deformation began ~70 Myr BP and continued until ~40 Myr BP (refs 24, 25). To the north and south of the Laramide foreland, Sevier-type retroarc thrusting continued[4,25]. The Laramide orogeny was a non-collisional, compressional event that resulted from the collapse and telescoping of the entire foreland region between Montana and New Mexico[26]. Faults that bound the ranges seem, mostly, to be low-angle thrusts that do not steepen at depth, indicating that horizontal compression and collapse of the foreland region was responsible for development of Laramide structures[22,27]. To the west of the Laramide foreland, arc volcanism ceased along the Sierra Nevada[28] and migrated inland, implying a rapid shallowing in the angle of subduction of the Farallon plate beneath the western US[29,30].

All these events may be interpreted as being the result of subduction of an oceanic plateau adjacent to this region. Subduction of a plateau of approximately the same dimensions as the Laramide foreland would result in flattening of the subduction angle, cessation of arc volcanism and increased compressive deformation, resulting in collapse in the foreland region (Figs 1 and 2). Therefore, tectonic patterns that characterized the Laramide orogeny such as cessation of arc volcanism and intense foreland deformation may be explained by inferring the subduction of an oceanic plateau adjacent to the Laramide foreland in the late Cretaceous/early Palaeogene, analogous with the situation presently found in South America.

Although it cannot be directly proved that such an oceanic plateau region ever existed or was subducted beneath the western US, the formation of numerous oceanic plateau regions in Cretaceous times, such as the Ontong Java and Manihiki plateaus, the mid-Pacific mountains and the present oceanic crust of the Caribbean, implies that these and perhaps other plateau regions lay within the Pacific Ocean during the late Mesozoic.

The Hess Rise is an oceanic plateau up to 800 km across lying just north of the westernmost extension of the Mendocino fracture zone and just south of the Great Magnetic Bight[31] (Fig. 2). The oldest sediments found on the Hess Rise are early Albian in age[10,32], implying that the Rise was formed sometime in the early Cretaceous. Watts *et al.*[11] and Vallier *et al.*[10] have presented evidence demonstrating that the Hess Rise formed by an intense on-axis volcanic event between 120 and 90 Myr BP (Barremian to Turonian). If this was the case, then symmetrical plateau twins may have been generated on two plates[12] (Fig. 2). That is, a Hess Rise twin could have formed on the Farallon plate symmetrically with the Hess Rise on the Pacific Plate.

Figure 2 shows reconstructed plate geometries for the Cretaceous[33] and the approximate positions of both the Hess Rise and postulated Hess Rise twin. Symmetrical spreading about the Pacific–Farallon ridge brings the Hess Rise twin into a position just opposite the future Laramide foreland by the late Cretaceous (Fig. 2). Continued convergence between the North American and Farallon plates at the rapid rate of ~ 14 cm yr^{-1} (ref. 33) would have resulted in subduction of a Hess Rise twin opposite the Laramide foreland during the late Cretaceous through the early Cenozoic. Thus, subduction of a Hess twin beneath the western US may have been the cause of the distinctive Laramide orogeny.

Indirect evidence within the Cordillera for the subduction of an oceanic plateau beneath the western US during the Laramide orogeny may exist. Because plateau regions lie at depths 2–3 km above oceanic crust of the same age, then during the subduction of an oceanic plateau, uplift would be expected along the entire fore-arc region as it rose to accommodate oceanic crust riding at a much higher elevation. Dickinson *et al.*[34] have documented such an event for the forearc region of California in the late Cretaceous that lifted the trench slope-break to a position near sea level resulting in widespread subaerial unconformities and filling of the fore-arc trough to the east to form a wide fore-arc platform area. Also, Winterer[35] has suggested that the Calera and Laytonville limestones found within the Franciscan melange may represent obducted slices of an oceanic plateau.

We thank J. F. Dewey, R. H. Pilger and W. R. Dickinson for preprints, and R. V. Ingersoll, R. H. Pilger, T. A. Cross and W. S. F. Kidd for reviews. Research at the State University of New York at Albany on oceanic plateaus has been partly supported by NSF grants 7614754 and 7803319.

The Nd-isotope analytical technique is a powerful tool for studying many geological processes: particularly the evolution of the upper mantle as seen through the isotope and trace element geochemistry of mantle-derived volcanic rocks[1–3], and magmatic processes along destructive plate margins[4,5]. However, previous studies of continental crust[6–8] have been largely restricted to Archaean examples and concerned primarily with dating their time of derivation from the upper mantle. In the present study we investigated the Nd- and Sr-isotope characteristics of rocks involved in a relatively young (800–450 Myr) orogenic event. Such events represent critical stages in the evolution of most of the Earth's continental crust—new material is added from the mantle, and pre-existing crust is remobilized by erosion and sedimentation, deformation and magmatic activity. Nd- and Sr-isotopes were used to outline the range in age and geochemical characteristics of rock sequences and provinces within both the upper mantle and the pre-existing crust which were sampled during the orogeny, and hence provided the major components of what is now a stable segment of continental crust.

The Damara high-temperature belt of Namibia (Fig. 1*a*), formed during the widespread orogenic event first categorized as Pan African by Kennedy[9] and it was chosen because it is arguably the best exposed orogenic belt of its age and has been studied in detail both geologically and geochemically (refs 10–13 and unpublished results). Some aspects of the stratigraphy and in particular the age and regional significance of the earlier tectonic events are still poorly understood, but an outline is presented in Fig. 1*b*.

Radiometric ages on pre-Damara rocks range from 1,100 Myr along the southern margin[14,15] to 1,700–2,000 Myr in the centre of the belt[16] and near the northern margin[17]. Within the Damara succession, the first major magmatic event is recorded in a suite of large ionic lithophile (LIL)-element-enriched lavas (Naauwpoort volcanics) and associated syenites and carbonatites exposed along the northern margin. U/Pb zircon results are variable, but they seem to cluster around an age of 800 Myr (ref. 18). In the north, Damara sediments reflect a well developed shelf facies, whereas in the centre and south, clastic sediments with only minor carbonates are followed by a thick flysch-type succession (Kuiseb schists). Within the flysch there is a thin band of basic rock, the Matchless amphibolite, which has been interpreted both as a fragment of tectonically emplaced ocean floor material[19], and as just one of several basic volcanic units within the flysch trough[10]. Whichever interpretation is correct an Rb/Sr whole-rock age of 765 ± 37 Myr

0028-0836/81/040278—05$01.00

from this Matchless amphibolite (A. Kröner, personal communication) is probably a minimum age for most of the sediments still preserved in the southern zone.

Granitic rocks, varying from diorites to granites and highly potassic alaskites, dominate the centre of the Damara belt (Fig. 1). Some, which intrude Damara sediments and have undergone extensive regional deformation, yield ages of 700–750 Myr (A. Kröner, personal communication). They are loosely termed 'early' granites and their relationship to later events is not understood. 'Late' granites, by contrast (Fig. 1*b*), all post-date the major regional deformation and many have been studied previously (refs 12, 20, 21 and unpublished results). Initial Sr-isotope ratios vary from 0.705 to 0.759 (unpublished results) and many of the younger granites, which tend to have the higher initial ^{87}Sr/^{86}Sr ratios were probably emplaced during late uplift in the centre of the belt.

The Damara orogenic cycle may therefore be broadly subdivided into four phases: (1) clastic sedimentation and LIL-element-enriched magmatism; (2) basic magmatism (possibly ocean floor) and predominantly flysch-type sedimentation; (3) early granites and regional tectonism; and (4) late, largely post-tectonic granites with associated high-temperature metamorphism. Our samples included volcanic and sedimentary rocks and a range of lithologies from the late granites (Fig. 1).

^{143}Nd/^{144}Nd ratios and the concentration of eight rare earth elements (REEs) were determined using techniques described previously[4] and the results are presented in Tables 1 and 2. Except for K211, all samples were selected from suites which plot on whole-rock Rb–Sr isochrons (unpublished results). Their initial ^{87}Sr/^{86}Sr ratios are thus representative of the particular rock unit. Initial Nd-isotope ratios vary from 0.51196 in the Matchless amphibolite to 0.51117 in the K_2O-rich Rössing alaskite. Figure 2 shows chondrite-normalized REE patterns for selected samples.

The carbonatite (28/32) from the Naauwpoort magmatic suite contains extremely high REE concentrations similar to those reported from carbonatites elsewhere[22]. Although we are unaware of other carbonatites with a similar 'concave-up' distribution (Fig. 2), such patterns are predicted by experimental work on the distribution of REEs between common mantle minerals and a CO_2-rich vapour phase[23].

The samples of Matchless amphibolite (AM 62, 63) exhibit higher Sm/Nd and ^{143}Nd/^{144}Nd ratios than the chondritic uniform reservoir (CHUR[2], presumed to be representative of the bulk Earth) at the time of their formation. This indicates that their source region had been relatively depleted in light REEs for a considerable time and, because such depletion is characteristic of recent mid-oceanic ridge basalts, these results are in keeping with the interpretation that the Matchless amphibolite represents a fragment of oceanic crust[19]. The Gariep Belt is another possible ophiolite sequence, probably of similar age to the Matchless, and whereas the dolerite sample (K211) is enriched in light REEs, it exhibits the same relatively high initial ^{143}Nd/^{144}Nd ratio (Table 1).

Kh 24 (Kuiseb schist) is a metamorphosed flysch-like sediment which was probably deposited 700–800 Myr ago (Fig. 1). Rb/Sr whole-rock results scatter about an 'errorchron' corresponding to an age of 548 ± 56 Myr, which has been interpreted as the time of widespread regional metamorphism (unpublished results). The REEs exhibit a negative Eu anomaly which is typical of post-Archaean sediments[24] and a Sm/Nd ratio in the range suggested for average continental crust[25] (0.17–0.21).

The Damara 'granites' sampled are from massive stocks of diorite and granite and from small bodies of K-rich alaskite. The diorite (RM586) and two granites (RM662 and SM2) range in age from 560 to 490 Myr, in initial ^{87}Sr/^{86}Sr from 0.7048 to 0.709, and in initial ^{143}Nd/^{144}Nd from 0.51186 to 0.51146. The diorite, with its initial Sr- and Nd-isotope ratios similar to CHUR 550 Myr ago, probably originated in the upper mantle although its generation must have involved considerable fractionation of the light REEs (Fig. 2). The granites have higher

a, Rb/Sr whole rock ages (unpublished results and A. Kröner, personal communication), except for the Lofdal carbonatite (U/Pb zircon[18]) and Gariep dolerite (assumed to be of the same age as the Matchless amphibolite).

b, Measured $^{143}Nd/^{144}Nd$ ratios. Normalized to $^{146}Nd/^{144}Nd = 0.7219$. Quoted errors are two standard errors on the mean. $^{143}Nd/^{144}Nd$, BCR-1 = 0.51266±2.

c, From Table 2, except AM63 (R.M., unpublished results).

d, Initial $^{143}Nd/^{144}Nd$ normalized to BCR-1 = 0.51262.

e, $$T^{Nd}_{CHUR} = \frac{1}{\lambda}\ln\left[\frac{^{143}Nd/^{144}Nd_{CHUR} - {}^{143}Nd/^{144}Nd_{sample}}{^{147}Sm/^{144}Nd_{CHUR} - {}^{147}Sm/^{144}Nd_{sample}} + 1\right]$$

where $\lambda = 6.54 \times 10^{-12}\ yr^{-1}$, $^{143}Nd/^{144}Nd_{CHUR} = 0.51262$, $^{147}Sm/^{144}Nd_{CHUR} = 0.1935$. The T^{Nd}_{CHUR} age for K211 is meaningless as its Sm/Nd ratio is probably much less than that in its source rock, whereas those for 26/59 and DG58 are probably slightly too old (see text).

f, Initial $^{87}Sr/^{86}Sr$ ratios (unpublished results and A. Kröner, personal communication).

initial $^{87}Sr/^{86}Sr$ and lower initial $^{143}Nd/^{144}Nd$ ratios and thus probably contain material with a crustal prehistory. Their much larger Eu anomalies (Fig. 2) show that their generation involved either separation from a plagioclase-bearing residue, or plagioclase fractionation. Alaskites in contrast were produced by partial melting at high levels in the crust, sometimes apparently *in situ*[26]. Samples 26/59 and DG58 are from 480- and 460-Myr old bodies with unusually high initial $^{87}Sr/^{86}Sr$ (0.724, 0.759) (ref. 21 and unpublished results) and low initial $^{143}Nd/^{144}Nd$ (0.51126, 0.51117) ratios. Note the low concentrations of Sr and the medium- and light-REE, especially in the samples from Rössing (DG58 and 59) and the 'concave-up' distribution patterns (Fig. 2). The low Sr concentrations are consistent with a small degree of partial melting in equilibrium with residual plagioclase. The REE distribution patterns could reflect the presence of minor phases in the residuum, or the scavenging of REE with U in the formation of the adjacent U mineralization. Rössing, for example, is the site of a major uranium deposit and monazite, xenotime and sphene (all minerals with very high crystal–liquid partition coefficients for medium- and light-REE)[27] are commonly found in association with the uranium mineralization (refs 4, 28, and Marlow, personal communication).

The initial $^{143}Nd/^{144}Nd$ ratios of these Pan African rocks are plotted against time in Fig. 3, with the evolution of the chondritic reservoir (CHUR[2]) shown for reference. The possible ocean-floor volcanics (amphibolites and dolerite) and the carbonatite and diorite have initial Nd-isotope ratios respectively higher than and similar to that of CHUR at the time of their formation, whereas the late granites and alaskites have progressively lower initial $^{143}Nd/^{144}Nd$ ratios. Moreover, as there is a broad inverse correlation between initial Sr- and Nd-isotopes (expressed as ε_{Nd} and ε_{Sr} respectively[29], Fig. 4), the lower initial $^{143}Nd/^{144}Nd$ ratios in the younger rocks is matched by their progressively higher $^{87}Sr/^{86}Sr$ ratios.

T^{Nd}_{CHUR} ages[8] are estimates of how long a rock (and its source region) have had different Sm/Nd, and hence $^{143}Nd/^{144}Nd$ ratios to CHUR. They denote the time at which the Nd-isotope evolution curve of a system with particular present day $^{143}Nd/^{144}Nd$ and Sm/Nd ratios intersects that of CHUR (see Fig. 3). T^{Nd}_{CHUR} ages are model ages because it is assumed that a simple two-stage history applies. The first stage is in a (mantle) province with the isotope and trace element characteristics of CHUR, and the second stage reflects the $^{143}Nd/^{144}Nd$ and Sm/Nd ratios in the rocks at present. If such a model is inapplicable as, for example, when light REE-enriched crustal rocks are derived from depleted mantle (higher $^{143}Nd/^{144}Nd$ than CHUR), the time of separation from the mantle may be

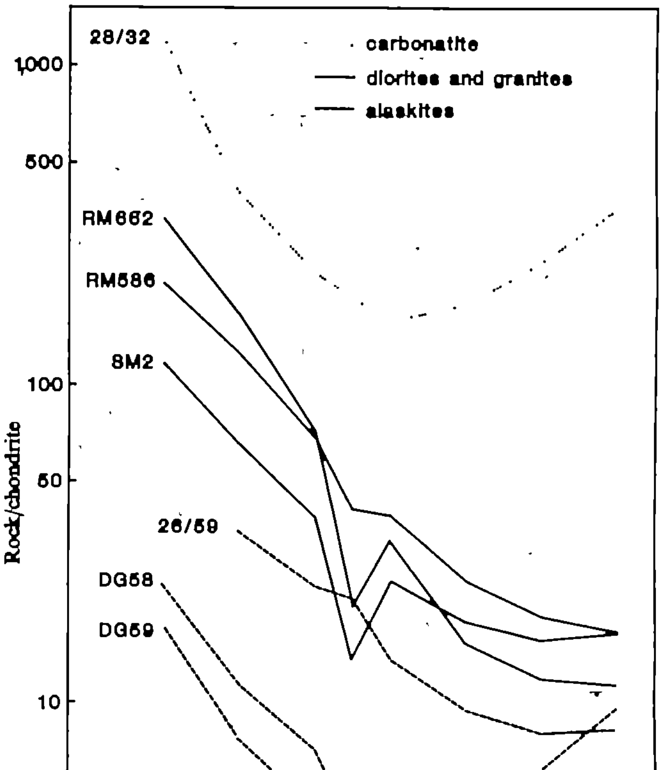

Fig. 2 Chondrite-normalized REE distribution patterns for selected Damara rocks.

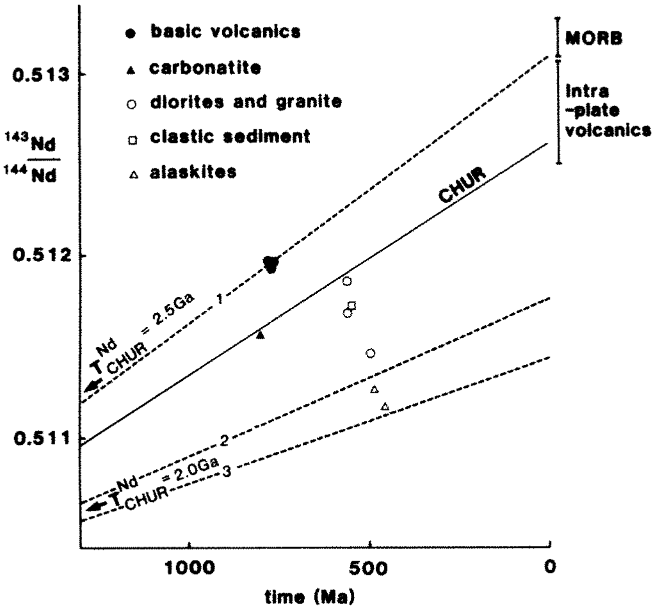

Fig. 3 Variations in initial ^{143}Nd/^{144}Nd ratios in the Damara rocks. CHUR (chondrite uniform reservoir), ^{147}Sm/^{144}Nd = 0.1935, present day ^{143}Nd/^{144}Nd = 0.51262. Evolution paths; 1, Sm/Nd = 0.366 (as in the samples of Matchless amphibolite); 2 and 3, Sm/Nd = 0.214 and 0.173 respectively (that is the range in average continental crust[25]). The samples between evolution paths 2 and CHUR have T^{Nd}_{CHUR} ages in the range 550–1,200 Myr (Table 1).

older than that implied by their T^{Nd}_{CHUR} age. Nonetheless, for mantle-derived volcanics, such model Nd ages reflect how long chemical variations have persisted in that part of the upper mantle, and for crustal-derived rocks (be they magmatic or sedimentary) they provide a useful estimate of the age of their source region. In all cases they require that the Sm/Nd and ^{143}Nd/^{144}Nd ratios of the rocks are similar to those in their source areas; inevitably this assumption is more valid for some rock types than for others.

The basic volcanic rocks probably reflect 10–20% partial melting of spinel peridotite and thus their Sm/Nd ratios are likely to be similar to those in their source regions[3]. Thus the evolution path of material with Sm/Nd = 0.366 (that is, as in AM62) has been plotted in Fig. 3; T^{Nd}_{CHUR} equals 2,500 Myr, and its present day ^{143}Nd/^{144}Nd is similar to those in recent MOR basalts. This suggests that these rocks were derived from mantle which had been depeleted in light REE since the Archaean and supports the interpretation that both the Matchless and Gariep Belts represent fragments of oceanic crust[19]. The anomalously high ε_{Sr} values of these samples (Fig. 4) probably reflects contamination, either with seawater on the ocean floor[30], or during post-emplacement metamorphism.

The low concentrations of REEs in the alaskites and 'concave-up' distribution patterns (Fig. 2) indicate that they have probably been modified—perhaps by processes associated with the uranium mineralization. Thus, rather than assuming that the Sm/Nd ratios of the individual alaskites were the same as their source rocks, we have plotted the evolution of material which was derived from a chondritic reservoir (CHUR) 2,000 Myr ago (that is, the oldest age reported from basement rocks in the Damara[16]) and had Sm/Nd ratios in the range for average continental crust (0.173–0.214, see ref. 25 for discussion). Its evolution path in Fig. 3 encompasses the low initial Nd-isotope ratios of the alaskites which strongly suggests that they were derived from crustal material which had been out of the mantle since 2,000 Myr.

The initial ^{143}Nd/^{144}Nd ratios of the granites (SM2, RM662) and the metasediment (Kh24) are intermediate between those of the alaskites and CHUR at the time of their formation (Fig. 3). Apart from equilibrium with minor phases (as presumably happened in the case of the alaskites), equilibration with a large amount of cumulus or residual amphibole is the most likely mechanism capable of altering significantly the Sm/Nd ratios of a crustal melt[31]. This would be reflected in a strong depletion in heavy REEs and, because this is not observed in any of these samples, we conclude that the Sm/Nd ratios of the granites SM2 and RM662 are likely to be similar to those in their source rocks. Sample Kh24, being a metasediment, is also likely to have an Sm/Nd ratio similar to that in its source terrain[8]. The T^{Nd}_{CHUR} ages for these two granites and the metasediment range from 1,000 to 1,200 Myr indicating that, unlike the alaskites, they were not derived from 2,000-Myr old crustal material alone. Two possibilities remain: the granites (and the metasediment) could simply have been derived from younger crustal sources (perhaps ~1,100-Myr old) or they could contain variable amounts of both mantle-derived and 2,000-Myr crustal material. For the granites this might reflect contamination of mantle-derived magmas within the crust, whereas the flysch-type sediment could contain a mixture of young volcanic and older continental detritus. At present there are insufficient data to choose between these two hypotheses, however: (1) significant quantities of new crustal material was generated 1,100 Myr ago along the present-day southern margin of the Damara[14,15], and crustal rocks of this age may also occur at depth elsewhere within the belt; (2) where contamination of magmas with continental crust has been convincingly demonstrated, it tends to result in a flat-lying trend between Nd- and Sr-isotopes[5]. This is not observed for the Damara diorite and granites (Fig. 4).

The inverse correlation of ε_{Sr} and ε_{Nd} observed in the crustal rocks studied is interesting. The inverse correlation in mantle-derived volcanics (also shown in Fig. 4) is generally accepted as an expression of coherent fractionation of Rb/Sr and Nd/Sm ratios during melting in the mantle. However, magmatic and sedimentary processes, particularly in the upper crust, fractionate Rb/Sr much more readily than Nd/Sm. Thus sediments and K_2O-rich granitic material develop with time relatively high ^{87}Sr/^{86}Sr ratios, resulting in a distinctive, curved inverse correlation between ε_{Nd} and ε_{Sr} at higher levels in the continental crust (Fig. 4). Furthermore, although magmatism in this orogenic event has sampled material from the upper mantle through to the upper continental crust, it does not seem to have sampled

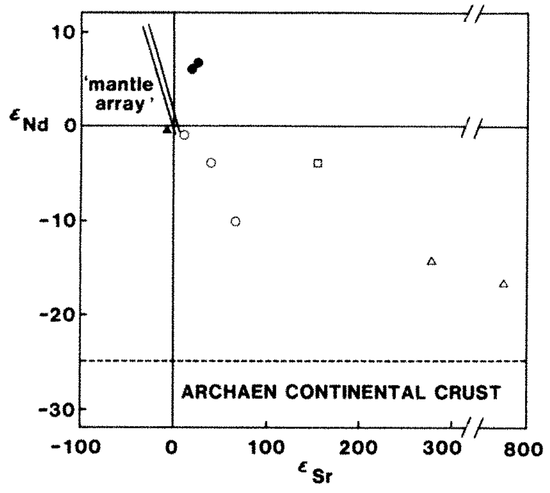

Fig. 4 ε_{Nd} against ε_{Sr} (ref. 2) for Damara rocks (key as for Fig. 3)

$$\varepsilon_{Nd}=\left[\frac{^{143}\mathrm{Nd}/^{144}\mathrm{Nd(initial)}}{^{143}\mathrm{Nd}/^{144}\mathrm{Nd}_{\mathrm{CHUR}(t)}}-1\right]\times 10^4$$

where ^{143}Nd/^{144}Nd$_{\mathrm{CHUR}(t)}$ is the ^{143}Nd/^{144}Nd ratio of a chondritic uniform reservoir at the time of formation of the rock in question. ε_{Sr} is similarly defined using the relevant ^{87}Sr/^{86}Sr ratios[2]. ε_{Nd} and ε_{Sr} calculated using the ages and initial Nd- and Sr-isotope ratios in Table 1, but note that the age of the sediment (Kh24) is believed to reflect regional metamorphism (unpublished results).

any old granulite facies rocks ($-\varepsilon_{Nd}$ and $-\varepsilon_{Sr}$, Fig. 4, refs 1, 7). Such rocks may not be ubiquitous in the lower crust, but it is also possible that such LIL-element depleted material is not readily mobilized.

We conclude that Pan African rocks in Namibia were derived from upper-mantle and continental sources which at the time of the Damara orogeny had already been respectively depleted and enriched in light rare earths for up to 2,000 Myr. High initial ^{143}Nd/^{144}Nd ratios on basic volcanic rocks support suggestions that they represent fragments of oceanic crust[18], and imply that their source regions had been depleted in light REEs since the Archaean. $T^{\mathrm{Nd}}_{\mathrm{CHUR}}$ ages of the granitic rocks range from 550 to 2,000 Myr. The older ages are from alaskites which, on field evidence, were generated at higher levels in the crust. The lower crust seems to contain younger (?1,100 Myr) crustal material. More generally this evidence for the remobilization of 2,000-Myr old crust highlights an important difference between high-temperature intracratonic Pan-African belts such as the Damara (Fig. 1) and those in north-east Africa which appear to be less deeply eroded, contain no evidence for significantly older continental crust, and are believed to reflect crustal accretion along convergent plate boundaries[32]. The Damara granitic rocks exhibit an inverse correlation between initial Nd- and Sr-isotopes (Fig. 4), although the alaskites and the metasediment are displaced to comparatively high ^{87}Sr/^{86}Sr ratios consistent with a relative increase in Rb/Sr at higher levels in the continental crust.

We thank M. P. Coward, C. J. Hartnady, J. Barnes, K. Downing and A. G. Marlow for discussions and A. R. Gledhill, J. C. Roddick and A. Kröner for unpublished results and comments, and also Professor Nicolaysen for his constructive review. Analyses were carried out at Leeds where isotope and REE research is funded by NERC and the Royal Society.

The term 'Plinian' has been widely used[1–4] to describe continuous gas-blast eruptions of large magnitude a typical example[5], of which is the AD 79 eruption of Vesuvius which destroyed Pompei and the surrounding region. We develop a new model here for the AD 79 event that explains the complete Plinian eruptive episode including pyroclastic fall, pyroclastic flow, base surge, laharic and phreatic activity. This model has widespread implications with regard to volcanic hazard evaluation and geothermal exploration at Vesuvius and other volcanoes with similar patterns of activity, such as Mount St Helens.

Three representative sections from archaeological excavationsdemonstrate the principal characteristics of the entire eruptive sequence, assuming emplacement of pyroclastic flows, surges and lahars above the pumice bed, during the 30-h eruptive period. Data from more than 30 sections included in the new model show that factors such as distance from the vent, topography and wind velocity, control the depositional facies.

At the Pompei excavation 4.5-m of section (Fig. 2) includes a lower white pumice-fall layer that grades into an upper grey, pumice-fall bed overlain by interbedded surge and grey pumice-fall levels and an uppermost surge sequence. There is an upward increase in lithic xenoliths from 12 wt% for the white part to 20 wt% for the grey[5]. The character of the xenoliths also changes with a slight increase in fraction of carbonates and a strong increase in cognate cumulates in the grey level. The lower group of surge beds is of the dry (superheated steam) massive and sandwave bed type[9,10]. This group includes two prominent phreatic fall levels rich in scoria and calcareous fragments. The contact between the grey pumice and the first surge beds is a prominent wave form. The uppermost part of the surge sequence probably represents emplacement of very wet (condensed steam) phreatomagmatic products. These massive fine-ash beds are full of accretionary lapilli and may have the widespread dispersal characteristic of phreatoplinian deposits[11].

At the Oplonti excavation the section is 8.5-m thick (Fig. 2). The grey pumice-fall layer, which is much thicker than the white,

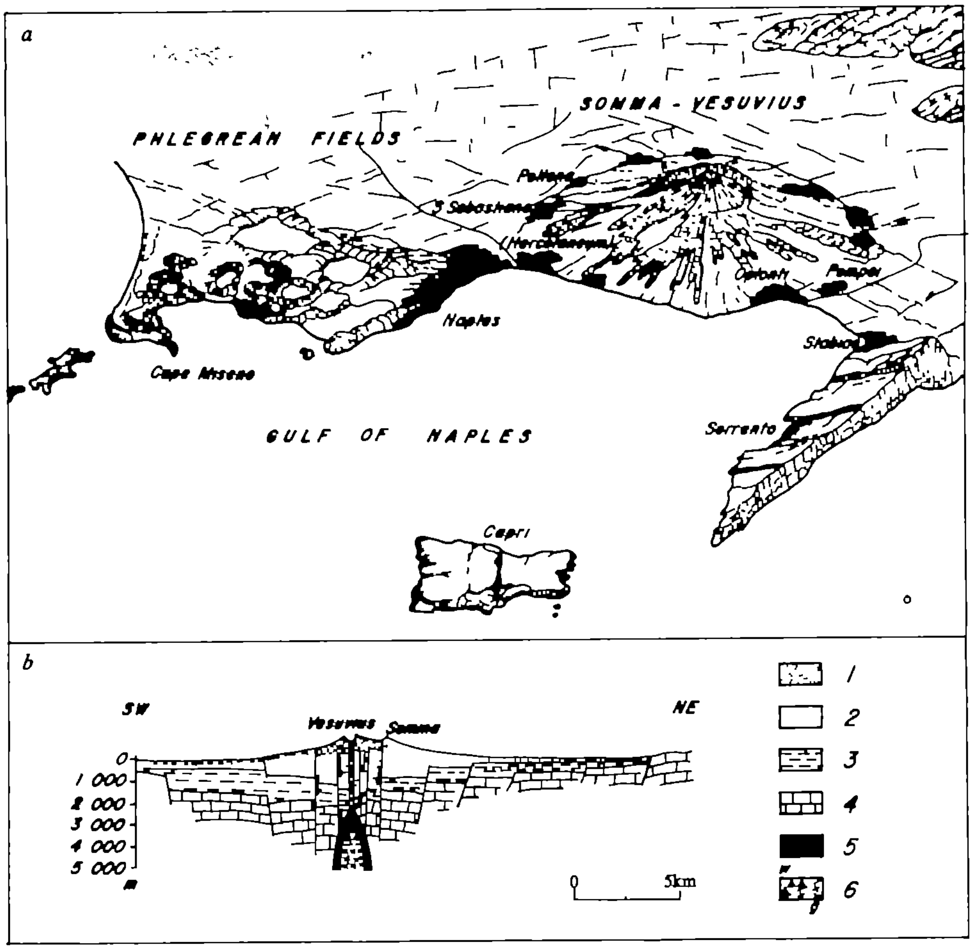

Fig. 1 Somma–Vesuvius Volcano. *a*, Location map. *b*, Schematic cross-section. Key: *1*, volcanic rocks of Vesuvius; *2*, volcanic rocks of Somma; *3*, Tertiary and Quaternary clastic sediment; *4*, Mesozoic limestone; *5*, chilled margin and contact metamorphic halo of the magma chamber; *6*, differentiated magma of the AD 79 magma chamber that produced the white (w) and grey (g) pumice of the Plinian eruption.

is interrupted by three prominent surge beds. The progressive strength of the surge blasts is indicated by the increase in cast diameter of destroyed trees from 10 cm for the lower surge to 20 cm for the upper one. Above the grey pumice is a prominent sandwave horizon that contains a broken tree trunk 25 cm in diameter, and a mould of a tree 40 cm in diameter. Above the surge sequence are two pyroclastic flows. The lower one is rich in grey pumice and lacks stratification, the upper one has numerous reversely graded laminations, probably indicating that it is at its distal reaches[12]. Above the pyroclastic flows is a series of wet surge deposits with planar and massive beds rich in pisolites.

The Herculaneum section is ~20 m thick (Fig. 2). There is no pumice-fall horizon: at the base are sandwave surge beds. Above is a pumice-rich pyroclastic flow containing fragments of houses, carbonized wood and fumarolic pipes towards the top.

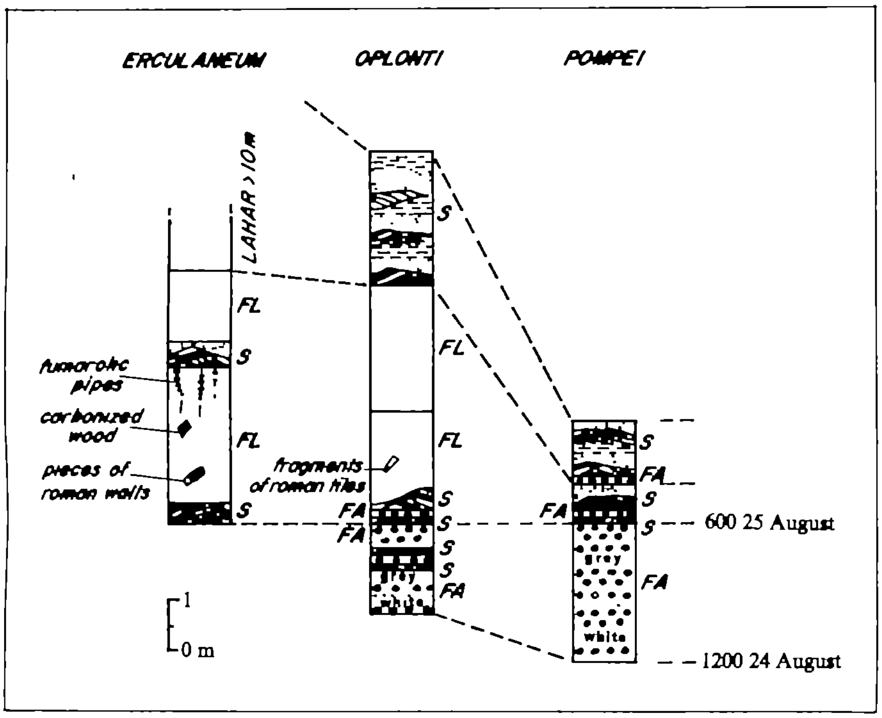

Fig. 2 Representative sections of AD 79 pyroclastic deposit from archaeological excavations. *FA*, air fall pumice; *S*, surge deposits, *FL*, pyroclastic flows.

The overlying sequence of sandwave surge deposits is followed by another pyroclastic flow. The remainder of the section is composed of lahars.

These deposits can be related to eruption phenomenology. A large volume (~2 km^3) of tephritic magma intruded a shallow (3–5 km deep) magma chamber within the Mesozoic limestone series[6–8]. The residence time of the magma was sufficient for a reaction skarn to form and a contact metamorphic halo that extended outwards into the carbonate country rocks to develop[7]. The metamorphic halo effectively sealed the differentiating magma system, although p_{CO_2} may have been significantly increased within the chamber as a result of decarbonation reactions in the carbonate wall rocks. A chilled magma margin may have originally formed, but with slow cooling and crystallization a coarser-grained syenite layer grew inwards from the upper part of the chamber as mafic cumulates settled to the bottom. The long period of differentiation produced a stagnant compositionally zoned upper zone of evolved magma rich in volatiles. The basic lower part was more homogenous, presumably due to circulation.

The eruption began (Fig. 3*a*) either when the gas pressure within the chamber became sufficient to rupture a conduit to the surface or, less likely, with the introduction of a new batch of hot magma from depth[13]. The initial eruption followed the model of Wilson[14–16] with decompression due to exsolving magmatic gas driving the gas thrust during the opening and widening of the conduit. Buoyant convective uplift of particles above the continuous gas thrust zone produced a persistent eruptive column from which the Plinian pumice-fall deposits were derived through lateral wind shear[17]. Using the average wind velocity at 9–11 km elevation (20 m s^{-1}) and terminal fall velocity data[5], a column height of ~17 km is computed. This corresponds well with the height of 16–26 km calculated from the theoretical formulae of Wilson *et al.*[16], assuming an average volume eruption rate of 4×10^4 m^3 s^{-1} for an 18-h period and an *F* value of 0.3–1.0.

The initial eruption produced the white highly fractionated grey pumice-fall with ~10 wt% lithic clasts in the approximate ratio of the stratigraphy traversed by the conduit. The eruption proceeded uninterrupted into the less-fractionated grey pumice-fall level with an increase in lithics and fraction of carbonates relative to other lithics and the appearance of felsic cumulates. This represents the removal of solidified magma and country rock surrounding the upper part of the magma chamber.

The greater density, larger size and wider dispersal of the grey pumice indicate a greater column height than for the white pumice. Lirer *et al.*[5] attribute this to tapping of a long (5 km) narrow (340 m diameter) magma chamber to provide sufficient increase in gas pressure to offset the decrease in gas content. The present data which indicate a magma chamber of ~2 km height and 1 km diameter, cast doubt on the above mechanism. Rather, the increased explosivity which widens the vent conduit system above the chamber could result from vaporization of a small mass ratio of external water to magma in the chamber during the grey pumice eruption. Minor surge layers within the upper part of the grey pumice deposit at Oplonti and other locations and an increase in abundance of lithic inclusions in the grey pumice support this interpretation.

The initial mass fraction of xenoliths in the white pumice was small and their ratio was proportional to their relative abundance in the stratigraphic column above the chamber. As the chamber became partially emptied during the eruption of the grey pumice, cavitation of the roof and the walls took place, (Fig. 3*b*) as indicated by the sharp increase in the proportion of deep inclusion types such as high-grade contact metamorphics, skarns and cognate plutonic nodules. The eruption may have become discontinuous at this stage.

Rupturing of the tight metamorphic encasement allowed interaction with the regional hydrologic system (Fig. 3*c*). Because the magma level within the emptying chamber was below the principal aquifer (Mesozoic carbonate sequence) an abundant source of water was available to the chamber when the venting pressure dropped below that of the hydrostatic head (~300–500 bar). The immediate effect was to generate strong hydromagmatic or phreatic explosions, depending on the degree of mixing of water and magma before decompression of the steam. The products included surges of fine-grained ashes, widespread phreatoplinian layers, vesiculated tuffs[18] and phreatic breccias.

At this stage, the production of small pyroclastic flows may have been directly related to contemporaneous hydromagmatic and magmatic activity occurring in different parts of the chamber. Marginal hydromagmatic explosions would have provided the fine fragmentation typical of pyroclastic flows[19–21] that is difficult to explain by other processes such as column collapse. Magmatic eruptions from the centre of the chamber would have produced the coarse pumice and provided a strong gas blast to maintain the eruption column. Homogenization within the chamber, vent and eruption column accounts for the rounding of the pumice and uniform texture characteristic of the pumice flows. Cooling of the system by water vaporization and enlargement of the vent due to strong explosions would have favoured column collapse.

At first hydromagmatic explosions alternated with purely magmatic activity; later they dominated. Because the eruptive system was gradually cooled through water vaporization during

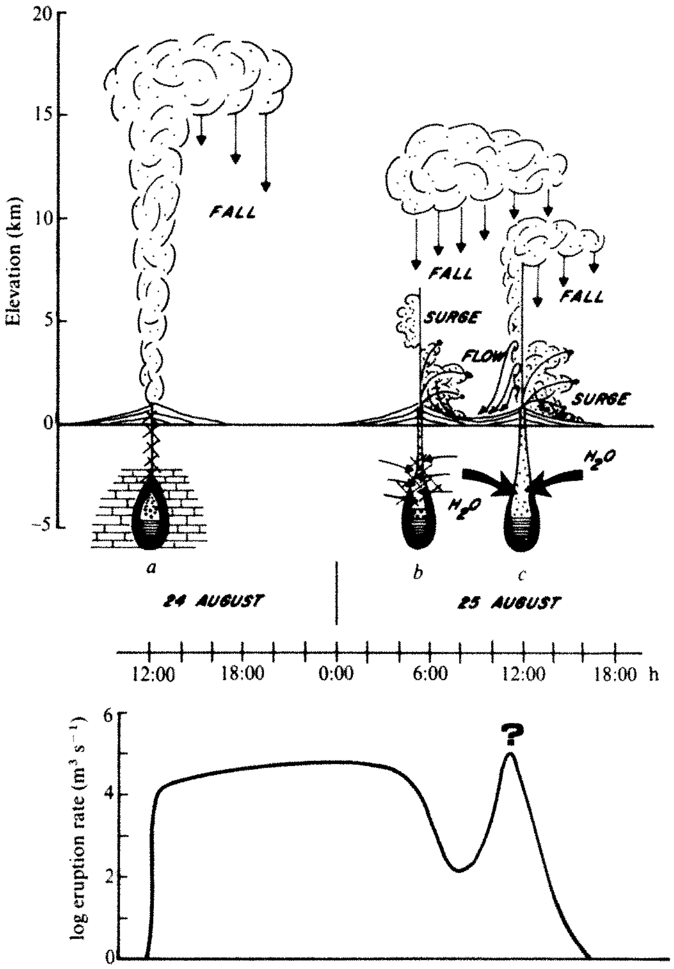

Fig. 3 Model of the AD 79 eruption of Vesuvius related to eruption phenomenology described by Pliney the Younger[23]. *a*, Gas pressure in the chamber ruptures a path to the surface producing an eruption column of about 17 km height. The eruptive rate during this phase averages 4.0×10^4 m^3 s^{-1}. *b*, A strong reduction in activity associated with cavitation of the chamber roof produces intermittent magmatic and hydromagmatic explosions. *c*, The terminal phase is dominantly hydromagmatic with pyroclastic flows and surges as the products. The eruption rate may reach 10^5 m^3 s^{-1}, close to the maximum theoretical rate for a prolonged maintained column[20].

the hydromagmatic phase, the products proceed through early hot dry surges and pyroclastic flows which are followed by colder wet surges and lahars and finally by phreatic explosion breccias. If the chamber had become completely evacuated of magma before significant hydromagmatic cooling, the final eruption would have been purely phreatic. These later products included xenoliths of syenite and mafic cumulates of biotite, olivine and pyroxene torn from the walls and floor of the chamber.

A similar pattern has been observed in four other Plinian eruption cycles identified at Vesuvius[22]: Avellino (3,500 yr BP), Gemelle (8,000 yr BP), Verdoline (13,000 yr BP) and Pomici di Base (17,000 yr BP). All began with a highly fractionated pumice-fall deposit in which the percentage of lithics increases with time. Those eruptions characterized by strong hydromagmatic activity (pyroclastic flow and surge) had a strong concentration of carbonate lithics in the pumice-fall immediately below the surge beds. This indicates an enlargement of the chamber roof within the regional aquifer by removal of the surrounding country rock. The surge deposits proceeded through an early hot dry type associated with pyroclastic flows to a final cold wet or even phreatic type.

The late-stage behaviour of the eruption depends both on internal magma dynamics, and on the hydrological framework. For example, the Verdoline magma chamber was located in the relatively impervious Tertiary flysch marls above the Mesozoic carbonate basement. Although there was an increase in amount of lithic clasts with time in the pumice fall deposit, the hydromagmatic phase was only minor. The other Plinian eruptions with magma chambers entirely within the carbonate basement, to the contrary, have produced extensive hydromagmatic and phreatic deposits.

Middle Ordovician chondrite in fossiliferous limestone from Brunflo, central Sweden

Per Thorslund

Frans E. Wickman

Department of Geology, University of Stockholm, Box 6801,
S-113 86 Stockholm, Sweden

The few discoveries of fossil meteorites have been attributed[1] to the ignorance about the appearance of meteorites among palaeontologists and other geologists who examine limestone quarries, coal mines, and other excavations in sedimentary rocks. We now report the first find of a fossil stony meteorite in Ordovician limestone. The meteorite is a chondrite, possibly an H-chondrite, and its terrestrial age is ~463 Myr. The fine structural details of the chondrules are often extremely well preserved, but the chemical composition and the mineralogy have changed dramatically, chromite being the only primary mineral preserved. The present major minerals are calcite, barite, a Cr–V– 'phengite' and a cobaltite-group mineral.

An earlier find reported by Yudin[2] consists only of isolated barred chrondrules in a Mesozoic bauxite. In 1952, a polished slab of Ordovician limestone was sent to one of us (P.T.) for examination because it contained an almost black clast about 10 cm across (Fig. 1). Thin sections were prepared of the foreign body and were examined by a petrographer, who reported that the clast was a metamorphic ultramafic rock consisting mainly of clinozoisite, calcite, magnetite and serpentine. This unusual discovery was explained by algae transporting the stone to its present position. However, as no similar ultramafic rocks were known on the continental (eastern) side of the Brunflo area the slab was set aside. The Siljan Ring, over 200 km to the south of Brunflo was one of Sweden's best areas for Ordovician and Silurian rocks, is an impact structure. In December 1979 the slab

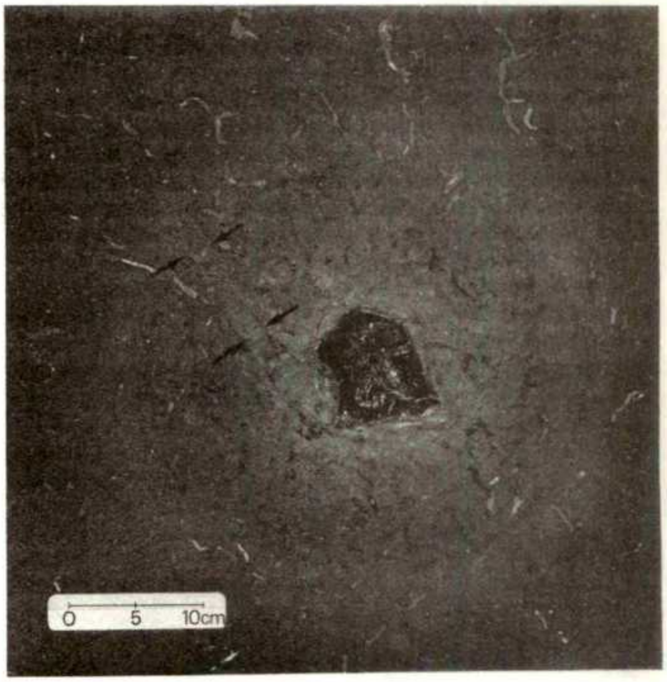

Fig. 1 The polished slab of limestone with the chondrite. The size of the slab is ~65 × 65 cm, and the meteorite ~10 cm across. The dark portions contain the structurally best preserved chondrules. The white portions are now calcite and barite. The cephalopod (arrowed) seems to have been struck by the meteorite. The differently coloured zones around the meteorite are visible.

Table 1 Electron microprobe analyses of chondritic chromites

	1	2	3	4	5	6	7	8	9
Cr_2O_3	56.8	56.9	56.1	54.4	55.9	60.8	57.2	56.7	57.2

MgO	1.98	2.66	1.99	1.62	2.72	2.32	2.73	2.51	3.0
MnO	0.50	0.94	0.74	0.63	1.03	0.79	0.86	0.99	0.81
ZnO	0.93	—	—	—	1.09	—	—	—	—
Total	100	100.61	100.66	100.81	100.21	100.48	100.52	100.35	100.77

Analyses 2–9 from ref. 4. Number in parenthesis gives number of meteorites analysed for 2–4, and number of grains analysed for 1, 5 and 6–9.
Analyses: 1, average present find, normalized to a sum of 100 after exclusion of 0.33 wt% CaO (11); 2, average H5 and H6 (10); 3, average L5 and L6 (7); 4, average LL5 and LL6 (6); 5, average Pultusk (4); 6, average H3 (12); 7, average H4 (21); 8, average H5 (28); 9, average H6 (11).

with its clast was re-examined with the idea that it could be a stony meteorite; the presence of chrondrule-like boundries was noticed.

The meteorite occurs in a reddish brown limestone from the Rödbrottet quarry (lat 63°7′ N, long 14°17′ E), near Brunflo, not far from Östersund, central Sweden. Determination of the conodonts in the slab shows that the meteorite fell during the Aseri Stage of the Middle Ordovician (~463 Myr ago).

In a ~3 cm-wide border zone, delicate structural details of chondrules are preserved, although the primary minerals have been replaced. Two examples are shown in Fig. 2, one barred chondrule and one radiating chondrule. The chondrules are well defined in a matrix, giving the impression of the petrologic types 3–5 of Van Schmus and Wood[3].

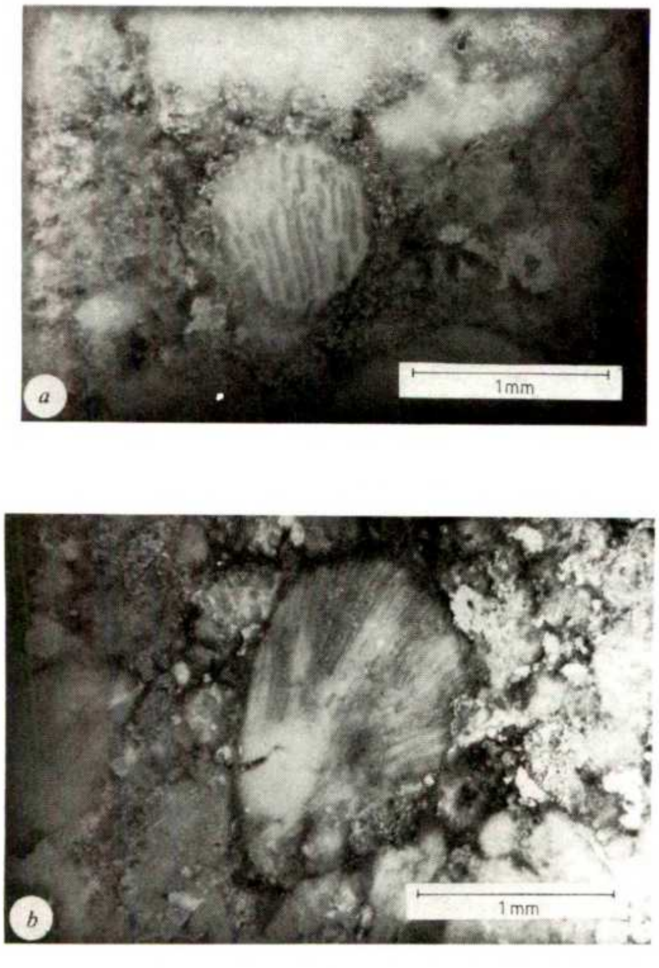

Fig. 2 Examples of well preserved chrondrules from the polished surface of the slab: *a*, a barred chondrule; *b*, a radiating chondrule.

The present mineralogy of the chondrite is quite different from the original one (and from that given by the petrographer). Olivine, pyroxene, nickel–iron and troilite no longer exist. In fact iron and magnesium have been lost almost completely from the meteorite. Instead, the dominating mineral is calcite, the other main constituents being barite, a Cr–V-bearing 'phengite' and a cobaltite—group mineral with more cobalt than nickel. Electron microprobe experiments reveal that only one primary mineral seems to have been preserved, chromite.

Table 1 shows some chromite analyses. The present chromite is seen to be a typical chrondrite chromite, with a homogeneous composition. The calcium content is interpreted as belonging to the calcite. The present chromite contains 0.93 wt% ZnO; the only chondrite found by Bunch *et al.*[4] to contain zinc-bearing chromite is the H5 Pultusk. It is very difficult to make a definite classification of the find, but it seems to be most similar to the H group, most likely the subgroups H4–H5. However, note that analysis 1 in Table 1 could be interpreted to indicate an unknown group of chrondrites.

Around the meteorite are concentric rings in different shades of brown, red, grey and green. They clearly represent reactions between the carbonate mud or, if later, limestone and the original meteoritic matter. These zones have not as yet been studied.

A badly preserved orthocone nautiloid cephalopod, which occurs in contact with the meteorite, could have been hit and killed by the meteorite.

Much of the discussion of the sources of chrondritic meteorites focuses on the part played by Apollo and Amor objects in their relationships to comets. Wetherill's results[5] indicate that for bodies in Earth-crossing orbits one half is eliminated in the first 10 Myr but that the rate of elimination then slows down greatly. He has shown that in steady state conditions and a population of ~800 Apollos (15 added per Myr) their median age will be ~200 Myr and ~35% of them will be more than 500 Myr old. Even if these figures were considered with great caution the present find is not inconsistent with Wetherill's conclusions.

The concentration of cosmic ray exposure ages around 4 Myr for modern H chondrites—this indicates that they come from another source than did the clast we have studied. Of course, it has been assumed that the composition of the chromite corresponds to those of H chrondrites and not to some unknown group. A detailed description of this first definite fossil stony meteorite will be given elsewhere[6].

Direct use of dissolved organic carbon by agglutinated benthic foraminifera

T. E. DeLaca*‡, D. M. Karl† & J. H. Lipps*

* Department of Geology, University of California, Davis, California 95616
† Department of Oceanography, University of Hawaii at Manoa, 2525 Correa Road, Honolulu, Hawaii 96822

Foraminifera are known to obtain nutrients in a variety of ways: they are omnivores, carnivores or herbivores[1-3] and some species are known to use the extracellular metabolites of their photosynthetic endosymbionts[1,2,4]. None, however, has previously been proven to utilize exogenous dissolved organic carbon directly, although this is well known in other marine species[5,6]. Knowledge of foraminiferal trophic positions is important because foraminifera are common in most marine communities[1] and may be the most abundant eukaryotic organism in the extensive deep-sea benthos[7-9]. Our studies of benthic foraminifera from an unusual Antarctic shallow water embayment now show that certain species utilize both particulate and dissolved organic material in their nutrition.

Our studies were conducted at McMurdo Sound, Antarctica, located in the southwest corner of the Ross Sea at latitude 77 °S and longitude 166°E (Fig. 1). The Sound is approximately 50 km wide; however, its eastern and western sides differ greatly in water column productivity and benthic biomass due to local oceanographic conditions[10] (see Fig. 1). The eastern side of McMurdo Sound is extremely productive during the austral summer, whereas the western side at New Harbor has very low productivity. The western side is rich in nitrate, phosphate and silica and low in plankton and particulate organic material (ref. 11 and D.M.K., unpublished data). Based on water analyses, species diversity and faunal affinities, New Harbor is more similar to the deep sea than to other shallow-water areas around Antarctica[11]. The organisms we discuss here were found only at New Harbor. Our investigation covered an area of 15–40 m depth, with a temperature of −1.8 °C. The sediments were rich in organic material. Analyses of dissolved amino acids, as shown by fluorometric analyses[12] of water collected in dialysis bags, demonstrated maximum concentrations in the sediment (20–30 μM at 1 cm) and smaller concentrations in the water column (5 μM at the sediment water interface, 1 μM at 10 cm from the bottom). This trend in the distribution of amino acids is similar to that of total dissolved organic carbon in the deep sea[13].

Our studies focused on *Notodendrodes antarctikos*[14] and an as yet undescribed species. Both are arborescent agglutinated foraminifera in the superfamily Ammodiscacea (Fig. 2). These large foraminifera are conspicuous components of the bottom assemblages at New Harbor, with abundances of >200 individuals per m^2 (ref. 14). Our initial studies on the physiology and trophic positions of these organisms revealed that they use captured suspended particulate organic material and dissolved organic materials in their nutrition. As seen by scanning electron microscopy of specimens which were fixed *in situ* and later dried using a critical-point technique, suspended particles are trapped in sticky cytoplasmic masses which extend from the branches of the tests. The foreign material caught in pseudopodia consists of benthic diatoms, bacteria, amorphous flocculent organic and inorganic material (such as silt, sand, broken diatom frustules and sponge spicules) with adhering bacteria. This material is probably suspended by the activities of larger invertebrates. Marine bacteria, labelled with ^{3}H-adenine (in the laboratory) were presented to foraminifera *in situ*, and these foraminifera were later fixed *in situ*. Microautoradiography revealed that the labelled bacteria are captured, digested and incorporated into the protoplasm of the organisms. However, the capture of particulate matter, in natural conditions, seems to occur infrequently in the population studied (3 of 32 specimens).

The foraminifera were tested for their ability to take up dissolved organic carbon by exposing them to several radiolabelled substrates, including amino acids (algal protein hydrolysate, Amersham), glucose and adenine (Table 1). We found that they took up the first two but did not absorb adenine. As bacterial contamination in our experiments could have produced erroneous results, we used ^{3}H-adenine (rapidly taken up by most bacteria[13]) in some of our experiments as a control in dual-label experiments with ^{14}C-labelled substrates. When tritium was detected in liquid scintillation analyses, those samples were assumed to be contaminated and were eliminated. 'Time zero' and NaCN- killed controls were used in all experiments.

Experiments measuring the uptake of dissolved organic carbon were conducted in the laboratory. Foraminifera cleaned in filter-sterilized sea water (0.22 μm) were placed in 10 ml of filtered (0.22 μm) sea water (1.0 μm free amino acids in solution) containing 2.5 μCi of ^{14}C-UL-protein hydrolysate

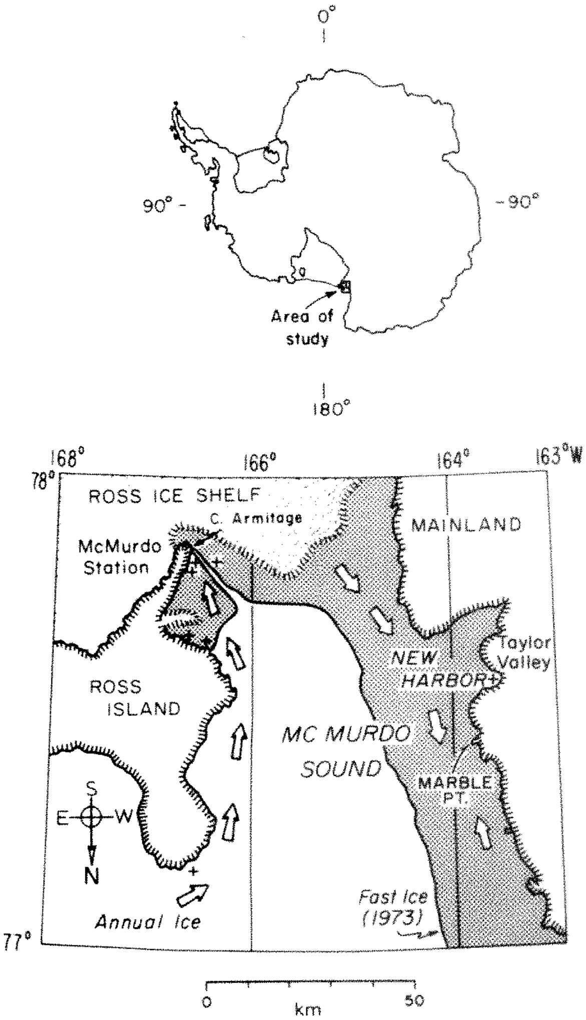

Fig. 1 Antarctica, showing the location of the study area. [During past investigations in McMurdo Sound we have surveyed several localities (+).] The two new species of foraminifera discussed in the present report were found only at New Harbor. Arrows indicate the probable direction of water movement. In the eastern and central parts of the Sound currents move south, advecting large standing crops of plankton from more northerly waters. The annual break up of sea ice on the eastern side allows local productivity to increase dramatically. In contrast to the highly productive eastern side, the western side of the Sound is bathed by northward moving currents[12] which probably originate under the Ross Ice Shelf and are poor in organic nutrients.

(0.0165 μmol free amino acids). The final concentration of free amino acids in solution was 2.65 μM, and incubation times of 0.58, 1.08, 2.25, 3.25 and 4.17 h were used, all experiments being conducted at −1.0 °C. Following incubation, the foraminifera were washed and: (1) solubilized in hot and cold 10% trichloroacetic acid (TCA), (2) placed in sealed reaction flasks with 10 ml of filtered sea water for measurement of $^{14}CO_2$ evolution, or (3) fixed for autoradiography.

Cellular contents of solubilized foraminifera were analysed using liquid scintillation. Uptake rates of 6.14×10^{-4} μmol h^{-1} (s.d. $= 4.26 \times 10^{-4}$, $n = 20$) were found. The tests of individual organisms were subsequently removed, washed three times in hot and cold 10% TCA to remove any remaining soluble material and re-analysed. Up to 41.3% of the label was incorporated into non-soluble material that remained in the test.

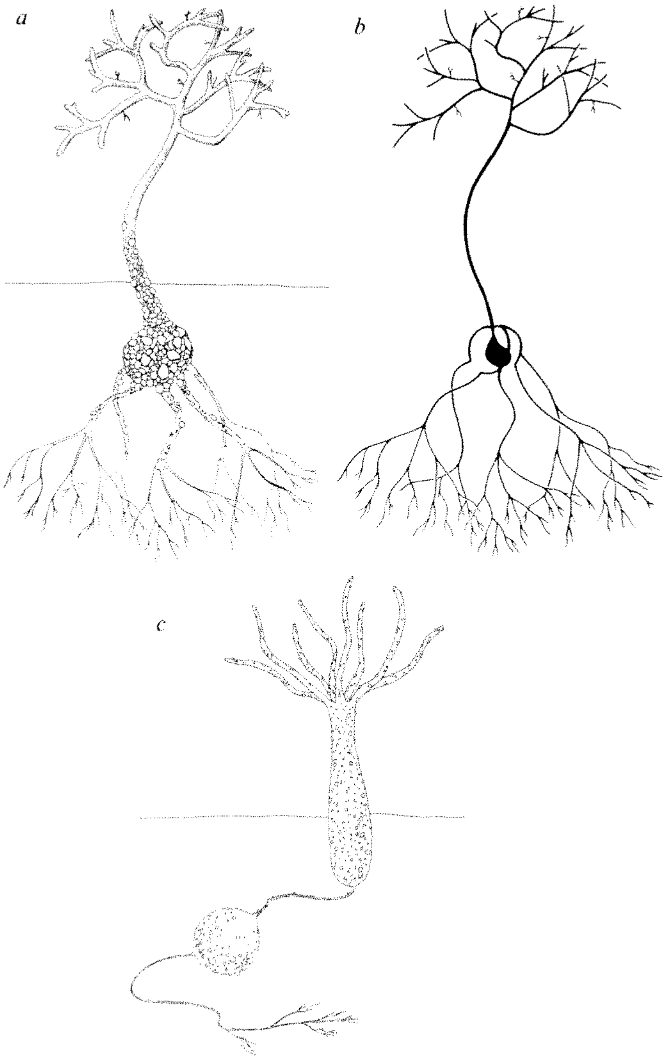

Fig. 2 *a*, *Notodendrodes antarctikos*[14] drawn in life position. The branching upper half extends above the sediment-water interface and the bulb and root system are buried in the sediment (average length 20 mm). *b*, The protoplasm of this species as would be seen if the test was removed. Cytological studies have shown that approximately one-third of the protoplasm (containing the nucleus) resides within the bulb. About one-third of the cytoplasm extends up the stem and occupies the branching system. Small pseudopods extend from the branches and upper portions of the stem. Particulate organic material is entrapped in these web-like projections. The remaining one-third of the cytoplasm resides in the extensive root system. Autoradiographic studies have shown that although dissolved organic material is taken up on all exposed cytoplasmic surfaces, the highest uptake occurs in the root system where the surface area is greatest. *c*, An unnamed agglutinated foraminfer (Notodendrodidae gen. et sp. n.) drawn in life position (average size 18 mm).

Table 1 Summary of uptake

Protein hydrolysate	
Total uptake	6.14 μmol h^{-1}
Incorporation into TCA-insoluble form	41.3% h^{-1}.
$^{14}CO_2$ liberated in 12 h	10%
Glucose	
Total uptake ^{14}C-glucose	6.1×10^{-2} μmol h^{-1}
$^{14}CO_2$ liberated in 12 h	46%
Adenine	
Total uptake	Undetectable

Experiments were conducted at −1 °C. Final concentration of free amino acid in laboratory experiments was 2.65 μM. Concentration of free amino acid in the sediment where the organisms are found was found to be 20–30 μM. See text for further explanation. Concentrations of glucose in the environment and laboratory experiments were not adequately measured.

The labelled foraminifera placed in reaction vials were incubated for 12 h at −1°C. The incubation was terminated with the addition of 0.2 ml of ethanolamine (placed on filter paper in the reaction vessel) and 1 ml H_2SO_4 (0.5 M) was injected into the seawater. After 2 h at room temperature (23 °C), the ethanolamine and filter paper were analysed by liquid scintillation. The results demonstrated that 10.0% of the total ^{14}C taken up was respired.

The results of autoradiography showed that the foraminifera took up dissolved organic carbon through any cell surface; consequently, uptake was a function of surface area. The 'root system', with its large surface area, was the principal site of uptake in the organisms analysed.

These two species of foraminifera seem to have ecological and physiological adaptations which are well suited to a highly seasonal oligotrophic environment. At New Harbor, primary productivity is very low and limited to a period of 1 or 2 months during the year, during which time the growth of a diatom flora on the undersurface of the 3–4-m thick sea ice or on the sediments of very shallow water (< 10 m) provides sparse organic input. The under-ice flora rains down to the bottom, where a portion is directly utilized while the remainder enters the detritus food web. Decomposition of this sedimented organic material generates relatively high concentrations of dissolved organic carbon in the sediment and supports a large and metabolically active microbial population (D. M. K., unpublished data). These foraminifera can capture and digest this particulate material either as it settles to the bottom or as it is resuspended by deposit-feeding invertebrates, although capture of particles seems to occur only infrequently. Dissolved organic carbon may contribute significantly to the nutrition of these foraminifera. During periods of no primary productivity, ~10 months of the year, they may sustain themselves on the high dissolved organic carbon reserves which are continually generated by the activities of heterotrophic microorganisms in the sediment.

Our results demonstrate that foraminifera are able to use both saprozoic and holozoic (phagotrophic) modes of nutrition. The amount and type of organic material available to foraminifera are therefore both much greater and more diverse than was previously thought. Re-evaluation of current ideas of the trophic positions of these extremely abundant organisms in benthic ecosystems is necessary, especially in deep-sea communities where they have been found to represent the highest test-free biomass of all eukaryotic organisms[9].

Present studies are analysing the metabolic rates of these organisms and will determine the proportion of their total energy requirements supplied by dissolved organic carbon.

We thank Professor A. E. V. Haschemeyer for her assistance in experimental design and encouragement, Drs W. L. Stockton and R. R. Hessler for reading the manuscript and Ms E. Bailey for drawing the figures. This research was funded by NSF grant DPP 76-17231.

Lichen recolonization in London's cleaner air

C. I. Rose* & D. L. Hawksworth†

* Department of Applied Biology, Chelsea College, University of London, Hortensia Road, London SW10 0QX, UK
† Commonwealth Mycological Institute, Ferry Lane, Kew, Surrey TW9 3AF, UK

Mean sulphur dioxide levels have fallen markedly in London, UK during the past 15 yr. Although lichens growing on trees are particularly sensitive to this air pollutant, there are few studies of lichen recolonization following pollution episodes. A survey of 29 sites in the north and west of Greater London, reported here, demonstrates that several species extinct or very rare in the area in 1970 have extended their ranges considerably. Studies on growth rates of the species concerned suggest that many of the sites discovered have been recolonized within the past 3–7 yr. If current trends continue, further improvements in the lichen flora can be expected in the next few years. However, it is unlikely that London will regain in the forseeable future many of the species lost during the past two centuries.

In the British Isles, smoke and sulphur dioxide (SO_2) levels have fallen by ~80% and 50% respectively in urban areas since 1960[1]; in Inner London, the mean annual level of SO_2 declined from 200–250 $\mu g\,m^{-3}$ to $<130\,\mu g\,m^{-3}$ in the same period[2]. Recorded changes in mean annual and mean winter SO_2 values at six stations in north and west London are shown in Fig. 1. Lichens have been used extensively as indicators of air pollution and have proved to be of particular value in estimating levels of SO_2 pollution in temperate regions[3–8]. Most studies have been concerned with changes in conditions of increasing levels of air pollutants but there are a few scattered reports of improving lichen vegetation in ameliorating conditions from Germany[9], Sweden[10,11] and several urban areas of the British Isles—Birmingham[12], Leeds[13–15], Newcastle-upon-Tyne[16] and Sheffield[17]. Some increases in the abundance of the SO_2-tolerant *Lecanora conizaeoides* between 1953 and 1967 at Holland Park, London, have been reported[18] and there are a few recent records of other more sensitive species from London, including a single plant of *Hypogymnia physodes* at Brent Reservoir in 1972 (ref. 19), and *Parmelia sulcata* on a wall at Brook Green in 1976 by P. W. James (personal communication). No detailed survey of the recolonization of lichens on trees in a large urban and suburban area has, however, been previously documented in the British Isles.

To determine what, if any, improvements of the lichen flora of the London area had taken place, 29 sites in the north and west of Greater London were studied between December 1979 and February 1980. The number of trees available for study varied but a minimum of five was examined at each site. Lichen abundance was estimated on a 1–5 scale (Table 1) and particular attention was paid to *H. physodes*, *Evernia prunastri*, *Parmelia caperata*, *Parmelia subaurifera*, *P. sulcata* and *Usnea subfloridana*, as these species have different ranges of tolerance to SO_2 (ref. 3) and are easily identified even when only a few millimetres in size. Additional interesting species were encountered in some sites, especially the Ruislip Local Nature Reserve, where 25 lichens not recorded from there in 1963 were found, including nine which are probably recent colonists (these results are presented in detail elsewhere[20]). Other notable records include *Buellia punctata* and *Xanthoria polycarpa* on dead elms near Northwood Hills (national grid ref. TQ 104898), the former also

in Pinner Park (TQ 135906) on dead elm stumps and *Rinodina exigua* on poplar in Eastcote (TQ 107889).

Comparison of the data presented in Table 1 with that of the same species in London in 1970 (ref. 18) leaves no doubt that there has been a marked incursion into north-west London in the past decade. To estimate the dates at which recolonization might have occurred, growth rates were studied by making direct area measurements, tracing 30 thalli of each of *H. physodes*, *P. sulcata* and *P. subaurifera* between April 1979 and March 1980 in the Ruislip Local Nature Reserve. These studies (to be reported in detail elsewhere) showed that the increases in area per unit time were significantly different (t-test between $P = 0.5$ and $P = 0.001$) between these three species. The annual increases in area at this site were 100–150% for *H. physodes*, 215–230% for *P. subaurifera* and 160–200% for *P. sulcata*, but no correlation between starting size and percentage increase per unit time was obtained (*H. physodes*, $R = -0.072$; *P. subaurifera*, $R = 0.019$; *P. sulcata*, $R = -0.002$; at $P = 0.05$ not significantly different from zero). In general, relative growth of circular lichen thalli expressed on a percentage basis is expected to be constant during the exponential growth phase, but to decline thereafter[21]; the exponential phase tends to last 10–15 yr and the Ruislip data therefore conform to the expected pattern. Reports of the effect of air pollutants on the growth rate of lichens are contradictory and the effect may vary both with the species and pollutant levels involved. However, a study on *Parmelia saxatilis* (a species closely related to *P. sulcata*) in north-east England indicated that growth was not significantly affected by substantial increases in ambient SO_2 levels[22]. Furthermore, in species where the growth rate is depressed, the amount of depression involved would not materially affect the results reported here[23]. Variations in the growth rate of a species can also arise from differences in humidity or aspect, or whether specimens are growing on vertical as opposed to horizontal surfaces[21,24]. Based on the mid-value between the mean of

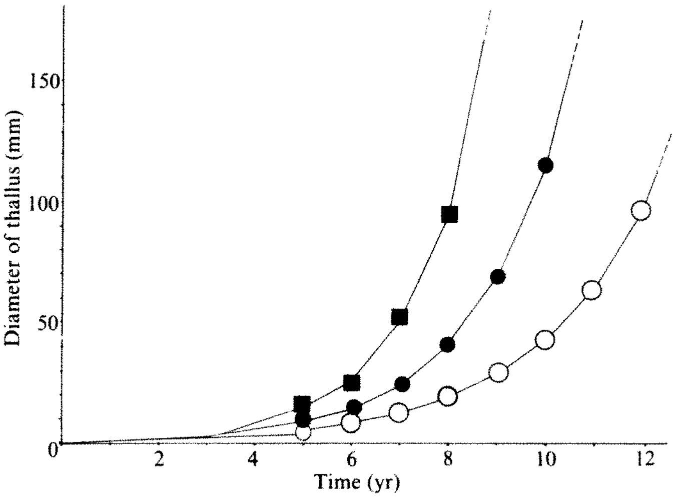

Fig. 2 Calibration curve used to estimate the minimum age of selected lichens from the diameter of their thalli. Based on the observed rates of increase in area per unit time at Ruislip Local Nature Reserve. ■, *P. subaurifera*; ●, *P. sulcata*; ○, *H. physodes*.

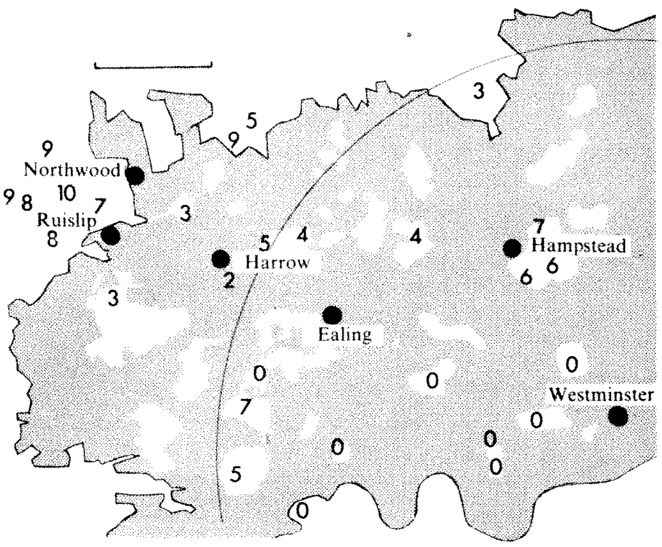

Fig. 3 North-west London showing the minimum age of foliose lichen colonies on trees (expressed in yr) calculated from observed thallus sizes and growth rates (Fig. 2). The arc indicates the limit of the survey by Laundon[18] (16-km radius from Trafalgar Square). Scale bar, 5 km.

readings for each species and the median of the range of values, the expected rate of increase in area per unit time was used to construct a calibration curve relating thallus diameter to age for these species (Fig. 2). This curve is designed to place a minimum age on individual colonies of the species concerned (where many specimens are present) rather than provide unequivocal dates for each individual thallus.

The results of the growth-rate study have been incorporated into Figs 3, 4, which show that recolonization by the foliose lichens considered has, subject to the above qualifications, taken place in the past 3–7 yr at most of the sites investigated, although this process was already in operation 8–10 yr ago in the Ruislip–Northwood and Harrow Weald areas. There is some collaborative data for these latter two areas: in Harrow Weald, populations of *H. physodes* declined between 1969 and 1971 but were still present at the latter date[25], while in the Ruislip Local Nature Reserve, foliose lichens were well developed in 1963 (ref. 20) (unfortunately there is no information on fluctuations in this site between 1963 and 1979). The results also show that the ranges of foliose lichens in the Ruislip area have extended considerably within the last 6 yr (Fig. 4).

As there is much evidence of the sensitivity of lichens to SO_2 pollution[3–8] and of the declines in SO_2 levels in the study area during the period when most of the lichen recolonization seems to have taken place, it is reasonable to suggest that the lichen recolonization now being seen is a direct response to falling mean SO_2 levels. Changes in levels of smoke would not be expected to cause responses in the lichen flora[26]. Air pollutants such as nitrogen oxides and ozone, which may have increased in the London area over the past two decades, would not have any adverse effects judging from experimental studies[27–29]. We therefore consider that these data demonstrate that London's lichens are responding to improvements in the air quality in the manner forecast by studies on deteriorating lichen floras. They also demonstrate that a cover of *L. conizaeoides* is insignificant in preventing the establishment of foliose lichens; indeed *H. physodes* and *P. sulcata* can establish directly on *L. conizaeoides*. Further, the lichenicolous fungus *Athelia arachnoidea*, which can kill many lichens and is especially common on *L. conizaeoides* in suburban areas, does not seem to oppose significantly re-establishment, as has been suggested[30]. It is also of interest that the sites in which recent recolonization has been found are not all contiguous. Recolonization has been more rapid in areas already with a nearby source of appropriate propagules, but dispersal has evidently been possible over considerable distances. Lichen diaspores are widespread in the air spora but soredia can also be carried on the feet of birds; as demonstrated at Brent Reservoirs[19], a site included in this survey.

The most suitable sites for recolonization are ones with well lit sheltered trees, in humid sites (for example, Ruislip Local Nature Reserve, Harrow Hill Pond, Wildwood Road), and often with willows overhanging a pond or marshy area surrounded by dense shrubs. In woodland sites, the earliest colonization tends to be at ground level, where air movements are less and the microclimate more favourable to growth; this would be expected as foliose lichens remain longest on tree bases in conditions of increasing SO_2 (ref. 3). In larger woodlands where the tree bases are very shaded and lichen growth is precluded, lichen communities including foliose species tend to develop on horizontal branches higher in the canopy where they can be easily missed. On willow, the first foliose lichen to colonize is *H. physodes*, followed by *P. subaurifera* and *P. sulcata*; *P. subaurifera* then tends to become more common (frequently growing where other species have died off) and *P. sulcata* dominant. On dry oak or birch, *H. physodes* seems better able to withstand competition from other species.

The investigations reported here concern only trees and studies in selected sites. We have not been able to undertake a tree-by-tree survey throughout north-west London and some recolonization sites will almost certainly have been overlooked. The sites listed in Table 1 are consequently representative rather than definitive as to the present position. Although the present survey was restricted to north-west London, the current improvement may be more general. For example, specimens of *Hypogymnia physodes* to 5 mm long were discovered on an oak stump near Pembroke Lodge in Richmond Park by F. S. Dobson in November 1980; this specimen was last recorded here in 1929 (ref. 17).

Lichens on man-made substrates, such as brick and asbestos-cement, can also be used as indicators of air pollutants but relatively little information is available on the way in which they respond, which is complicated by variations in the chemical nature of the substrate. However, our superficial observations suggest that they are responding in a parallel manner to the results presented here. In particular, *Lecanora muralis*, a species which changes its substrate range as SO_2 levels increase[23], can now grow on less basic substrates in the Kew area than it did in 1970; increases in this species have even led to comments in the local press arising from the general public's concern about this 'green fungus' on pavements[31,32].

Calcutta

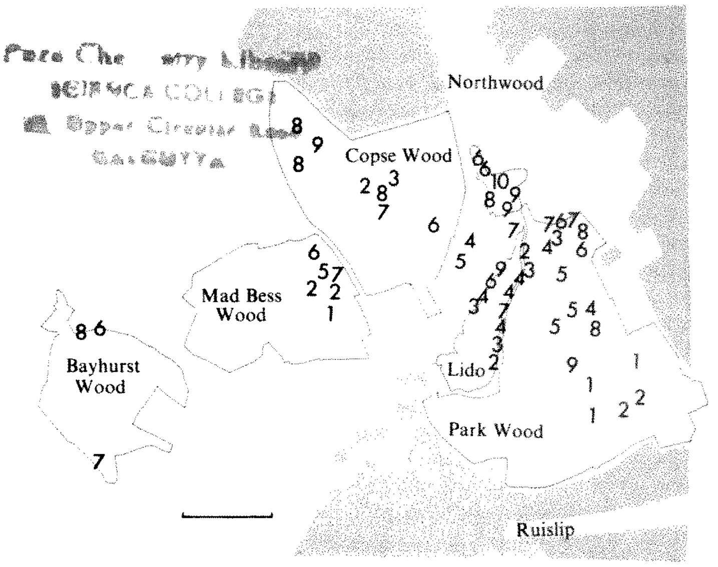

Fig. 4 Ruislip–Northwood Woods showing the minimum age of foliose lichen colonies on trees (expressed in yr) calculated from observed thallus sizes and growth rates (Fig. 2). Scale bar, 500 m.

The lichen flora of London has been studied since the early seventeenth century[33] and the historical records were combined into the survey of Laundon[18,34]. These records show a serious and progressive decline starting at least by the early nineteenth century, but which was particularly pronounced in the later decades of that century (for example, in Epping Forest[25]) and continued into the 1950s–60s. The loss of 129 lichen species from the area within a 16-km radius of Trafalgar Square has been attributed to increases in air pollution between 1800 and 1970 (ref. 18). Although the slight improvements reported here are encouraging, more drastic reductions in mean SO_2 levels are required before the environment is again suitable for many of the eliminated species. Indeed, a reduction in Inner London from the current mean of about 130 $\mu g\,m^{-3}$ to around 40–50 $\mu g\,m^{-3}$ would be necessary for survival of many of the more attractive foliose and fruticose species; transplant experiments have shown how hostile the Inner London environment is to some of these[35]. It has been estimated that mean SO_2 levels in urban areas will tend to fall until 1985, but thereafter return to 1975 levels due to changes in fuel-mix[1]. If this is true, only a limited rather than a substantial improvement in the lichen flora of the area seems likely.

We thank Mr P. W. James, Mr M. P. Jones, Mr J. R. Laundon and Drs C. J. Muskett and F. Rose for help. This work was carried out while C.I.R. was in receipt of a Chelsea College (University of London) Research Studentship.

Vacuoles as storage compartments for nitrate in barley leaves

Enrico Martinoia, Urs Heck & Andres Wiemken

Department of General Botany, Swiss Federal Institute of Technology, Sonneggstrasse 5, CH-8092 Zürich, Switzerland

Nitrate, the principal nitrogen source of most plants, can accumulate in large quantities in certain crop plants, notably members of the Chenopodiaceae (spinach and beet), Gramineae, Cruciferae (radish and kale) and Compositae (lettuce). Concentrations may exceed 2% fresh weight (17–24% dry weight) in extreme physiological conditions[1]. This is alarming because nitrate is readily reduced in organisms to the toxic nitrite, which may react with amines to form very potent carcinogenic nitrosamines[2]. Large stores of nitrate can be maintained in plant cells even in the presence of high nitrate reductase activity[3–8]. Incoming nitrate does not seem to mix with existing stores[4–6,9] and a steady influx of nitrate into the cells was found to be necessary to keep nitrate reductase stably induced[3,6]. Such observations have been explained by postulating a small 'metabolic' pool of nitrate accessible to nitrate reductase[4] and presumably also responsible for the induction of the enzyme[3], and a large 'storage' pool separate from the sites of metabolism[3–9,14]. Repeated attempts to measure these pools by an indirect method[4] have given equivocal results[1,10], but storage pools of nitrate have been generally thought to be located in vacuoles, which are difficult to isolate and analyse. However, we were able to isolate and purify the large central vacuoles of barley mesophyll cells and found most of the accumulated nitrate in the vacuoles.

Vacuoles were isolated from protoplasts as described in Fig. 1 legend and purity was confirmed by phase contrast microscopy (Fig. 1*c*). Contamination with intact protoplasts never exceeded 5%. Purity was further tested using marker enzymes. The specific activity of α-mannosidase[11,12] was much higher in the vacuolar fractions than in the homogenate of whole protoplasts (Table 1). Activities of α-mannosidase measured per 10^6 protoplasts and per 10^6 vacuoles were about the same (Table 1), indicating that almost all the enzyme was located in the vacuoles, of which each protoplast has only one (Fig. 1*b*). The vacuolar fraction contained 13% of the total activity of α-mannosidase present in the homogenate of protoplasts. On a basis of number protoplasts lysed the yield of α-mannosidase (that is of vacuoles) was 26%. The activities of two other hydrolytic enzymes, β-*N*-acetylglucosaminidase and protease, were also mostly restricted to the vacuoles (Table 2), supporting results obtained with other plants[11–13,15]. However, enzymes attributed to the chloroplasts (aldolase) and the cytosol (glucose-6-P isomerase, nitrate reductase[16]) were hardly detectable in the vacuolar preparation (Table 2).

We measured the contents of nitrate and amino acids in our pure preparation of vacuoles. As soluble substances can be easily lost from the vacuoles by leakage during isolation, we were surprised to find that almost all the nitrate in the protoplasts was contained in the vacuoles, together with about half of the soluble amino acids (Table 2). Vacuolar pools of amino acids have been reported elsewhere[17–19].

This demonstration of the vacuolar localization of nitrate raises the question of the value of nitrate storage pools to the plants. These pools could be nitrogen reserves. The rapid accumulation of nitrate from the soil could also help to prevent

Table 1 α-Mannosidase as vacuolar marker

	α-Mannosidase activity (nmol min^{-1})	
	Protoplasts	Vacuoles
Per (mg) protein	6.8	138*
Per 10^6 protoplasts or vacuoles	8.6	8.3†

* The specific activity of α-mannosidase in the isolated vacuoles is 20.3 times higher than that in the homogenate of protoplasts.

† Assuming that each protoplast has only one vacuole, 97% (±12%) α-mannosidase was found in the vacuoles. Procedures described in Table 2 legend.

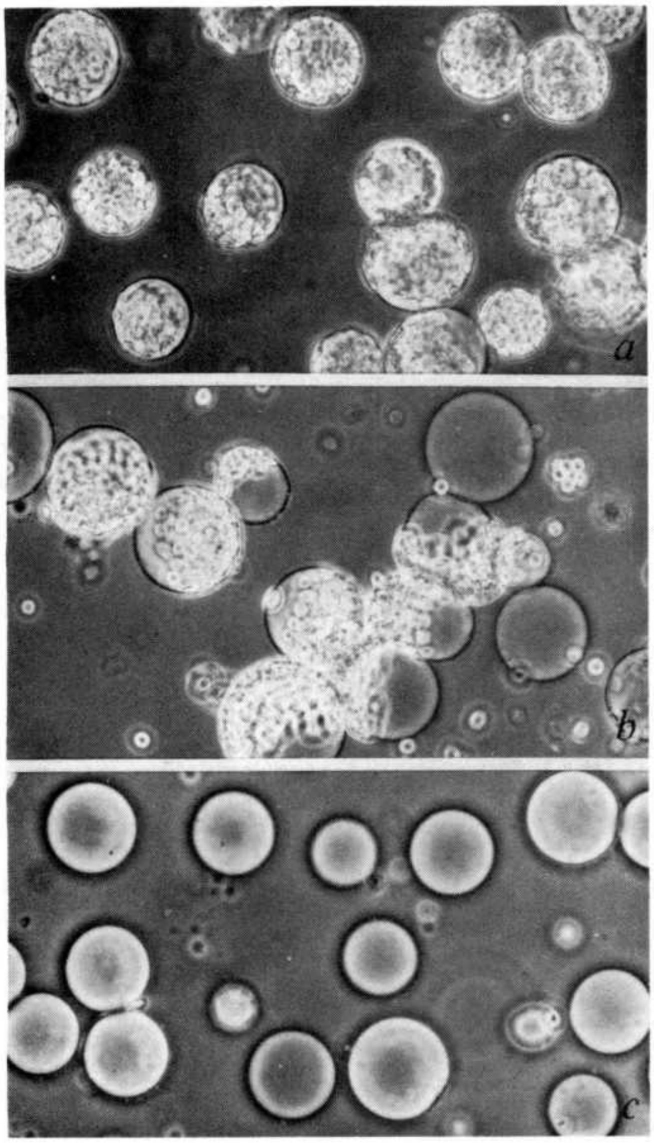

Fig. 1 *a*, Barley mesophyll protoplasts; *b*, protoplasts releasing their single large vacuole; *c*, isolated vacuoles. Phase contrast micrographs × 300. Protoplasts were prepared from the mesophyll of primary leaves of barley seedlings (*Hordeum vulgare* L. cv Nymphe) grown for 8 days on vermiculite, irrigated with 30mM KNO_3 (27 °C, 12 h light/dark cycle, 60% humidity). The leaves were cut into pieces (1 mm^2) which were incubated in medium containing 2% Onozuka R-10 cellulase (supplied by Welding & Co. Hamburg, Germany), 1‰ Pectolyase (Seishin Pharma, Noda, Chiba, Japan), 0.4M sucrose, 20mM citrate-Na^+ buffer, *p*H 5.6 (2 g fresh weight of leaves per 10 ml in a Petri dish). After 3 h at 20 °C the protoplasts, which came only from the mesophyll, were filtered through a 80 μm nylon net and purified by flotation (7 min at 1,400*g* in a swingout rotor) through a three-step density gradient: (step 1), 10 ml suspension of protoplasts diluted with 10 ml of 10% Ficoll 400 (Pharmacia Uppsala, Sweden), 0.4M sucrose, and 'supplements' (15mM phosphate buffer (*p*H 7.6), 2mM EDTA-Na (but not for nitrate determination), 10mM cystein-HCl (only in nitrate reductase determination)); (step 2), 10 ml 2.5% Ficoll, 0.4M sucrose and 'supplements'; (step 3), 4 ml 0.4M sorbitol and 'supplements'. The protoplasts recovered after centrifugation from the interface above step 2 were diluted with an equal volume of 10% Ficoll, 0.4M sucrose plus 'supplements' and flotated a second time through an identical density gradient. Vacuoles were liberated from the purified protoplasts by pressing the suspension (3×10^6 protoplasts per ml, 4 °C) through a long needle (10 cm × 0.2 mm) using a syringe. After this treatment about half of the protoplasts were ruptured and about two thirds of these released their single large vacuole intact. The vacuoles were immediately purified by flotation (2 min at 200*g*, followed by 3 min at 1,000*g* in a swingout rotor) through a three-step density gradient: (step 1), 5 ml lysate in 0.4M sucrose, 2.5% Ficoll and 'supplements'; (step 2), 5 ml 0.2M sucrose, 0.2M sorbitol and 'supplements'; (step 3), 2 ml 0.4M sorbitol and 'supplements'. Purified vacuoles were recovered from the step 3 layer. The whole isolation procedure from the time of rupturing of the protoplasts, was no longer than 8 min.

Table 2 Subcellular localization of enzymes and substances

	Activities or contents

Protoplasts were counted in a haemocytometer. The number of vacuoles was calculated from the α-mannosidase activity (the activity of α-mannosidase per 10^6 vacuoles (Table 1) was known and remained fairly constant (±8%) from one experiment to another). Per cent in vacuoles was calculated by assuming that 100% of the α-mannosidase is located in the vacuoles. The calculation was as follows: % activity or content in the vacuolar faction divided by % activity of α-mannosidase in the same fraction multiplied by 100. Enzyme activities were measured by standard methods: aldolase[22], malate dehydrogenase[22], nitrate reductase[23], α-mannosidase and *N*-acetylglucosaminidase with the corresponding nitrophenol substrates[12], and acid protease with haemoglobin as substrate in 0.1M sodium acetate buffer, *p*H 3.9, as described elsewhere[11]. Amino acids were measured with ninhydrin and protein by a modified method of Lowry[11]. Nitrate concentrations were determined potentiometrically with an ion-selective liquid membrane electrode as described elsewhere[24,25]. The membrane composition was 6% (by weight) methyl-tridodecyl-ammonium-chloride, 65% dibutylphthalate and 29% polyvinylchloride (by weight). The calibration for measurements in solution with protoplast lysate were done in solutions of the composition given in Fig. 1 legend (step 2) and in 10^{-4}, 10^{-3} and 10^{-2} M sodium nitrate. For the determination of nitrate in vacuoles the solution of step 3 was used as background. The detection limit for this experiment was checked using barley which had not been irrigated with nitrate.

leakage, or uptake by neighbouring plants. It may also play a part in ionic and osmotic balance of the cells. This is particularly likely in plants in which nitrate reaches high concentrations of up to 300 mM (ref. 1) (generally halophytes) and in which nitrate may be accumulated as an alternative to chloride[20]. The answer to the question on the control of transport of nitrate through the vacuolar membrane could shed light on the relationship between the nitrate pools and the highly complex regulation of nitrate reductase activity[21].

We thank D. Ammann and P. Anker for help with nitrate measurements and S. Türler for reading, and D. Furrer for typing the manuscript.

Subpopulations of cultured chick sympathetic neurones differ in their requirements for survival factors

David Edgar, Yves-Alain Barde & Hans Thoenen

Abteilung Neurochemie, Max-Planck-Institut für Psychiatrie,
D-8033 Martinsried, FRG

Peripheral autonomic and sensory neurones derived from the neural crest will survive *in vitro* only if the culture medium is supplemented with specific factors (for review see ref. 1). For example, the nerve growth factor (NGF), although supporting the survival of sympathetic and spinal sensory neurones[2], is ineffective on parasympathetic neurones[3], whereas medium conditioned by chick heart cells (HCM) supports the survival of all three neuronal types[4]. We showed previously that the requirements of cultured spinal sensory ganglion neurones for survival factors changed during development, and so provided a basis for the classification of such factors[5]. We now demonstrate that cultured post-mitotic neurones from chick paravertebral sympathetic ganglia respond differentially to NGF, HCM and medium conditioned by C6 glioma cells (GCM). Thus, these three survival factors are functionally distinct in that they support the survival in culture of discrete subpopulations of sympathetic neurones. Those subpopulations responding to HCM and NGF are shown to differ not only in their requirements for survival factors but also in their contents of the cholinergic and adrenergic marker enzymes choline acetyltransferase (ChAT) and tyrosine hydroxylase (TH).

Cultures were established using methods similar to those previously described[5,6], the age of the chick embryos being checked by staging according to the criteria of Hamburger and Hamilton[7]. Lumbar and sacral paravertebral sympathetic ganglia were taken from embryos incubated between 8 and 18 days, dissociated and the cells pre-plated to remove most of the non-neuronal cells[5,6]. The few remaining non-neuronal cells in the cultures were easily distinguishable from neurones, the latter having compact, round cell bodies with thin neurite processes at least five cell diameters in length. NGF, GCM and anti-NGF antibodies were prepared as previously described, GCM being used in the present experiments after 10-fold concentration[5]. HCM was prepared by the method of Collins[8], except that 5% heat-inactivated horse serum was substituted for fetal calf serum to cultivate the heart cells, and the HCM was concentrated two-fold by ultrafiltration (Amicon UM 10) before use.

Table 1 Survival of cultured 12-day chick sympathetic neurones

	% Neuronal survival in response to:			
	Factor shown	Double concentration of factor	Factor plus NGF (5 ng ml^{-1})	Factor plus HCM
Control medium	0.09 ± 0.10			
NGF (5 ng ml^{-1})	37.1 ± 4.5	39.0 ± 5.0		
HCM	45.0 ± 3.0	41.0 ± 6.0	88 ± 9.5	
GCM	6.1 ± 2.1	8.0 ± 2.5	55 ± 4.5	71 ± 7.8

Mean values ± s.e.m. are given ($n = 3$). Sympathetic neurones were taken from paravertebral ganglia of 12-day old embryonic chicks. After trypsinization and dissociation, the cells were pre-plated in 10-cm plastic tissue culture dishes for 150 min as previously described[5,6]. The culture medium was F14 (ref. 14), supplemented with 10% heat-inactivated horse serum, penicillin (100 U ml^{-1}) and streptomycin (100 μg ml^{-1}). The neuronal suspension was then removed, those cells excluding trypan blue (>90%) counted using a haemocytometer and plated in poly-DL-ornithine-coated dishes[8] at a density of 5,000–8,000 cells per 35-mm dish (equivalent to one ganglion) in 1.5 ml medium containing the factors shown. Where NGF was not added, the media were supplemented with 500 ng ml^{-1} anti-NGF antibodies to inhibit any endogenous NGF, as found, for example, in GCM[5]. Neurones were counted after 48 h culture, the number being checked to remain constant on two subsequent days.

Table 2 Enzyme levels of 12-day chick sympathetic neurones

	Specific activity (pmol per min per mg) ± s.e.m. ($n = 3$)		
	ChAT	TH	Ratio ChAT/TH
After 48 h culture with:			
NGF	102 ± 44	281 ± 75	0.36
HCM	842 ± 77	137 ± 31	6.07
NGF + HCM	855 ± 45	310 ± 40	2.76
After 48 h culture with NGF, followed by 48 h with both NGF and HCM	85 ± 30	210 ± 40	0.40
Paravertebral sympathetic chains	680 ± 28	266 ± 20	2.56

Cultures were set up as described in Table 1 legend, the number of cultured neurones being increased to 50,000–80,000. After culture for 2 days, neurones were collected and ChAT activity was measured[15] using the ChAT inhibitor naphthylvinyl pyridine[16] (50 μM) to confirm specificity of the assay. Tyrosine hydroxylase was measured by a modification of the method of Levitt *et al.*[17], the difference being that a tetrahydrobiopterin cofactor (640 μM) was used[18], in the presence of 20 mM ascorbate, 10^{-4} M ferrous ammonium sulphate and 24,000 U ml^{-1} catalase[19]. The tyrosine concentration was 23 μM and specificity of the assay was checked using the TH inhibitor α-methyl-tyrosine (10^{-4} M)[20]. Initial reaction rates were linear with time and amount of sample. Protein was estimated by the method of Bradford[21] using bovine γ-globulins as the standard.

After removal of most of the non-neuronal cells by pre-plating and in the absence of added factors, less than 0.1% of the sympathetic neurones taken from 12-day old embryos survived after 2 days in culture (Table 1). Addition of NGF, HCM or GCM at the start of the culture period resulted in the survival of differing proportions of neurones, although each of the three factors was shown to be at saturating concentration: doubling the concentration of a given factor did not increase the number of surviving neurones. Culture with a combination of factors, however, resulted in an additive effect (Table 1), a maximum of 90% 12-day old neurones surviving in the presence of both NGF and HCM. Because such a high survival is possible in culture, and because there was no great loss of cells during the dissociation procedure which led to a complete disruption of the ganglia, this system provides an opportunity to observe *in vitro* a representative picture of the whole neurone population present *in vivo*. The differing proportions of neurones surviving in response to the different factors and the additivity of the effects of those factors point to the presence of discrete subpopulations of sympathetic neurones, the survival in culture of each being selectively supported by a given factor. This conclusion supports and extends the previous observation that not all chick sympathetic neurones respond to NGF in cultured ganglion explants[9].

To analyse further the relationships between the survival factors and their responsive neurones, we examined the effects of NGF, HCM and GCM on the survival of neurones taken from sympathetic ganglia of different embryonic ages. Figure 1 shows

0028-0836/81/040294—02$01.00

that NGF supports the survival of a maximum of 37% cultured neurones taken from 12-day old embryos, whereas HCM is maximally active on 14-day old neurones (57% survival) and the effect of GCM increases with age throughout the time period studied. The developmental patterns of sympathetic neuronal survival in response to NGF and GCM are strikingly similar to those previously obtained for dorsal root ganglion neurones[5]. Thus, NGF and GCM act as functionally distinct factors for both sensory and sympathetic neurones, and HCM may be differentiated from the other two on the basis of the age of the neurones on which it is maximally active. We have not demonstrated whether those neurones which are maximally dependent on NGF for their survival at day 12 become dependent on either HCM or GCM later during development. Furthermore, a relationship remains to be established between the various subpopulations defined here by their factor requirements in culture, and those subpopulations defined by morphological criteria *in situ*[10].

To approach these problems, we characterized biochemically the two major subpopulations of 12-day old neurones which survived in culture in response to either HCM or NGF. Table 2 shows that the HCM- and NGF-responsive neurones differ in their contents of TH and ChAT, necessary for the synthesis of the sympathetic neurotransmitters noradrenaline and acetylcholine, respectively. Thus, the cultured HCM-responsive neurones have a ChAT/TH ratio of 6.1, some 17-fold greater than that of those neurones surviving with NGF. Cells cultured with both NGF and HCM have an intermediate ChAT/TH ratio of 2.8, similar to that determined for freshly dissected 12-day old sympathetic chains.

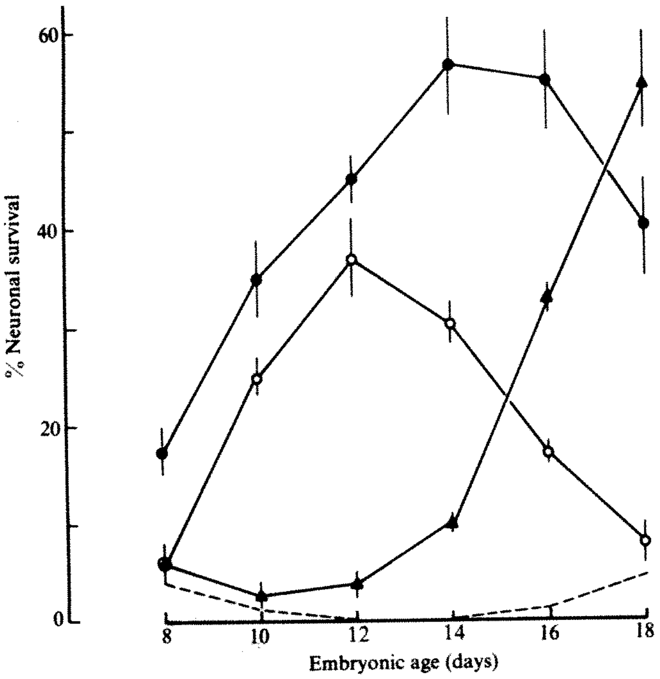

Fig. 1 Neurones were dissociated from paravertebral sympathetic ganglia taken from chicks of embryonic ages shown. After pre-plating, 5,000–8,000 neurones were plated on poly-DL-ornithine as described in Table 1 legend. Neuronal survival was estimated between days 2 and 5 after the start of culture, and it was checked that the percentage neuronal survival did not decrease significantly on two subsequent days. The dashed line shows the low basal levels of neuronal survival without added factors. An increased neuronal survival seen in control cultures of neurones from 8- and 18-day old chicks is a consequence of the slower death rate of the younger cells, and of the presence of more non-neuronal cells which support neurones in the cultures from older embryos. Parallel cultures were set up with supplements of: 5 ng ml^{-1} NGF (○), HCM plus 500 ng ml^{-1} NGF antibodies (●) and GCM plus 500 ng ml^{-1} NGF antibodies (▲). Results are expressed as percentages of surviving neurones ± s.e.m. ($n = 3$).

We do not know whether the high ChAT levels found in the HCM-responsive neurones is a consequence of a selection of those cells in culture which had pre-existing high ChAT activity *in vivo* or whether this enzyme was induced in the chick neurones by HCM in a manner similar to that shown for neonatal rat sympathetic neurones (for review see ref. 11). Note in this connection that HCM maintains the ChAT activity in cultured neurones at the levels measured in the embryonic sympathetic chains (Table 2, see also ref. 12) at a time when preganglionic (cholinergic) innervation is largely undeveloped[13], that is, when most of the ChAT may be in ganglionic neurones rather than innervating axons. Furthermore, HCM does not induce ChAT activity in that subpopulation of neurones previously selected by culture with NGF (Table 2). These observations are consistent with the hypothesis that NGF and HCM selectively support the survival of distinct subpopulations of embryonic chick sympathetic neurones which differ in their contents of adrenergic and cholinergic marker enzymes.

We thank Veronika Böhm for technical assistance.

The number of polarizing region cells required to specify additional digits in the developing chick wing

C. Tickle

Department of Biology as Applied to Medicine, The Middlesex Hospital Medical School, Cleveland Street, London W1P 6DB, UK

A group of mesenchyme cells at the posterior margin of the developing wing—the polarizing region—can have a dramatic effect on the pattern of structures which develop across the antero-posterior axis of the limb. If one grafts a polarizing region to the anterior margin of a wing bud so that this bud now has one polarizing region at the anterior margin and one at the posterior margin, the wing that develops has duplicated structures across the antero-posterior axis in mirror-image symmetry[1-3]. That is, the normal pattern of digits 2 3 4 (reading from anterior to posterior) becomes 4 3 2 2 3 4. The ability of the polarizing region to specify additional digits from adjacent tissue can be progressively attenuated by γ-ray radiation[4]. If this attenuation is caused by progressively fewer cells remaining viable to signal, there should be a quantitative relationship between the number of polarizing cells used and the digit specified next to the graft. Here, two tests are reported which confirm this idea. The results suggest that the apical ridge cooperates with a small number of polarizing region cells in a monolayer to specify structures across the antero-posterior axis of the wing.

Fig. 1 Diagram to show how grafts of pieces of cell pellet were made to host wing buds (stage 20–21). The grafts were cut from a centrifuged pellet of cells which had been incubated for 1 h at 37 °C. The grafts were ~150–200 μm per side and contained about 6,000 cells (estimated from serial sections: average for 4 pieces = 5,979, s.d. 464). The cell suspensions were prepared from polarizing regions and equivalent-sized pieces of anterior mesenchyme tissue dissected from the wing buds of chick embryos (stage 22: Hamilton–Hamburger) following removal of the ectoderm with 2% trypsin (Difco). Various mixtures of polarizing region cells and inactive cells from anterior margins were made. For each suspension a total of 20 pieces of tissue was used. The standard grafting procedure, shown in *a*, involved removing a piece of mesenchyme plus overlying apical ridge from the anterior margin of the host limb bud opposite somite 16 or 17 and placing the piece of pellet in the hole. The graft was held in place by a pin of platinum wire. In the other grafting procedure, shown in *b*, a cut was made along the base of the apical ectodermal ridge over the anterior part of the host bud with a sharpened tungsten needle. The apical ectodermal ridge was raised up from the underlying mesenchyme and the piece of pellet was placed between. No mesenchyme tissue was removed. The apical ridge was stretched away from the mesenchyme and once the graft was in place it contracted back to hold the pellet in position.

In the first set of experiments, cells from the polarizing region were mixed with inactive cells from the region along the anterior margin of the wing bud. By progressively diluting disassociated polarizing region cells with these inactive cells and grafting the mixture after re-aggregation to an anterior position in another bud, a clear relationship between the number of polarizing region cells and the digit formed next to the graft can be shown.

The results of grafts carried out by the standard procedure (Fig. 1*a*), but with varying proportions of re-aggregated polarizing region cells and inactive anterior cells, are listed in Table 1*a*. As the proportion of polarizing region cells in the grafts decreased, the digit formed next to the graft changed progressively: first a digit 3 (Fig. 2*c*) instead of a digit 4 (Fig. 2*a*) was produced, then a digit 2 (Fig. 2*d*) instead of a digit 3, and finally no additional digits at all (Fig. 2*b*) were specified. A

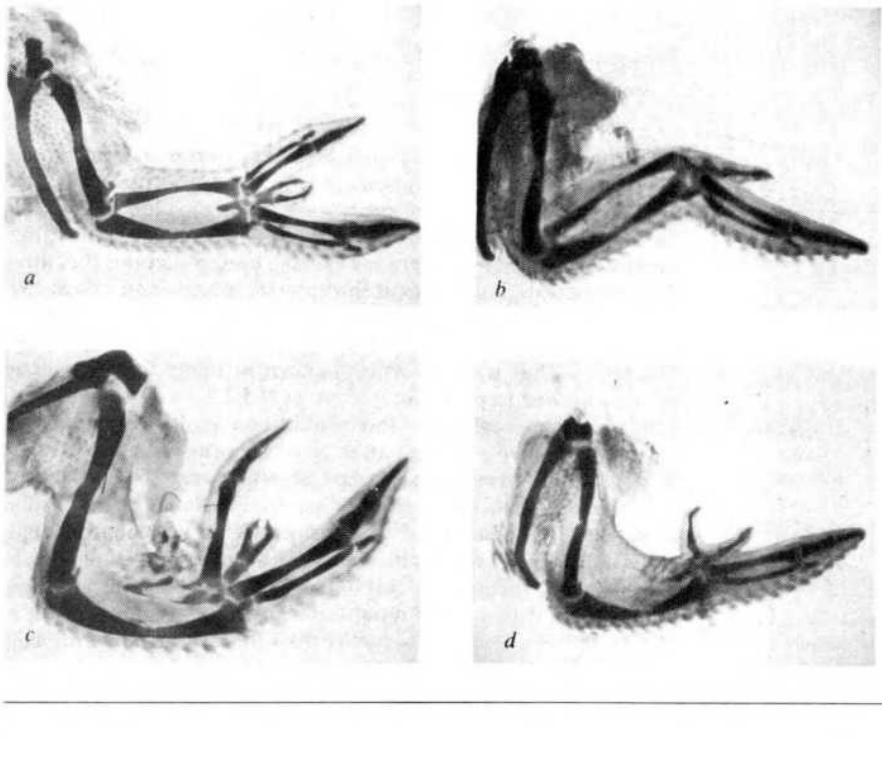

Fig. 2 Dorsal views of whole mounts of wings obtained following grafts of re-aggregated cells made as shown in Fig. 1*a*. *a*, 100% polarizing region cells. Pattern of digits is 4 3 2 2 3 4. *b*, 100% anterior margin cells. Pattern of digits is 2 3 4. *c*, 50% polarizing region cells and 50% anterior margin cells. Pattern of digits is 3 2 2 3 4. *d*, 5% polarizing region cells and 95% anterior margin cells. Pattern of digits is 2 2 3 4.

Table 2 Comparison of independent estimates of the number of polarizing region cells, placed under an intact apical ridge, which are required to specify each additional wing digit

	Digit 4	Digit 3	Digit 2
a	100(1)	79(10)	35(12)
b	164	64–32	32 or less

a, Mean numbers of polarizing cells on pieces of plastic film grafted under the apical ridge with the cells facing the ridge; *b*, number of polarizing cells on a face of a piece of pellet of re-aggregated polarizing and anterior mesenchyme cells grafted under an intact apical ridge. In *b*, data were calculated from the average number of cells on a face of a pellet and % polarizing cells in mixed pellet required to specify each digit. Values in parentheses indicate number of cases.

similar effect has also been obtained when polarizing region cells are diluted with BHK cells (unpublished observations). Even when only 5% of the cells were from the polarizing region, an additional digit 2 was obtained in one-third of the cases (Fig. 2*d*). Because the same order of loss of duplicate digits is found when the polarizing region is treated with increasing doses of γ-ray radiation[4], it seems likely that the effect of the irradiation is to diminish the number of viable cells in the graft.

To investigate whether close contact with the apical ridge leads to more efficient signalling, as suggested by the recent work of Saunders[5], another series of grafts, in which the polarizing region cells were progressively diluted with anterior mesenchyme cells, was carried out (Table 1*b*). In this series, however, the apical ridge was left intact (Fig. 1*b*). It is clear that these grafts placed under an intact apical ridge are much more effective. For example, if the effects of grafts containing 50% polarizing region cells are compared, digit 4 was still specified in some cases when grafts were placed under the ridge, whereas an extra digit 4 has never been obtained with a standard graft.

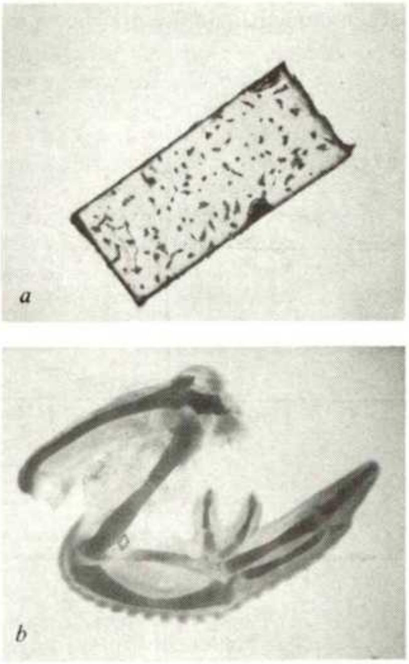

Fig. 3 *a*, Piece of plastic film (Melinex, ICI) after 3 h incubation on Parafilm (American Can Company) with a drop of suspension of polarizing cells prepared from at least eight polarizing regions. This piece of plastic (scale bar is 100 μm) has been fixed and stained with Leishman's to show attached cells, some of which have spread. To count the numbers of cells on such pieces of plastic (100–250 μm on a side) before grafting, the pieces were transferred with a spatula to a dish and viewed in an inverted phase-contrast microscope. The piece of plastic with a known number of polarizing cells was then carried into position over the host wing bud on a spatula and manoeuvred into the grafting site. *b*, Wing which developed after grafting of a piece of plastic film carrying 28 polarizing cells. The graft was made to a slit beneath the apical ridge and the film was oriented so that the cells faced the ridge. Digit pattern is 2 2 3 4. Note that the piece of plastic has ended up at the elbow of the developed wing.

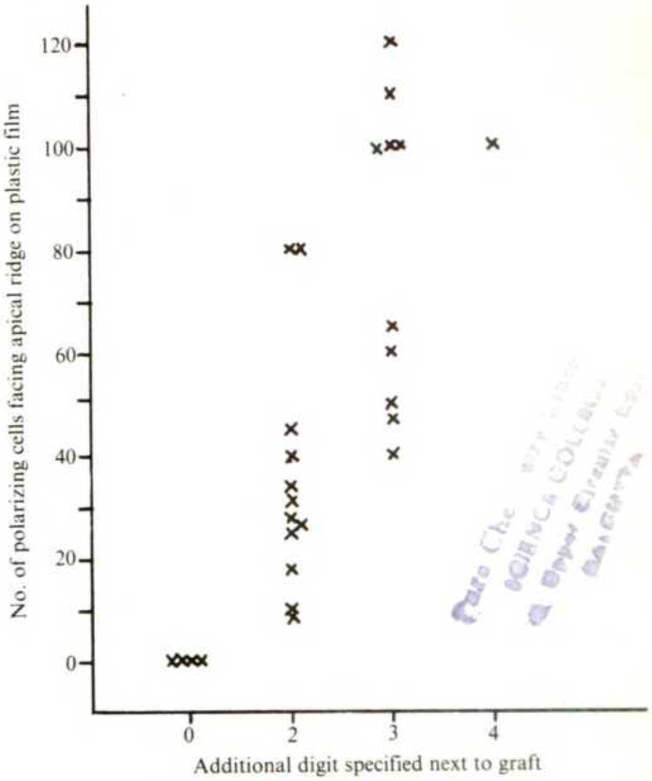

Fig. 4 Data on the digit which formed next to the graft after implantation of pieces of plastic film carrying varying numbers of polarizing cells. The plastic film was grafted to a slit beneath the apical ridge with the cells facing the ridge.

From the total numbers of cells in pieces of pellet the following estimates can be made: with the standard grafting procedure, at least 6,000 polarizing region cells (100% polarizing region cells in the graft) are required to obtain digit 4 next to the graft; to obtain digit 3, 3,000–6,000 cells are required, and for digit 2 between 3,000 and as few as 300 are needed. For grafts made under an intact apical ridge, a digit 4 requires about 3,000 polarizing region cells, but only about 600 cells are required for a digit 3 and even fewer for a digit 2.

In the second set of experiments, small numbers of polarizing cells stuck to pieces of plastic film (Fig. 3*a*) were implanted just beneath the apical ridge. Figure 4 shows that remarkably small numbers of polarizing cells can now specify additional digits in the chick wing (Fig. 3*b*). Grafts of pieces of plastic with small numbers of anterior mesenchyme cells (five cases) always resulted in normal wings. Figure 4 also shows a clear relationship between the number of polarizing cells grafted on the piece of film and the digit which developed next to the graft. The estimate of the mean number of cells required to specify each wing digit is shown in Table 2. Thus, to specify digit 4 at least 100 polarizing cells must be grafted beneath the apical ridge, whereas specification of digit 3 requires 79 cells and digit 2, 35 cells. In one case, the transfer of only nine polarizing cells led to a wing with an additional digit 2.

The two independent estimates of the number of polarizing cells in contact with the ridge that are required to specify each additional wing digit are apparently very different. However, if the number of polarizing cells on only the face of each mixed pellet, used for grafts under the apical ridge, are considered, the number of cells required for signalling agrees well with the estimates obtained from implanting known numbers of cells on pieces of plastic film (Table 2). Thus, it seems likely that the signalling ability of the polarizing region involves only a monolayer of cells, the rest of the cells in a grafted pellet being superfluous or inactive. Both this finding and the observation that the mixed aggregates signal best when grafted under an intact apical ridge suggest that cooperation between the monolayer of polarizing cells and the apical ectodermal ridge is essential for positional signalling.

This work was supported by the MRC. I thank Professors L. Wolpert and B. Alberts for their enthusiastic encouragement. I also thank Professor Alberts for two visits to his laboratory supported by NIH grant GM23928, and M. Goodman and A. Crawley for help with photography and histology.

Flow cytometry analysis of T cells and continuous T-cell lines from autoimmune MRL/l mice

D. E. Lewis, J. V. Giorgi & Noel L. Warner

Immunobiology Laboratories, University of New Mexico School of Medicine, Albuquerque, New Mexico 87131

The study of spontaneous autoimmunity in mouse models affords an opportunity to determine the cellular basis of the immune dysregulation observed in this disease. Recently, a new mouse strain, MRL/Mp-*lpr*/*lpr* (MRL/l) has been developed[1] which carries an autosomal recessive gene (*lpr*) that results in massive lymph node enlargement concomitant with the development of several autoantibodies[1–4]. The interest in this strain lies in the possibility that the defect in T-cell regulation of the immune response is manifested at a different level from that in the NZB mouse[3]. It has been reported that the proliferating population of lymphoid cells in the nodes of these mice are T cells, but that many of them are devoid of Lyt surface antigens[4]. We have accordingly initiated several lines of research with these mice, including quantitative flow cytometry characterization of Lyt antigen expression of cells in the lymph nodes of the mice. In an approach to isolate and study the properties of these cells, we have also established continuous cell lines from the lymph node cells of MRL/l mice, using techniques similar to those used to establish continuous lines of antigen-activated cytotoxic T cells[5,6] and helper T-cell populations[7].

Lymph node cells from MRL/l and MRL/n mice at various ages, and T-cell lines which were established from MRL/l lymph node cells were examined for Lyt-1, Lyt-2 and Thy-1.2 cell surface density using indirect immunofluorescence. Xenogeneic (rat) hybridoma-derived monoclonal antibodies which have specificities for Lyt-1, Lyt-2 (both framework determinants) and Thy-1.2, were provided by Drs Ledbetter and Herzenberg of Stanford University[8]. The lymph node cells were stained for 20 min on ice, washed three times in Eisen's balanced salt solution (BSS) and then fluorescein-conjugated (Fl) goat anti-rat immunoglobulin was added as a second step reagent. The cells were incubated for an additional 20 min, washed three times in BSS and examined using the flow cytometry systems at Los Alamos Scientific Laboratories[9,10] or a Becton Dickinson FACS-III cell sorter.

Table 1 Comparison of cell-surface markers on *in vivo* MRL/lpr lymph node cells and *in vitro* MRL/lpr cell lines

Surface marker	MRL/lpr MLN cells	MRL/lpr T-cell line
Thy-1.2	Moderate density (lower than MRL/n)	Moderate density
Lyt-1	Increased % positive Lower density	Most positive Low density
Lyt-2	Marked reduction in % positive	Most lines variable
Lyt-3	As for Lyt-2	As for Lyt-2
T-30	Lower density	Most lines positive Low density
Th-B	Negative	Negative
FcR	Negative	Negative

Surface marker was detected by flow cytometry with monoclonal antibodies. Results for MRL/lpr are intensity and per cent cells relative to age matched control MRL/n mice. The MRL/lpr T-cell line is representative of most MRL/lpr cell lines. MLN, mesenteric lymph node.

Attempts were made to establish continuous cell lines from MRL/l, MRL/n and C57BL/6 mesenteric lymph node cells by plating 5×10^5 to 1×10^6 cells ml^{-1} in 5-ml volumes of Dulbecco's modified Eagle's medium (DMEM) supplemented with non-essential amino acids (1 ml 100 ml^{-1}, 100x, Gibco), 10^{-4} M 2-mercaptoethanol, 10% fetal calf serum and 25% T-cell growth factor (TCGF) (v/v), which was prepared from rat spleen cells stimulated with 5 μg ml^{-1} concanavalin A (Con A) for 46 h (ref. 5).

The results of the analysis of Lyt phenotypes of lymph node cells from MRL/l and MRL/n mice are shown in Fig. 1. The

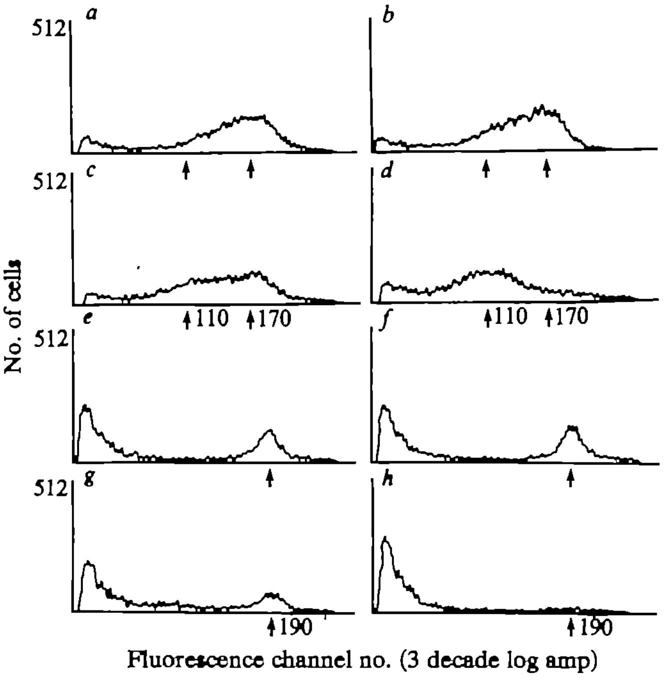

Fig. 1 Flow cytometry analysis of Lyt-1 and Lyt-2 expression on mesenteric lymph node cells of MRL/lpr and MRL/n mice. In each analysis cell suspensions were stained with the hybridoma-derived supernatants followed by fluorescein-conjugated SJL anti-rat immunoglobulin. The left column of panels (*a*, *c*, *e*, *g*,) shows cell suspensions from 2-month old mice, and the right-hand column of panels (*b*, *d*, *f*, *h*) those from 5-month old mice. *a*, *b*, MRL/n cells stained with anti-Lyt-1; *c*, *d*, MRL/lpr with anti-Lyt-1; *e*, *f*, MRL/n with anti-Lyt-2; *g*, *h*, MRL/lpr with anti-Lyt-2. The key distinction between MRL/lpr and MRL/n mice is the presence of a low density Lyt-1 peak around channel 110, and a selective reduction in Lyt-2 cells in older MRL/lpr mice

Fig. 2 Dependence on T-cell growth factor (TCGF) of MRL-III continuous T-cell line. Four aliquots of MRL-III cells were seeded at $10^5\,\mathrm{ml}^{-1}$ in the presence of Dulbecco's medium with the indicated additive. Growth occurs in the presence of 25% TCGF either with or without α-methylmannoside. Growth of the line is not supported by the addition of Con A alone.

MRL/l lymph node population at 8 weeks of age is characterized by a shift in the surface density of Lyt-1, in that, compared with MRL/n lymph node cells, a population of cells with lower Lyt-1 expression is evident. By 5 months of age this low surface density population of Lyt-1 cells has become the predominant population and by 5 months of age there are very few Lyt-2-positive lymph node cells (that is, either Lyt-1^+2^+ or Lyt-1^-2^+). The Thy-1.2 staining characteristics indicate that the MRL/l mouse lymph node cells, which are all Thy-1.2 positive, have lower amounts of Thy-1.2 antigen than do MRL/n lymph node cells. As the cell population is also somewhat larger, the actual cell-surface density is considerably lower than in the MRL/n mice.

Seven MRL/l cell lines have now been established and several of the lines have been in culture for up to 8 months. The lines were all established from mesenteric lymph node cells from 3–5-month old MRL/l mice. The cells will not grow in DMEM without TCGF, nor will they grow in DMEM supplemented with $5\,\mu\mathrm{g\,ml}^{-1}$ Con A (Fig. 2). Furthermore, addition of 60 mM α-methylmannoside to the growth medium does not inhibit the effect of the TCGF. These data indicate that the growth of the MRL/l cell lines is dependent on a growth factor in the TCGF medium which is not Con A itself.

Attempts made to establish continuous cell lines from MRL/n and C57BL/6 lymph node cells were unsuccessful. The cells multiplied much more slowly than the cells from MRL/l mice, and never reached high cell densities *in vitro*. These lymph node cells were occasionally maintained in culture for periods of up to 2 months.

Because it is important to know whether these *in vitro* continuous T-cell lines are representative of the abnormal proliferating cells *in vivo*, we have compared the *in vivo* and *in vitro* cell lines using a range of surface markers. After several weeks in culture, the *in vitro* lines show a complete absence of B cells, and all cells are Thy-1.2 positive. The Lyt phenotype of the cells has fluctuated, however, and as shown in Fig. 3, includes both Lyt-1^+2^- and Lyt-1^+2^+ lines. The predominant phenotype of most of the lines has been Lyt-1^+2^-, with fluctuations primarily among cells that are Lyt-2^+. Some lines thus contain many Thy-1^+ Lyt-null cells. These may, however, have lower undetectable amounts of Lyt-1.

Using a broader range of cell-surface markers, we show in Table 1 that the *in vitro* lines, as studied here, are generally similar to the predominant population of cells *in vivo*.

Our results indicate that the massive lymphoproliferation observed in MRL/l mice is associated with a decline in the proportion of Lyt-2-positive T cells. This population includes both Lyt-123- and Lyt-23-positive cells. The majority of the cells present in these large nodes are Lyt-1 positive, but have a distinctly lower density of Lyt-1 on their surfaces than normal cells. These results are in contrast to those of Theofilopoulos *et al.*[4], who reported that about 50% of the cells in the MRL/l lymph node are Lyt-null T cells, although they did suggest that the 'Lyt-null cells' may not be completely devoid of Lyt antigens. With flow cytometry we find only approximately 10%

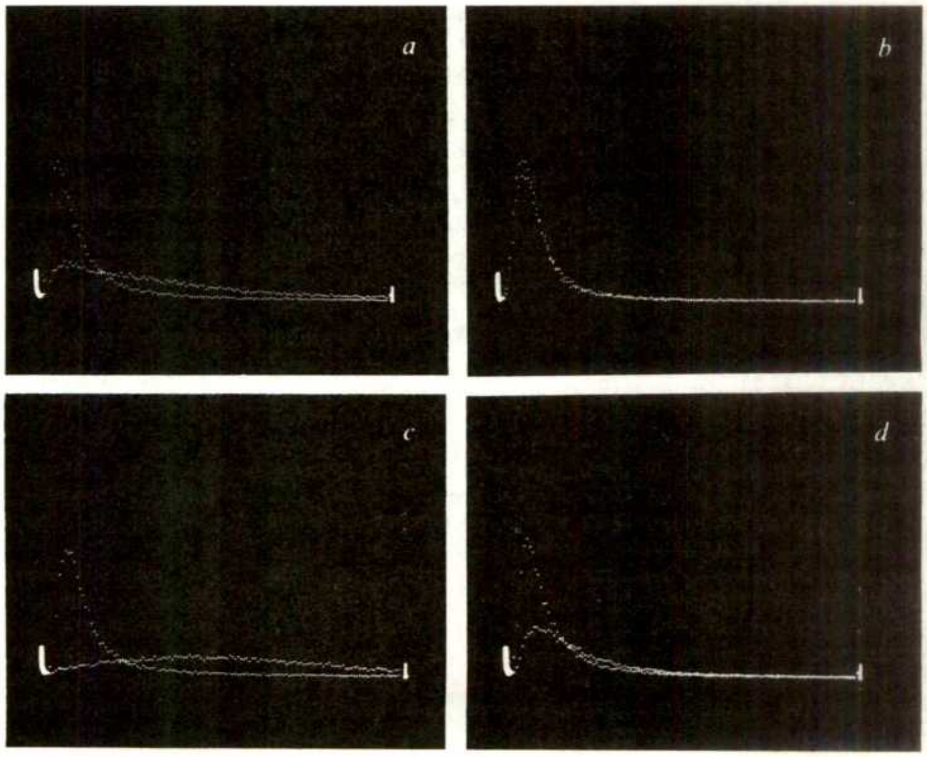

Fig. 3 Flow cytometry analysis of Lyt-1 and Lyt-2 expression on two MRL continuous T-cell lines. Each panel shows the fluorescence profile (FACS-III histogram) of the cell suspension stained with either medium or hybridoma supernatant, followed by fluorescein-conjugated goat anti-rat immunoglobulin. Panels *a* and *b* show cell line MRL-VI stained, respectively, with anti-Lyt-1 and anti-Lyt-2, and panels *c* and *d* cell line MRL-VII stained, respectively, with anti-Lyt-1 and anti-Lyt-2. In each panel the number of cells is on the ordinate and the relative fluorescent intensity on the abscissa.

of the T cells in the MRL/l lymph node to be of Lyt-null type (but Thy-1.2 positive). Thus, this quantitative analysis clearly indicates that the proliferating T-cell population in the MRL/l lymph node may be a relatively homogeneous T-cell subset. Further analysis of these cells with other differentiation antigens is proceeding.

The present report also extends the findings of other investigators which indicate that continuously proliferating lines of T cells can be readily established in long-term culture as long as T-cell growth factors are present. Our results indicate that it is possible to establish cells from MRL/l mice (but not cells from normal mice) in continuous culture without deliberate exogenous antigenic stimulation. Thus, it might be proposed that antigenic stimulation for these lymph node cells from MRL/l mice is from an autoantigenic source, probably derived *in vivo* before culture, as the lines do require continual TCGF for maintenance.

It is interesting that the cell lines generated from the lymph nodes of MRL/l mice are variable in their Lyt expression, although all are T cells. Cloning and cell sorting experiments are in progress to resolve this problem and to determine whether this variability truly represents instability in Lyt expression in a continuously proliferating clonal line. The fact that cell lines can be established at all in the absence of antigenic stimulation may allow the development of pure subpopulations of specific Lyt antigen-bearing cells for further dissection of the functional role of Lyt subsets in the aberrant immune response observed in these autoimmune mice.

This work was supported by NIH research grants AM19841 and fellowships AI05779 and CA05921. We thank Mrs Jerri Davis for maintenance of the MRL mouse colonies.

Cyclosporin A (CSA) is a fungal metabolite which exerts profound effects on the immune system and has potential as a selective immuno-suppressive agent[1]. Clinical trials with human renal allograft recipients have confirmed this potential but there have been disturbing reports of lymphoma in a significant number of patients[2,3]. Despite extensive animal studies, the specificity of this drug for human lymphocyte subpopulations is largely unknown[4]. We demonstrate here that *in vitro* CSA has no apparent effect on Epstein–Barr virus (EBV)-induced B-lymphocyte activation, but totally inhibits the T-cell dependent pokeweed mitogen (PWM) B-cell response. In addition, CSA markedly facilitates the outgrowth of B-lymphoblastoid cell lines from both EBV-infected and non-infected lymphocytes of EBV immune donors cultured *in vitro*. These results indicate that CSA can interfere with the lymphocytes normally responsible for maintaining the life-long carrier state initiated by primary infection with EBV, allowing outgrowth of the persistently infected cells circulating in the peripheral blood.

We have investigated the effects of CSA on human polyclonal B-cell activation *in vitro*. Figure 1 demonstrates the differential effects of CSA on activation induced by two mechanistically different activators, EBV and PWM. The results clearly show that CSA completely inhibits PWM-induced B-cell activation which is T-cell and monocyte dependent[5,6] whereas the polyclonal activation produced by the T- and monocyte-independent EBV[6] is actually enhanced early in the culture period at 6 days. CSA did not influence cell viability in the PWM cultures but markedly reduced morphological blast transformation.

We next studied the effects of CSA on the generation of lymphoblastoid cell lines from individuals of known EBV immune status whose lymphocytes were either infected *in vitro* with EBV or uninfected. Table 1 summarizes the results obtained from a number of individuals. In cultures of lymphocytes not treated with CSA, lymphoblastoid cell lines were only obtained from cultures to which EBV had been added. In agreement with the results of others[7,8], cell lines were easily obtained from lymphocytes from a seronegative donor infected

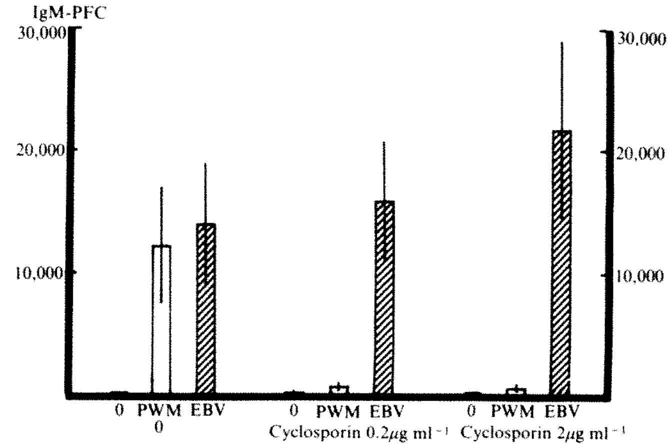

Fig. 1 The effects of cyclosporin A on the polyclonal activation of human blood lymphocytes by EBV and PWM. Lymphocytes from seven adult volunteers of known EBV immune status were cultured at a final density of 10^6 ml^{-1} in RPMI 1640 medium supplemented with 10% human AB serum (anti-VCA positive) and antibiotics. Cultures were incubated for 6 days in 50-ml plastic flasks (Falcon 3013) in the presence of 5% CO_2. EBV infection was achieved by 1 h pre-incubation at 37 °C of a suspended pellet of 5×10^6 lymphocytes with 1 ml of B95-8 cell line supernatant. PWM was added to appropriate cultures at a final concentration of 20 μg ml^{-1}. Cyclosporin A (Sandoz) was initially dissolved in a small volume of 95% ethanol and then diluted in Earle's balanced salt solution to give a concentration of 100 μg ml^{-1}. The drug was added to cultures to give a final concentration of 2.0 or 0.2 μg ml^{-1}. Cultures were assayed for the presence of antibody-secreting cells by use of the protein A plaque assay which has been described elsewhere[6]. Results are expressed as IgM plaque-forming cells (PFC) per 10^6 viable cells at the end of culture. A similar relation was found for IgG PFC (data not shown).

Immune status of the donors was examined by determination of the antibody titre to EB-viral capsid antigen (VCA). Cultures were established as in Fig. 1 and were regularly examined for cell line formation. This was determined visually by the appearance of progressively growing foci of transformed cells[7]. The scores above are from 4–12 weeks of culture. In many cases the presence of lines was confirmed by transferring the cells into secondary cultures. Cell lines arising in non-EBV-infected lymphocytes were examined for the presence of EBNA by the method of Reedman and Klein[9].

with EBV, but, despite initial transformation in all seropositive donor cells, regression of cell lines occurred in eight out of nine donor cultures. Addition of CSA allowed cell lines to be established by 4 weeks with ease and without regression from all seropositive donors so far tested. More significantly, B-cell lines have also been obtained from cultured lymphocytes from six out of nine seropositive donors exposed to CSA but not infected with EBV. These cell lines contained the EB-determined nuclear antigen (EBNA), a characteristic of EBV transformation[9] and they were of similar morphology to those derived from cells exposed to EBV (K. Nilson, personal communication).

These results clearly demonstrate that CSA exerts profoundly selective effects on human lymphocyte subpopulations *in vitro*. The enhancement of the polyclonal immunoglobulin response induced by EBV and abrogation of that by PWM strongly suggest that at least the fraction of B cells activatable by EBV is refractory to the action of CSA. We interpret the abolition of PWM responsiveness to mean that the site of action of CSA is the T lymphocyte or, less likely, the monocyte—both essential for a PWM-induced polyclonal immunoglobulin response.

Furthermore, CSA seems to promote the early and complete outgrowth of EBV B-lymphoblastoid cell lines from immune donors *in vitro*. It has been shown that at a cell density of 10^6 ml^{-1}, lymphoblastoid cell line generation from EBV-infected lymphocytes from immune donors is inhibited by the *in vitro* appearance of immune T lymphocytes[7]. It seems that CSA specifically deletes or functionally inactivates these T cells, allowing the rapid appearance of EBV-transformed cell lines from all immune donors tested. In six out of nine seropositive individuals, EBV-bearing cell lines have been directly established from the blood merely by the addition of CSA alone. It is known that EBV-infected B cells persist in the lymphoid system of immune donors and can grow out into lines in appropriate conditions if T lymphocytes are removed[7]. CSA seems to facilitate this outgrowth, probably by its specific action on the T lymphocyte.

The experimental conditions we have used are certainly unfavourable for *de novo* infection of B cells by *in vitro* released infectious particles[10], because cells were grown in human AB anti-VCA positive serum. In the presence of specific antibody EBV cannot activate B lymphocytes[11]. Although we cannot exclude transfer of virus between cells in intimate contact we suggest that the lymphoblastoid cells growing out from CSA-treated blood of EBV immune donors really represent the progeny of the latently infected cell.

There have been recent disturbing reports of lymphomas presenting in renal allograft recipients treated with CSA and there is a general tendency for anti-EBV titres to rise in patients on treatment with CSA. In one reported case lymphoma followed asymptomatic infectious mononucleosis[12] and in another EBNA was present in the lymphomatous B cells[3]. On the basis of these *in vitro* experiments we suggest that in the presence of CSA, T-lymphocyte surveillance of EBV-infected B cells is no longer effective. The result is a polyclonal proliferation of EBV-transformed B cells which *in vitro* from B-lymphoblastoid lines but *in vivo* manifest as the polyclonal immunoblastic proliferation characteristic of immunosuppressed patients[13].

We thank Kicki Hild for technical assistance, Kenneth Nilson for characterizing the lines and G. Klein for supplies of B95-8 supernatant. This work was supported by the Swedish MRC and in part by a grant from the North of England Cancer Research Campaign.

Inhibition of *P. falciparum* growth in human erythrocytes by monoclonal antibodies

L. H. Perrin, E. Ramirez, P. H. Lambert & P. A. Miescher

WHO Research and Training Centre, Department of Medicine,
Hôpital Cantonal, 1211 Geneva 4, Switzerland

Malaria is increasing in incidence and prevalence in most tropical areas and is a major problem for both individuals and communities[1]. Current malaria research is aimed at developing vaccines[2–4] and, for this, it may be useful to define *Plasmodium* antigen(s) related to the development of a protective immune response in the host. Monoclonal antibodies have recently been shown to interfere with rodent malaria infection (*Plasmodium berghei*) at the sporozoite[5] or merozoite[6] stage. We have now raised monoclonal antibodies against single antigenic determinant(s) of *Plasmodium falciparum* and report that some of them inhibit the growth of erythrocytic forms of *P. falciparum in vitro*.

Red blood cells (RBCs) parasitized with *P. falciparum* were obtained from a European patient on his return from Senegal and were adapted and maintained in *in vitro* culture according to

Table 1 Inhibition of *P. falciparum* growth by monoclonal antibodies

		% Parasitaemia		
Culture medium + 10% ascitic fluid from various hybridomas	Ig class	Total	Intact parasites	% Growth inhibition
Hb28 cl1	IgG3	0.2	0	100
Hb26 cl3	IgG2a	1.5	0.6	96
Hb31 cl2	IgG3	1.2	0.5	95
Hb12 cl4	IgG1	9.6	9.4	19
Hb9 cl1	IgM	9.7	9.5	18
Medium + 5% NMS		9.8	9.6	17
Medium + 10% NaCl		11.8	11.4	0
P3-X63-Ag8 (Fo)		9.6	9.4	19

The inhibition of *P. falciparum* growth *in vitro* by various monoclonal antibodies was analysed by a modification of the technique described by Wilson and Phillips[14]. Synchronized cultures of ring forms of *P. falciparum* were diluted with uninfected human RBCs to provide a final suspension of 1.5% RBCs and 0.5% parasitaemia. Aliquots (150 μl) of this suspension were placed in 96 flat-bottomed wells (3040 Falcon plates). Each microculture was done in triplicate. The medium used for the culture (RPMI 1640 with 10% normal human serum)[7] was supplemented with either 10% ascitic fluid produced by various hybridomas or as control with 5% serum of normal BALB/c mice (NMS), 10% isotonic NaCl, or ascitic fluid induced by myeloma cells used for fusion. The culture medium was removed from the settled cells each day and replaced with fresh medium. The plates were incubated at 37 °C in a candle jar[9]. Parasitaemia was determined on Giemsa-stained thin blood smears after 80 h of incubation. In these conditions, more than two cycles of replication took place in the wells containing the medium +10% NaCl. At the end of the experiment, some of the parasites were pyknotic, especially those in cultures supplemented with Hb28 cl1, Hb26 cl3 and Hb31 cl2. Therefore, the percentage inhibition was determined over the number of intact parasites. The results reported here represent three hybridomas with inhibitory activity and two out of a group of eight hybridomas without any significant inhibitory activity (10–19%).

the method of Trager and Jensen[7]. These cultures were not synchronized and contained all the various developmental erythrocytic stages (rings, trophozoites, schizonts, merozoites). Synchronization was induced by two treatments with 5% mannitol at an interval of 34 h (ref. 8); this treatment lysed the mature forms (trophozoites and schizonts), leaving only the ring forms. Approximately 30 h after treatment with mannitol, merozoites were released from schizonts and non-infected RBCs were invaded.

In the first series of experiments, 8-week-old female BALB/c mice were immunized intraperitoneally (i.p.) three times at 2-week intervals with 100 μg of merozoite and schizont antigen in Freund's incomplete adjuvant. Four days before the fusion experiment a booster of 5 μg of the antigenic preparation was administered intravenously (i.v.). Merozoites and schizonts were purified from a synchronized culture of *P. falciparum* by Plasmagel sedimentation[9] and contained < 10% normal RBCs. In a second series of experiments, BALB/c mice were infected i.p. with 1×10^5 erythrocytic forms of *P. berghei*, treated with chloroquine[10] and 3 weeks later injected i.v. with 5×10^5 erythrocytic forms of *P. berghei* 4 days before the fusion procedure. For each experiment, 2×10^7 immune spleen cells in suspension were fused by polyethylene glycol with 1×10^7 non-secreting mouse myeloma cells derived from P3-X63-Ag8 (clone FO given by Dr Fasekas, Basel Institute of Immunology). Conditions for fusion were essentially as described by Galfre *et al.*[11]. Positive hybrids were clone purified twice on mouse macrophage monolayers by limiting dilution and further grown in T75 Falcon flasks. 5×10^6 cells were injected i.p. into BALB/c mice which had been primed 1 week previously with 0.5 ml Pristan i.p.

An indirect immunofluorescence technique was used to assay hybrid supernatants. Acetone-fixed *P. falciparum*-parasitized human RBCs or *P. berghei*-parasitized mouse RBCs were used as antigenic preparation and rabbit fluoresceinated anti-mouse $F(ab')_2$ as the developing second antibody[10,12]. Antibodies specific for the surface antigen or merozoites were similarly detected by reacting hybrid supernatants or ascitic fluid with a suspension of unfixed schizonts and merozoites (~10^5 per 25 μl) purified by Plasmagel[9].

Spleen cells from nine mice immunized with *P. falciparum* merozoites and schizonts and two mice immunized with *P. berghei* were fused in 11 experiments: 47 of 978 supernatants tested reacted with *P. falciparum*-parasitized RBCs; two of these supernatants obtained from mice immunized with *P. berghei* reacted with both *P. berghei* and *P. falciparum*. From each fusion experiment, hybrid cells from one or two wells (total 15) were selected, clone purified twice on macrophage monolayers and grown in large amounts. The cells were injected i.p. into mice, and the ascitic fluid was collected. When the 15 ascitic fluid samples were tested by indirect immunofluorescence against the different developmental stages of acetone-fixed parasites, 10 samples (including Hb28 cl1 and Hb31 cl2) reacted with trophozoites and schizonts only, two (including Hb26 cl3) reacted with schizonts only, and three reacted with all stages. The ascitic fluid samples were positive by indirect fluorescence at dilutions of 1/5,000–1/100,000.

The culture medium used for *P. falciparum* culture[7] was supplemented with 10% of the various ascitic fluids and the mixtures were tested for their ability to inhibit the multiplication of erythrocytic forms of *P. falciparum*. An 80-h assay corresponding to more than two cycles of multiplication in normal culture conditions was used. Three out of 11 ascitic fluids tested had an inhibitory activity, two of them, Hb26 cl3 and Hb31 cl2, were produced with spleen cells from mice immunized against *P. falciparum* antigens, and the third one, Hb28 cl1, with spleen cells from mice infected with *P. berghei* (Table 1). Sera from

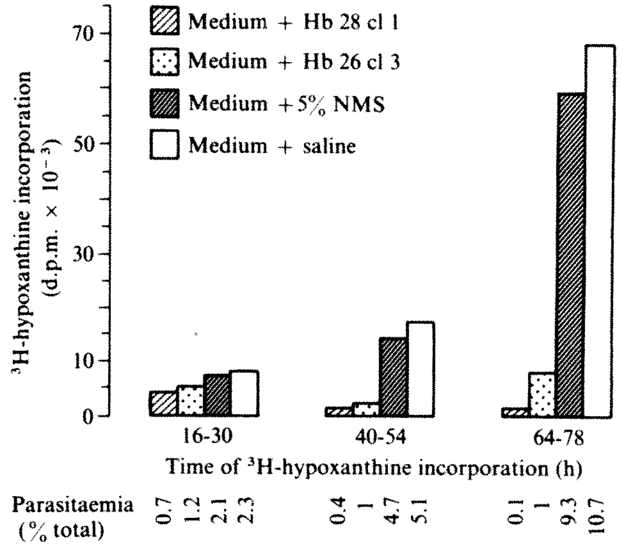

Fig. 1 Incorporation of ^{3}H-hypoxanthine was determined in *P. falciparum* cultures supplemented with 10% ascitic fluid from Hb26 cl3 and Hb28 cl1 hybridomas, 5% BALB/c normal serum and 10% isotonic NaCl, three times during an interval of 14 h. The experimental design was identical to that described in Table 1 legend, except that 10 μl of ^{3}H-hypoxanthine (1 μCi) were added to each culture at the beginning of the labelling period ($18.5–55.5 \times 10^{-3}$ Bq mmol^{-1} specific activity, NEN). The percentage parasitaemia was determined at the end of each labelling experiment on Giemsa-stained thin blood smears.

Table 2 Specificity of the inhibition of *P. falciparum* growth

Culture medium supplemented with:	% Parasitaemia	% Growth inhibition
1. Hybridoma Hb26 cl3		
10% ascitic fluid	0.8	91
IgG-depleted 10% ascitic fluid	7.2	15
Purified IgG fraction (0.5 mg ml^{-1})	0.9	89
2. Mouse immunoglobulins		
IgG2a (LPC-1) (1 mg ml^{-1})	7.8	7
IgG2b (MOPC-195) (1 mg ml^{-1})	9.1	0
Normal mouse IgG (1 mg ml^{-1})	7.7	9
3. Medium + 10% NaCl 0.9%	8.4	0

The specificity of the inhibition of *P. falciparum* growth was analysed in experimental conditions identical to those described in Table 1 legend. The IgG fraction from Hb26 cl3 ascitic fluid was purified by 50% ammonium sulphate precipitation and DEAE cellulose chromatography and shown to be devoid of contaminants when analysed by immunoelectrophoresis. As a control, Hb26 cl3 ascitic fluid was depleted of IgG by passage on a Sepharose–protein A column (Pharmacia) and reconstituted to its original volume by negative pressure dialysis. Mouse immunoglobulin was purified from normal BALB/c sera and the IgG2a and IgG2b from the ascitic fluid of BALB/c mice bearing LPC-1 and MOPC-195 myeloma tumours. These immunoglobulins were prepared by precipitation in 50% ammonium sulphate followed by DEAE column chromatography. The concentration indicated in parentheses for IgG is the final concentration in the medium.

mice injected with hybrid cells of Hb26 cl3 and Hb28 cl1 were also tested and gave, respectively, 78% and 99% inhibition of *P. falciparum* growth when added at a final concentration of 5% to the culture medium.

Hb26 cl3, Hb28 cl1 and Hb31 cl2 monoclonal antibodies inhibited the development of schizonts and the invasion of normal RBCs by merozoites. Normal development of ring forms into trophozoites was observed when differential counts of the developmental stages were monitored on synchronized cultures supplemented with either normal medium or medium containing 10% ascitic fluid from each of the inhibitory monoclonal antibodies. Subsequent maturation of trophozoites into schizonts occurred; however, the schizonts frequently showed morphological signs of degeneration in cultures supplemented with any one of the three monoclonal antibodies. (At the end of the first cycle, these degenerated schizonts represented 15–35% of the expected number of schizonts.) In normal culture, 7.6 new ring forms were generated in the second cycle from each late trophozoite and schizont present in the previous cycle. However, in cultures supplemented with Hb26 cl3, Hb28 cl1 or Hb31 cl2, the number of ring forms per trophozoite and schizont fell to 0.5, 0.2 and 0.4, respectively.

Incorporation of ^{3}H-hypoxanthine during a 14-h pulse was also measured in synchronized cultures supplemented with ascitic fluid. In the absence of ascitic fluid, there was a low rate of incorporation from 16 to 30 h, increased incorporation from 40 to 54 h and the highest rate of incorporation from 64 to 78 h. The increase in incorporation paralleled the increase of parasitaemia. In cultures supplemented with Hb28 cl1 or Hb26 cl3 there was a low rate of incorporation from 16 to 30 h followed by a decrease in incorporation for Hb28 cl1 and a slight increase for Hb26 cl3 from 64 to 78 h. Here again, the rate of incorporation paralleled the level of parasitaemia (Fig. 1).

The IgG fraction of Hb26 cl3 ascitic fluid was shown to have full inhibitory activity (Table 2); the activity of Hb26 cl3 ascitic fluid was lost after depletion of IgG. Similarly, IgG fraction purified from Hb28 cl1 at a final concentration of 0.25 mg ml^{-1} showed an inhibitory activity of 95%. In such cultures inhibited by IgG fractions, schizont degeneration was also present.

The amount of monoclonal antibodies needed to cause 50% inhibition of the culture growth after two multiplication cycles of *P. falciparum* was 8 μg ml^{-1} of culture medium for Hb28 cl1 (1/80 dilution of ascitic fluid) and 16 μg ml^{-1} for Hb26 cl3. *P. falciparum*-infected cultures were also internally labelled with ^{35}S-methionine for 4 h and lysed by 0.5% Nonidet P40 (ref. 13). The lysate was used as antigen in double immunoprecipitation experiments using monoclonal antibodies (Hb26 cl3, Hb28 cl1 and Hb31 cl2)[13]. The washed immune precipitates were analysed on 10% SDS-polyacrylamide gel electrophoresis gels. By autoradiography it was shown that Hb28 cl1 and Hb31 cl2 monoclonal antibodies reacted with a polypeptide of molecular weight (MW) 41,000 whereas Hb26 cl3 reacted with two polypeptides of MWs 96,000 and 36,000. These polypeptides are probably present on the merozoite surface. This was indicated by results of the indirect fluorescence test when an unfixed suspension of *P. falciparum* was reacted with monoclonal antibodies. Intense surface staining was seen using monoclonal antibodies Hb26 cl3, Hb28 cl1 and Hb31 cl2. In contrast, no surface staining was observed with Hb12 cl4 or Hb9 cl1.

Previous investigators have shown that some sera from individuals living in areas endemic for malaria inhibit the growth of *P. falciparum* culture[14–16], but they have not identified the specificity of the 'protective' antibodies. In the present experiment, antigens recognized by monoclonal antibodies inhibiting the growth of *P. falciparum* have been characterized. Interestingly, monoclonal antibodies with inhibitory activity were obtained from the Hb28 cl1 hybrid after fusion of spleen cells from mice infected with *P. berghei*, and reacted by immunofluorescence with *P. berghei* (trophozoites and schizonts), suggesting the presence of a common antigenic determinant on the surface of *P. falciparum* and *P. berghei* merozoites. Several hypotheses can be raised to explain the inhibitory activity of the monoclonal immunoglobulin. First, these antibodies may prevent the merozoite invasion of RBCs by binding to the merozoite surface and interfering directly or indirectly with the parasite ligand–RBC receptor. Second, they may bind to parasite antigens at the surface of infected RBCs at the schizont stage and thus modify the intracellular parasites' metabolism. Third, because schizonts containing RBCs are known to have an increased permeability, one cannot exclude the possibility that some antibody molecules would reach intracellular parasites at the last stage of development.

These monoclonal antibodies provide new tools for the purification of potentially protective antigens of *P. falciparum*, although the large-scale production of *Plasmodium* antigens is still limited by technical problems. An alternative approach is to use DNA recombinant technology to produce defined malarial antigens. In this respect, the protective monoclonal antibodies may be useful for the identification of *Escherichia coli* colonies secreting putative protective antigens[17].

Respective roles of laminin and fibronectin in adhesion of human carcinoma and sarcoma cells

Israel Vlodavsky* & Denis Gospodarowicz†

* Department of Radiation and Clinical Oncology, Sharett Institute, Hadassah University Hospital, Jerusalem, Israel
† Cancer Research Institute and the Departments of Medicine and Ophthalmology, University of California, Medical Center, San Francisco, California 94143

In a previous study[1], Ewing's sarcoma cells and colon carcinoma cells[2] failed to attach to plastic and to dishes coated with various collagen types I, III and IV, but adhered rapidly to extracellular matrix (ECM) produced by cultured corneal endothelial cells. However, although carcinoma cells required ECM and did not adhere to fibronectin, the sarcoma cells adhered and flattened almost equally well on either substrate[1]. Thus, different adhesive proteins may mediate the attachment of sarcoma- and carcinoma-derived cells to extracellular matrices, the most likely being fibronectin[3,4] and laminin[5,6]. Fibronectin stimulates the adhesion of fibroblasts, but not epidermal cells, to collagen type IV (ref. 7) and could mediate the attachment of sarcoma cells. Laminin is confined to the lamina lucida region of basement membranes[6] and has been localized to cellular adhesion sites[8]. Studies of the attachment of epidermal cells *in vitro* (V. P. Terranova, personal communication) suggest that it is adhesive for epithelial cells, and so could have the same role for carcinoma cells as that played by fibronectin for sarcoma cells. Cultured vascular endothelial cells secrete fibronectin[9–11] and laminin[12] into both the ECM and the culture medium, and we report here that pre-exposure of plastic dishes to such conditioned medium induces the attachment and flattening of both human colon carcinoma and Ewing's sarcoma cells. While laminin mediates the attachment and spreading of the former fibronectin is responsible for the attachment and flattening of the latter.

Figure 1 shows the time-course of attachment of carcinoma cells to various substrata. Less than 30% of cells seeded on plastic or fibronectin-coated dishes became firmly attached and no flattening was observed, regardless of time in culture (up to 10 days) and whether or not serum (10%) was present. In contrast, 70 and 80% of the seeded cells firmly attached and flattened within the first hour of incubation on dishes pre-exposed to conditioned medium or coated with ECM, respectively (Figs 1, 2). This was observed regardless of whether or not carcinoma cells were seeded in the presence of serum (10%). The best results, in terms of adhesion and percentage of firmly attached and flattened cells, were obtained with medium from endothelial cell monolayers cultured for more than 8 days. Serum-free conditioned medium collected 5–7 days after the cells had reached confluence also promoted obvious cell attachment and flattening. Similar results were obtained with dishes exposed overnight for 2 h (Fig. 2) to the conditioned medium and seeded with either trypsinized single carcinoma cells (Fig. 2*b*, *c*) or cell aggregates (Fig. 2). In the latter case flattening and migration of peripheral cells were observed within 1 h and led to complete dispersion of aggregates 6–8 h after seeding (Fig. 2*b*). When similar tumour cell aggregates were seeded on ECM-coated dishes, flattening and migration were observed within 30 min (Fig. 2*a*). Pre-exposure of dishes to medium conditioned by human skin fibroblasts, vascular smooth muscle cells, or corneal endothelial cells (Fig. 3), or to fresh medium containing 10% serum supplemented or not with fibroblast growth factor (FGF), did not promote cell adhesion, flattening and migration. Studies of the production of laminin by vascular and corneal endothelial cells have shown that depending on the growth stage (sparse actively growing versus confluent resting cultures) the medium conditioned by corneal cells contains 20- to 100-fold less laminin than medium conditioned by vascular endothelial cells.

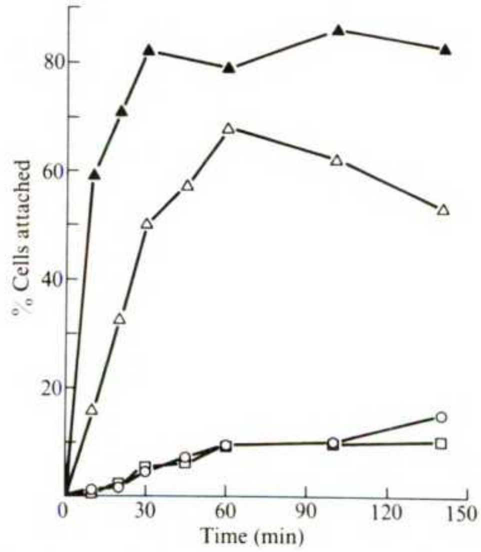

Fig. 1 Time-course of attachment of carcinoma cells to various substrates. Stock cultures of colon carcinoma cells grown on ECM-coated dishes were dissociated by treatment with STV (0.05% trypsin, 0.02% EDTA), and then 2×10^5 cells were seeded on plastic dishes (□), dishes coated with 10 μg each of affinity purified bovine plasma fibronectin (○, ref. 1), dishes coated with ECM (▲, ref. 1), or dishes coated with vascular endothelial cell conditioned medium (△). To coat them with conditioned medium, dishes were exposed to a medium (DMEM, H-16 supplemented with 10% calf serum) taken from vascular endothelial cells maintained for 8 d in culture (from the day of seeding until 3–4 d after reaching confluence). This medium was centrifuged (1,500*g* for 5 min), incubated (14 h, 37 °C) on the dishes, and replaced with fresh conditioned medium before cells were seeded. Serum-free conditioned medium was collected from subconfluent endothelial cultures 7–9 d after they had been supplied with DMEM (H-16) containing no serum. Because the production and secretion of proteins by endothelial cells is greatly reduced when they reach confluence[11,12], medium conditioned by confluent cultures was less active than medium conditioned by actively growing vascular endothelial cells. At various times after seeding unattached carcinoma cells were removed by gentle pipetting and rinsing of the dishes (twice) with phosphate-buffered saline (PBS). The remaining firmly attached cells were dissociated with STV and duplicate cultures were counted with a Coulter counter. The variation in different determinations did not exceed ±10% of the mean.

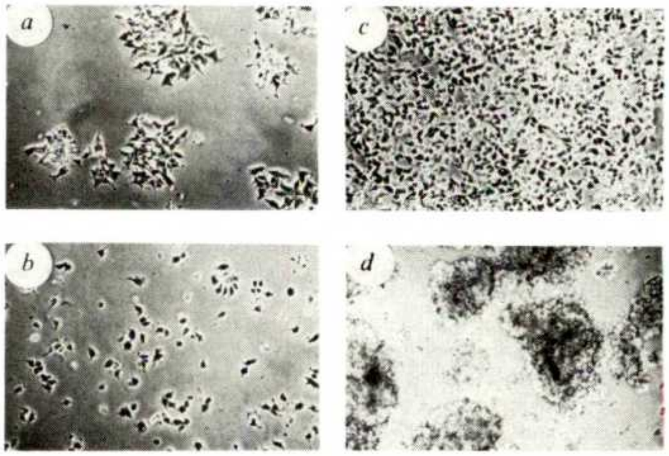

Fig. 2 Morphological appearance of carcinoma cells seeded on dishes pre-exposed to endothelial cell-conditioned medium. Floating cell aggregates (*a*, *d*) from stock cultures maintained on plastic or trypsinized single cells (*b*, *c*) from stock cultures maintained on ECM-coated dishes were seeded in DMEM containing 5% fetal calf serum on plastic (*d*) or on dishes pre-exposed (2 h, 37 °C) to endothelial conditioned medium as described in Fig. 1 legend (*a*, *b*, *c*). *a*, Cell spreading and migration from cell aggregates 8 h after seeding. *b*, Single cells 1 h after seeding. *c*, Confluent culture 6 d after seeding. The cells proliferate and form a layer of firmly attached and flattened cells.

0028-0836/81/040304—03$01.00

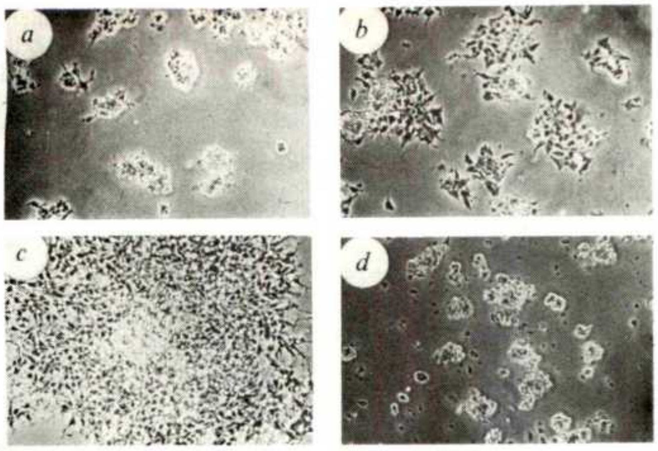

Fig. 3 Effect of conditioned media from various cell types on carcinoma cell attachment and spreading when cells are seeded and maintained in conditioned medium or seeded and maintained in fresh medium. Tissue culture dishes were pre-exposed (14 h, 37 °C) to media conditioned for 8 d by vascular endothelial cells (*a–c*) or corneal endothelial cells (*d*). Carcinoma cell aggregates taken without trypsinization from a culture maintained on plastic were seeded directly into the conditioned medium and observed 6 h later (*a*). Cell aggregates attached loosely to the substrate and only a small degree of cell flattening and migration was observed, even after 1 week in culture. When the conditioned medium was replaced with fresh medium, good cell attachment and spreading were observed after 2 h (*b*). This effect was then long-lasting (*c*, 1 week in culture). This demonstrates that, when carcinoma cells are seeded into conditioned medium-coated dishes, the conditioned medium has to be removed and replaced with fresh medium to promote cell attachment and spreading. Because poor cell attachment and flattening are observed when dishes contain conditioned medium (*a*), it is suggested that, although coating the plastic surface with conditioned medium induces cell flattening, soluble factor(s) which can adversely affect that process is also present in the conditioned medium. *d* shows cell aggregates 4 d after seeding in fresh medium into dishes coated with medium conditioned by corneal endothelial cells. Similar results were obtained with medium conditioned by vascular smooth muscle cells or human skin fibroblasts. In either case, and as was the case with uncoated tissue culture dishes, cell aggregates attached poorly and cell flattening was not observed.

Pre-exposure of dishes to the endothelial cell conditioned medium (either serum-free or containing fibronectin-depleted calf serum) also induced attachment of sarcoma cells. However, in this case and in contrast to carcinoma cells, coating of dishes with purified fibronectin was either more or as effective in promoting cell attachment and subsequent flattening.

The nature of the agents mediating attachment and flattening was analysed by subjecting the conditioned medium to specific double immunoprecipitation with either rabbit anti-laminin[6] or anti-fibronectin antisera[9], followed by goat anti-rabbit IgG antiserum[11]. Experiments with ^{35}S-methionine-labelled vascular endothelial cells had shown that these antisera, as determined by SDS-polyacrylamide gel electrophoresis, precipitate specifically and quantitatively the laminin[12] and fibronectin[11] present in endothelial cell conditioned medium. As Fig. 4*b* shows, carcinoma cells no longer became attached to dishes pre-exposed to conditioned medium if laminin had been removed by immunoprecipitation. On the other hand, immunoprecipitation of fibronectin (Fig. 4*a*) or collagen type IV (not shown) by specific antibodies had no effect on the attachment and flattening of carcinoma cells. In contrast, when the same immunoprecipitated fibronectin-free conditioned medium was used to coat dishes, sarcoma cells no longer became attached (Fig. 4*d*). The induced attachment and flattening of sarcoma cells were not affected by subjecting the conditioned medium to immunoprecipitation with anti-laminin (Fig. 4*e*), anti-collagen type IV or non-immune rabbit serum (Fig. 4*f*) followed by coating the dishes. These results show that the human carcinoma- and sarcoma-derived cells show a specific response to different adhesive glycoproteins, such as laminin and fibronectin, respectively.

Immunofluorescence has shown that the *in vivo* distribution of laminin is identical to that of collagen type IV (refs 6, 8) and so we compared the attachment of carcinoma cells to dishes coated with collagen types I, III, IV or V before being coated with conditioned medium. (Collagen would not promote cell attachment unless dishes were subsequently exposed to conditioned medium.) Collagen type IV gave the best results in terms of adhesion, percentage of firmly attached cells and prevention of retraction of flattened cells within days of initial attachment. Other collagens had either a small effect (type I) or were inhibitory (type II and in particular type V, Fig. 5*d*) compared with direct exposure to conditioned medium. When conditioned medium with a relatively low cell attachment-promoting activity was used (Fig. 5*a*), its effect was potentiated by precoating the dishes with collagen type IV (Fig. 5*b*). These results suggest that laminin may mediate the attachment of human carcinoma cells

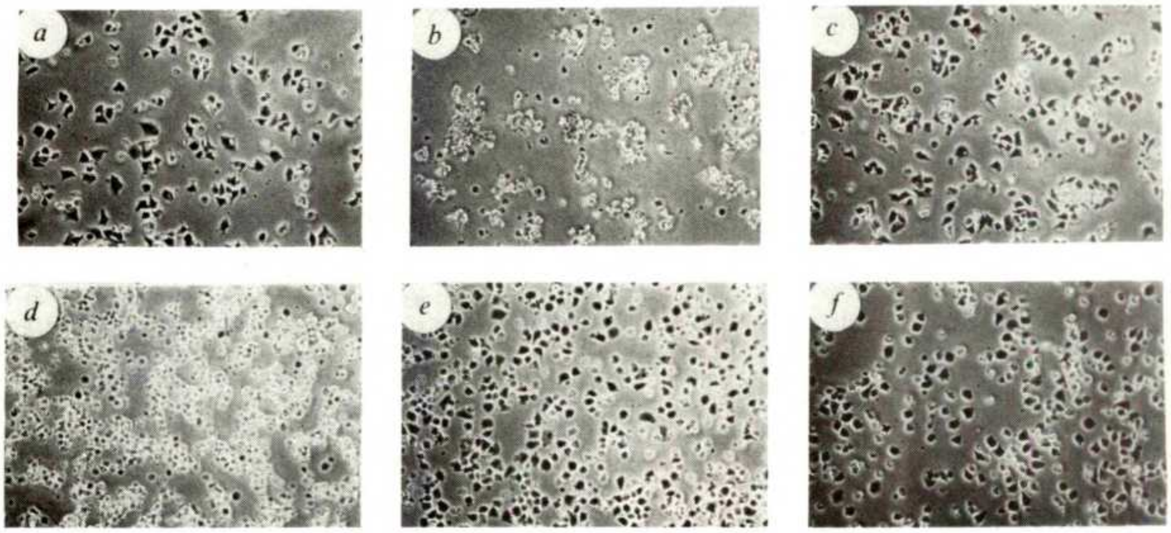

Fig. 4 Induction of tumour cell attachment promoted by coating dishes with vascular endothelial cell conditioned medium from which fibronectin or laminin had been removed by double immunoprecipitation. Vascular endothelial cell conditioned medium (1 ml) was preincubated (1 h, 37 °C) with 10 µl of rabbit antisera against fibronectin (*a, d*) or laminin (*b, e*), or with 10 µl of non-immune rabbit serum (*c, f*). Antibodies to laminin[5,6] and bovine plasma fibronectin[9,11] were the same as those used previously[5,6,9,11]. The specificities of the antisera and lack of cross-reactivity between the various antigens have been established in these previous reports. The conditioned media were then incubated (2 h, 37 °C, followed by 14 h at 4 °C) with 30 µl of goat anti-rabbit IgG antiserum (35% ammonium sulphate cut), centrifuged (12,000*g* for 5 min) and the supernatant incubated in 35-mm tissue culture dishes for 12 h at 37 °C. The conditioned media were then removed and 2 ml of DMEM supplemented with 5% fibronectin-depleted calf serum and containing either 2×10^5 colon carcinoma cells (*a–c*) or Ewing's sarcoma cells (*d–f*) were then added to the dishes. Phase micrographs of cell attachment and spreading were taken 3 h after seeding. Conditioned medium pre-exposed to anti-collagen type IV (refs 5, 6) gave results similar to those observed after pre-incubation with non-immune rabbit serum. Similar results were obtained with serum-free vascular endothelial cell conditioned medium and with tumour cells seeded in DMEM containing 0.1% bovine serum albumin rather than 5% bovine serum.

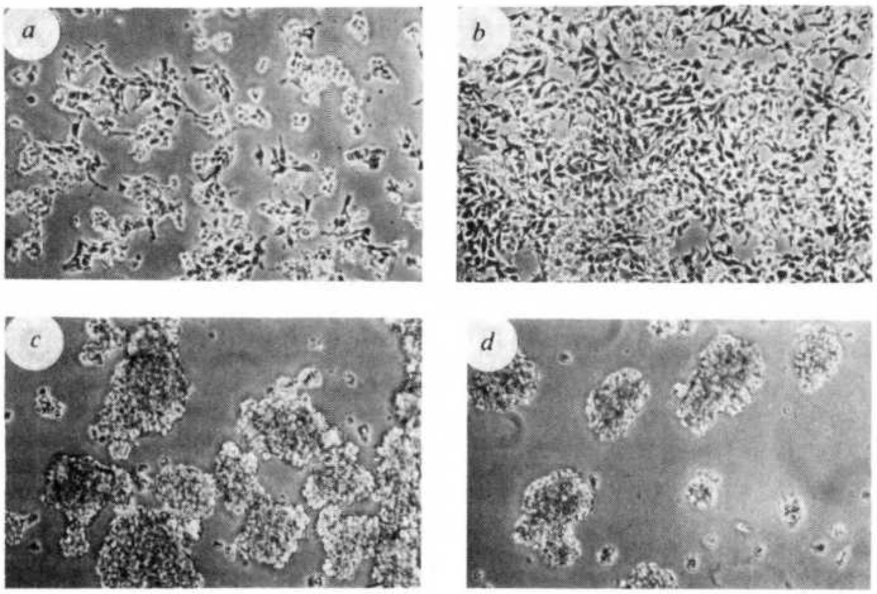

Fig. 5 Effect of precoating with types IV and V collagen on colon carcinoma cell attachment induced by a subsequent exposure to the vascular endothelial cell conditioned medium. Tissue culture dishes (35 mm) were coated with purified preparations of types IV (human placenta) or V (bovine cornea) collagen (10 μg per dish) as previously described[7]. Plastic and collagen-coated dishes were then exposed (12 h, 37 °C) to conditioned medium taken 5 d after replacing the growth medium of subconfluent endothelial cultures. Carcinoma cells (10^5 per dish) were seeded in fresh medium (DMEM, 10% FCS) and phase micrographs taken 3 d later. *a*, Pre-exposure to conditioned medium alone. *b*, Precoating with collagen type IV followed by exposure to conditioned medium. *c*, Dishes coated with collagen type IV alone. *d*, Precoating with collagen type V, followed by exposure to conditioned medium.

to type IV collagen which is characteristic of basement membranes.

Both laminin and fibronectin have been shown to be secreted underneath the endothelial cell layer and to be part of the ECM produced by these cells[12]. In the ECM, they may function as conditioned medium does, and may promote the attachment and rapid spreading of carcinoma- and sarcoma-derived cells[1]. The production of both laminin and fibronectin by vascular endothelial cells may facilitate the arrest of blood-borne metastatic cells[13] that produce little or no such adhesive glycoproteins[14]. Metabolic labelling with ^{35}S-methionine of the Ewing's sarcoma and colon carcinoma cells (cultured on ECM) followed by specific immunoprecipitation had shown that these cells secrete no detectable laminin and small amounts of fibronectin (less than 3% and 0.1% of the newly synthesized proteins, respectively). Interaction of highly metastatic cells with the luminal surface of the vascular endothelium is followed by endothelial retraction and exposure of the underlying ECM, to which the tumour cells adhere strongly[13], possibly through specific attachment-promoting molecules such as laminin and fibronectin. Cell attachment is then followed by migration, degradation and invasion of the tumour cells through the endothelial basement membrane[13,15]. The presence of specific attachment factors in basement membranes, the ability or inability of cells to produce and/or interact with such factors, as well as the preferential interaction of these adhesive factors with a specific type of collagen may determine the localization of a given cell type to specific matrices[7]. Such specific cell–matrix interactions may direct the growth, migration and differentiation of normal cells[16,19], as well as the invasiveness and metastasis of tumour cells[13,15].

The colon carcinoma cell line (HS703T) was provided by Dr R. B. Owens, and the Ewing sarcoma cell line by the laboratory of J. E. Fogh (Sloan Kettering Institute). We thank Dr J. M. Foidart for affinity purified antibodies against laminin and collagen type IV, Dr S. Tseng for collagen types, G. M. Lui for technical assistance, Mr Harvey Scodel for assistance with the manuscript, and Professor Zvi Fuks for support and discussion. This work was supported by a grant from NIH to D.G.

cis-Interacting genes in the *S* region of the murine major histocompatibility complex

James Michaelson, Arturo Ferreira & Victor Nussenzweig

Irvington House Institute and Department of Pathology, New York University Medical Center, 550 First Avenue, New York, New York 10016

Insight into the control of gene expression may be gained by analysing genetic systems marked by both regulatory and structural variants. In such systems one can determine whether a regulatory element controls structural genes on both chromosomes or only on the chromosome to which it is linked. The latter may be detected in individuals heterozygous at both the regulatory and structural loci, in which case the effect of each regulatory allele is seen to be exerted only on the *cis*-located structural allele. In prokaryotic organisms, the identification of *cis* interaction of this sort has allowed elucidation of many features of genetic regulation, first for the *lac* operon[1] and subsequently for a variety of other systems[2]. In higher organisms, however, there have been few opportunities to observe *cis*-interacting genes[3–13]. The most thoroughly characterized mammalian system in this regard is the murine β-glucuronidase locus described by Paigen and his colleagues[14–16], in which *cis* interaction has been shown to occur between two closely linked genetic elements—the β-glucuronidase structural gene itself and an androgen-activated regulatory gene which controls the quantity of β-glucuronidase expressed. We report here that *cis*-interacting genetic elements are also found in the *S* region of the mouse major histocompatibility complex *H–2.*

Table 1 *S*-region γ-chain variants detected by IEF

	Haplotype	pI of γ chain
Ss(C4)	$H\text{-}2^{s,p,f,j,w17,w19}$	7.4
	$H\text{-}2^{d,k,r,u,q,b,w7}$	6.9
	$H\text{-}2^{w(\text{undesignated})}$	6.5
Slp	$H\text{-}2^{d,p,u,s,j}$	6.7
	$H\text{-}2^{w7}$	6.5

Results are summarized from refs 25–27.

The *S* region controls two structurally similar serum proteins[17,18], Ss (which has been shown to be C4 of the complement system[19–22]) and Slp (sex-limited protein). Ss(C4) and Slp are each composed of three chains, α (molecular weight (MW) 100,000), β (MW 75,000) and γ (MW 35,000); in both cases the three subunits are derived from 200,000-MW precursors[18,23]. Ss(C4) may be found in two phenotypes—high and low quantity in plasma (a 20-fold difference)—with the *S* region containing the genes determining phenotype[17,24]. We have analysed the Ss(C4) and Slp proteins for biochemical variants which would serve as markers of the structural genes themselves. Recently, we described such variants (herein called *pI* variants)[25–27], identified by the isoelectric point of the γ chain (Table 1). The genetic determination of isoelectric point was found to map to the *S* region, where the previously described regulatory genes are located. Although the most straightforward explanation of the *pI* polymorphism is that of allelic variants of the structural genes, this has not been proved directly and other explanations are possible. Peptide mapping experiments to resolve this question are now underway. In any event, this need not hinder the formal argument of *cis* interaction between *pI* genes and the genes controlling expression.

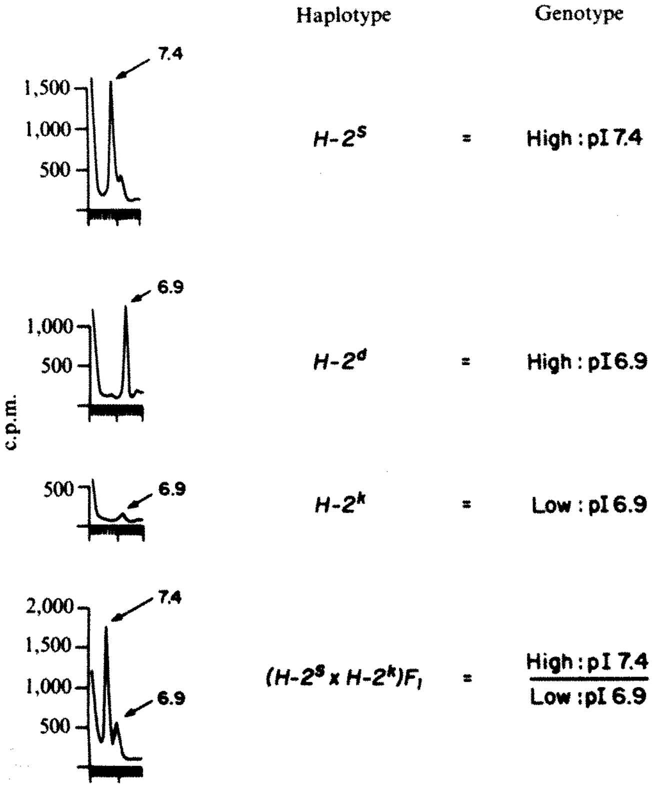

Fig. 1 Cylindrical IEF gels of the γ chain of Ss protein from $H\text{-}2^s$, $H\text{-}2^d$, $H\text{-}2^k$ and $(H\text{-}2^s \times H\text{-}2^k)F_1$ plasma. Ss precipitation was performed after removing Slp from plasma. Analogous results were obtained when Ss was analysed by two-dimensional separation (slab IEF, followed by SDS-polyacrylamide gel electrophoresis).

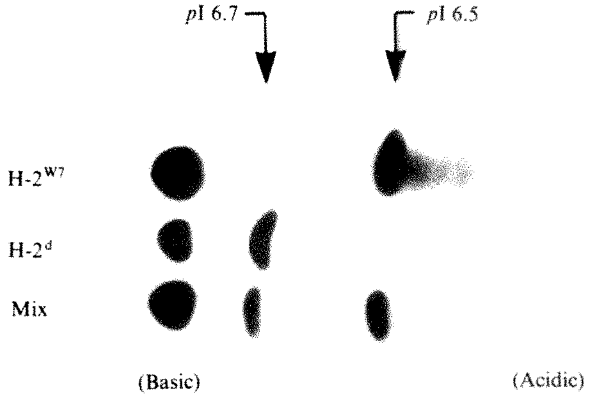

Fig. 2 Slab IEF (*p*H gradient 7.0–3.7) showing Slp γ chain of $H\text{-}2^{w7}$ (C3H.W7) and $H\text{-}2^d$ (DBA/2) mice, and a mixture of the two samples. The identification of the *p*I 6.7 and 6.5 spots as γ chains of MW 35,000 was made by applying individual strips to the top of an SDS-polyacrylamide gel, thus separating the components according to molecular weight (not shown) (see refs 25–27 for technical details).

In our analysis of Ss(C4) expression, we examined the interaction between two genetic elements: that determining the *p*I of the γ chain ($H\text{-}2^s = p$I 7.4, $H\text{-}2^k = p$I 6.9) and that determining the quantity of Ss(C4) ($H\text{-}2^s$ = high, $H\text{-}2^k$ = low). $(H\text{-}2^s \times H\text{-}2^k)F_1$ mice (*high*: *7.4*/*low*: *6.9*) were constructed. It was reasoned that, if the *regulatory* and *pI* genes interacted in *trans* (that is, through a diffusible control substance), equal quantities of 7.4 and 6.9 would be seen. If the interaction was *cis* only, however, a high quantity of 7.4 would be seen, with a low quantity of 6.9, and indeed this was what was found (Fig. 1).

We realize, however, that even though *cis* interaction is formally demonstrated, this might be due to differential labelling or breakdown of the two types of molecules. That the two genes are not precisely the same is seen by the fact that strains of both *Ss high* : *pI 7.4* and *Ss high* : *pI 6.9* type have been detected (Fig. 1). However, we do not know whether the *S*-region *regulatory* and *pI* genes are separate or overlapping entities (in terms of genetic fine structure).

We then performed the same type of analysis for the control of Slp expression. In most Slp$^+$ strains of mice (such as the $H\text{-}2^d$ strain described here), Slp is found in the sera of males but not females[28]. This sex limited expression occurs because androgens are necessary to induce the Slp protein, as has been shown by Passmore and Shreffler[29] (castrated males are Slp$^-$, whereas females which are injected with testosterone propionate become Slp$^+$ (ref. 29)). Mice of an exceptional haplotype ($H\text{-}2^{w7}$), however, are Slp$^+$ in both males and females because expression is independent of androgen, as has been demonstrated by Hansen and Shreffler (such mice continue to produce Slp after castration, and indeed after being made genetically insensitive to testosterone by the *Tfm* mutation[30]). Taken together, these observations identify a hormone-driven regulatory gene controlling the expression of Slp. It has two allelic forms: androgen dependent (*AD*) (that is, $H\text{-}2^d$) and androgen independent (*AI*) ($H\text{-}2^{w7}$). We have found that these two haplotypes also differ at their *pI* genes ($H\text{-}2^d = p$I 6.7, $H\text{-}2^{w7} = p$I 6.5)[27] (Fig. 2). We constructed $(H\text{-}2^d \times H\text{-}2^{w7})F_1$ mice (*AD*: *6.7*/*AI*: *6.5*). If the interaction between the *regulatory* and the *pI* genes occurs by a *trans* mechanism, both males and females would be positive for both *p*I 6.7 and 6.5 Slp's. If, however, interaction occurred in a strictly *cis* fashion, males would be positive for the *p*I 6.7 and 6.5 forms, but females (lacking androgens to turn on *cis*-located *p*I 6.7 product) would express only *p*I 6.5 Slp. Comparison of the isoelectric focusing (IEF) gels of Slp from males and females suggests that this is indeed the case (Fig. 3). Thus, for both Ss(C4) and Slp, the interaction of *regulatory* and *pI* alleles occurs only when they are located *cis*.

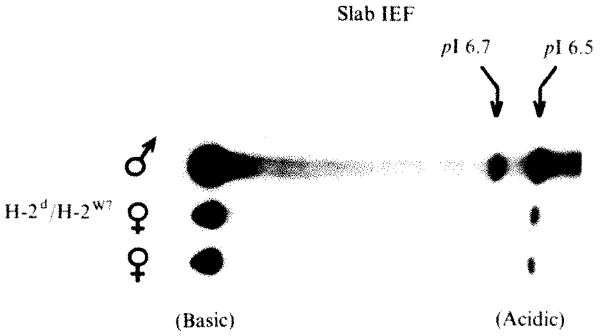

Fig. 3 Phenotype of the γ-chain Slp of (C3H.W7 × DBA/2)F_1 ($H\text{-}2^d/H\text{-}2^{w7}$) = (AD: pI 6.7)/(AI: pI 6.5), seen on slab IEF gels (pH gradient 7.7–4.0). (Components other than the γ chains are nonspecific contaminants.)

As seen in these experiments, the use of IEF to detect *S*-region structural polymorphism permits the simultaneous measurement of both allelic gene products in heterozygotes. From such data, inferences can be drawn about the properties of the genes which control the expression of the variants, as, for example, *cis* restriction of *S*-region regulatory genes. Further experiments of this sort should reveal in greater detail the properties of these regulatory genes. Two features of *S* region expression are noteworthy in this regard. First, because androgens control the serum levels of Ss(C4) (quantitatively)[24] and Slp (absolutely), the analysis of these two proteins may well elucidate some features of the nature of hormone regulation of gene activity. Second, Ss(C4) and Slp have been shown to be synthesized in macrophages and liver parenchymal cells, but not in a variety of other cell types[31]. Presumably, there are genetic elements which control this pattern of synthesis, but where they are or how they exert their effects is unknown. These regulatory elements would be identifiable by tissue-specific genetic polymorphism of Ss(C4) and Slp, if indeed such variation exists. The possibility of such polymorphism is suggested by the observation of Roos *et al.*[18] that *in vitro* synthesis of Slp is seen in macrophages of $H\text{-}2^{w7}$ but not $H\text{-}2^s$ or $H\text{-}2^d$ genotype, although mice of all three types have the protein in their sera. The detailed analysis of this sort of polymorphism, including the use of IEF to test for *cis* and *trans* interaction with *pI* genes, should be informative both for the specific case of the *S* region and with respect to the general question of the control of gene expression during differentiation.

We thank Drs E. A. Boyse, L. Silver and D. Bennett for critical review of the manuscript, and Dr Yuri Bushkin for help with the IEF technique. We also thank Ms Holly Yudkowitz, Mr Victor La Regina and Mr Daniel Eichinger. This work was supported by NIH grants AI-13224, AI-00270 and CA-09149.

Detection of CML determinants associated with *H-2* controlled E_β and E_α chains

Antonio Juretić*†, Zoltan A. Nagy* & Jan Klein*

* Max-Planck-Institut für Biologie, Abteilung Immungenetik, Tübingen, FRG
† Department of Physiology, Faculty of Medicine, University of Zagreb, Zagreb, Yugoslavia

The serologically detectable molecules encoded by the *H-2* complex, the major histocompatibility complex (MHC) of the mouse, fall into two classes—class I and class II (ref. 1). The class I molecules encoded by the *K* and *D* loci have a molecular weight of 44,000 and are noncovalently associated with β_2 microglobulin which is not controlled by the MHC. The class II molecules are of two kinds, A and E, each consisting of two noncovalently associated polypeptide chains, α (M_r ~34,000) and β (M_r ~28,000)[2,3]. Three of the four chains, A_α, A_β and E_β, are controlled by loci in the *I-A* subregion, whereas the locus controlling the E_α chain is located in the *I-E* subregion of the *H-2* complex. Thus the loci coding for the E_α and E_β chains are separated by at least one (*J*) and perhaps more loci[3,4]. It has been shown that the E_α and E_β chains are synthesized independently, and that the E_α chain is required for the insertion of the E_β chain in the plasma membrane[4]. We demonstrate here that the $E_\alpha E_\beta$ complex (the E molecule) can evoke *in vitro* cell-mediated lymphocytotoxicity (CML) without previous sensitization *in vivo*, and that the strong CML reactivity is directed against allele-specific determinants on the highly polymorphic E_β chain.

To generate CML against the E molecules, we used three strain combinations selected from the *H-2* recombinant pool such that the responders differed genetically from the stimulators only in the region between the *A* and *S* loci (Table 1). The region may contain, in addition to the loci controlling E_α and E_β chains, the *B*, *J*, *C* and perhaps other, as yet unidentified loci. Four lines of evidence support the conclusion that the CML is directed against E rather than against other molecules encoded by the A–S interval. (1) When tested on a panel of *H-2* recombinant strains, reactivity of some of the effector cells with some of the strains excludes the *B*, *J* and *C* loci from coding for the target-cell determinants. (2) The same panel test indicates that the strain distribution pattern of the determinants detected by the effector cells correlates with the distribution pattern of alleles at E_α- and E_β-encoding loci. (3) The CML typing data fit well with what is known about the expression of E_α- and E_β-encoding loci[3,4]. (4) Cytotoxicity generated across disparities from the *I-B* to *S* region is specifically blocked by a monoclonal antibody against the Ia.7 determinant on the E_α chain[5].

The CML was generated by incubating unprimed spleen cells of the responder strain in a standard mixed-lymphocyte culture (MLC) with γ-irradiated spleen cells of the stimulator strain for 5 days. After incubation, the effector cells were tested on a panel of lipopolysaccharide (LPS)-stimulated, ^{51}Cr-labelled target cells and specific release of radioactivity was taken as a measure of cell lysis. In all three strain combinations, reproducibly high

CML were set up with 10×10^6 responder and 8×10^6 irradiated stimulator spleen cells in 4.5 ml of Alpha minimal essential medium (Gibco) containing 10% fetal calf serum, and 3×10^{-5} M 2-mercaptoethanol. After 5 days in culture, the cells were tested for lysis of ^{51}Cr-labelled LPS-blasts at different effector : target (E : T) ratios. For designation of target-cell haplotypes see ref. 8. *H–2* regions coding for potential CML determinants are shown. Alleles of the E_β locus in brackets mean failure of cell-surface expression of the relevant polypeptides. Only plateau levels of killing, obtained at E : T 100 : 1 to 160 : 1, are shown. At high E : T ratios, the % net release, that is, the difference between % specific killing of various targets and % specific killing of responder haplotype targets, showed little variation between individual experiments, and was characteristic of the CML combination tested. (Calculation of % specific release was as in Fig. 1 legend.) This fact allowed pooling of data from several experiments. The data are expressed as mean and range of % net release obtained in 2–16 experiments. Superscript numbers show the number of individual experiments (not shown where target haplotypes were tested once).

specific lysis was observed. However, in each combination the reaction was unidirectional—reaction was obtained in the direction B10.A(4R) anti-B10.A(2R) (hereafter 4Rα2R), B10.S(7R) anti-B10.S(9R) (7Rα9R) and B10.GD anti-B10.D2(R101) (GDαR101); all attempts to generate effector cells in the opposite direction have failed. This unidirectional response agrees well with present knowledge concerning the expression of E molecules in the plasma membrane. Jones *et al.*[4] demonstrated that *H–2* haplotypes *b*, *q*, *s* and perhaps also *f* failed to produce functional E_α chains and that this failure prevents the E_β chains from being inserted into the plasma membrane. Thus cells of these four haplotypes bear no E molecules on their surface. In the strain combinations used, one of the strains in each pair always expresses E molecules on the cell surface and the other does not, and we obtained CML only when the responder was the nonexpressor and the stimulator the expressor—never in the opposite direction. In the combination 4Rα2R, unidirectional response was previously observed in MLC, and a complicated explanation involving unequal crossing-over and gene deletion was proposed[6]. Such explanations are no longer necessary; the nonexpression of the E molecule in the membrane fully explains the data—the β-encoding gene cannot be deleted in the B10.A(4R) strain because the E_β chain is present in the cytoplasm of this nonexpressor.

When tested on a panel of strains carrying independent and recombinant *H–2* haplotypes (Table 1), the three effector-cell types gave two kinds of reactivity, one that was comparable in strength with that obtained against the stimulator strain, and one that yielded approximately half as much specific ^{51}Cr release as the lysis of stimulator-type targets (Fig. 1). We shall refer to these two types of response as 'strong' and 'intermediate', respectively. The distinction between the strong and intermediate reactions was also confirmed by cold-target inhibition studies (example shown in Fig. 1).

Table 1 also shows the distribution of alleles at the E_α- and E_β-encoding loci among the tested strains. The E_α locus is shown to possess only two alleles, one designated '*7*' because it

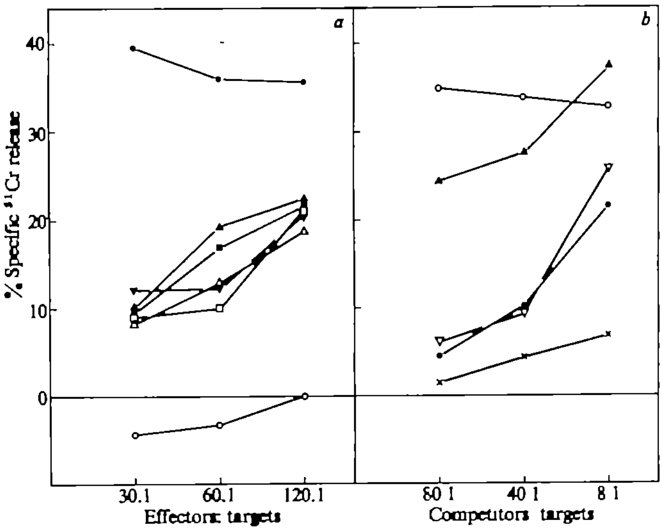

Fig. 1 Reactivity patterns of B10.S(7R) anti-B10.S(9R) effector cells. *a*, Direct cytotoxicity; *b*, cold-target inhibition of cytotoxicity against B10.S(9R) targets. Targets or competitors: ▲, t1 (A.TL); ○, t2 (B10.S(7R)), ▽, t3 (B10.HTT); ●, t4 (B10.S(9R)); △, i3 (B10.A(3R)); □, a(A/J); ■, a(B10.A); ▼, a(A.Tla^b); ×, both targets and competitors are t2. Per cent ^{51}Cr-release was computed using the formula:

$$\frac{\text{c.p.m. supernatant}\times2}{2\times\text{c.p.m. cell lysate}+\text{c.p.m. supernatant}}\times100$$

where the denominator represents total counts per well, when the sample size is half-volume supernatant and half-volume saponin-lysate. Per cent specific ^{51}Cr release was calculated by subtracting per cent release in control groups from that in experimental groups. The controls consisted of labelled target cells mixed with normal spleen cells at ratios corresponding to E : T ratios in the experimental groups. Spontaneous release (control groups) ranged from 17 to 35%, depending on the target strain.

codes for the serologically detectable antigen Ia.7 (ref. 7) and another designated '*0*' because it codes for the absence of Ia.7 in the plasma membrane (however, in reality, there may be only one allele at the E_α-encoding locus and the expression as opposed to nonexpression of the E_α chain in the membrane may be controlled by another locus). The distribution of the *7* allele is that determined by biochemical methods and serological typing for Ia.7 (refs 7, 8).

The E_β-encoding locus is shown to possess at least as many different alleles as there are independent *H-2* haplotypes. This conclusion is based on biochemical data which demonstrate that the E_β chains controlled by independent *H-2* haplotypes differ in their peptide maps[3] (the E_β alleles *b*, *s* and *k* have not yet been distinguished serologically, probably because correct strain combinations for the production of the relevant antibodies have not been used).

The CML combinations 7Rα9R and GDαR101 gave strong CML reactivity only against target cells carrying the *7* allele at the E_α-encoding locus and, at the E_β-encoding locus, the same allele as the stimulator cell (Table 1). As the E_α chains of most Ia.7-positive strains tested derive from H-2^k, the data strongly indicate that these two types of effector cell recognize allele-specific (private) determinants on the E_β chain. The third combination 4Rα2R gave strong CML against target cells carrying the *k* and *b*, but not the *d* and *s* alleles at the E_β-encoding locus, together with the *7* allele at the E_α-encoding locus. The panel test in Table 1 also demonstrates that recognition of the E_β determinants is not restricted by class I antigens, as target cells that share the E molecule with the stimulator cells, but differ from them at the *K* and *D* region, are lysed with equal efficiency. We conclude that the allelic forms of the E_β chain are not only chemically distinct, but also differ functionally, in terms of recognition by cytotoxic T lymphocytes.

The intermediate CML reactivities in all three combinations depend on the presence of E molecules in the target cells' plasma membrane, and thus correlate with the expression of Ia.7 (E_α chain) by the cells (Table 1). Our most recent results suggest that the determinants detected by intermediate CML reactivity are also found on the E_β chain. So far, direct contribution of the E_α chain to the formation of CML determinants could not be demonstrated[5]. Target cells which carry the *0* allele at the E_α-encoding locus, and thus do not express the E molecule on the membrane, are not lysed. The marginal killing of *b* and *i7* target cells by 4Rα2R effectors is an apparent exception; however, the absence of this reactivity on *g2* target cells maps the determinant(s) recognized to the *K* or *I-A* region.

We have also obtained CML reactivity against the E molecule in the strain combination B10.D2(R107) anti-B10.A(3R). This CML combination involves multiple genetic disparities at the *E* and *C* regions, the *Tla* locus and possibly also at other loci to the right of the *S* region[8,9]. This effector-cell type seemed to preferentially recognize target cells of the *i3* and *i5* haplotypes, which express the *b* allele at the E_β-encoding locus together with the *7* allele at the E_α-encoding locus. In addition, they exhibited cross-reactivities independent of the recognition of the E molecule. The genetic basis for these cross-reactions is being investigated.

In conclusion, our results, together with other data[10], demonstrate that the two gene-controlled E molecule serves as a target antigen for recognition by cytolytic T lymphocytes. The CML determinants seem to be localized primarily, if not exclusively, on the highly polymorphic E_β chain. The implications of these findings with regard to the function of the E molecule in immune responses will be discussed in detail elsewhere[11]. But as the E_β and E_α chains also bear serologically detectable determinants[12], participate in Ir-gene control of the immune response and immune suppression[13], and stimulate mixed-lymphocyte reaction[14], there is obviously no need to postulate separate loci for all these functions.

Harvard Medical School, Boston, Massachusetts 02114

The biosynthesis of *trans*-3- and *trans*-4-hydroxyprolines and 5-hydroxylysine in animal cells requires polypeptide proline or lysine, enzymes and cofactors including iron, and possibly involves peroxidatic intermediates[1]. Several laboratories have reported the presence of low-molecular-weight hydroxyproline and hydroxylysine peptides in cell and organ cultures[2–5]. We found that these small peptides contained the *trans*-3 and *cis*-4 isomers of hydroxyproline as well as *trans*-4 ones and that their production was not completely inhibited by α,α-dipyridyl, an iron chelator and effective inhibitor of enzyme-mediated hydroxylations[5]. It is known that oxygen or hydrogen peroxide in the presence of metal can hydroxylate proline and other aromatic compounds[6–11]. We show here that reduced oxygen derivatives can hydroxylate both free and polypeptide-bound proline and lysine, and that scavengers of hydroxyl radicals suppress, but do not completely inhibit, this reaction. Reduced oxygen derivatives can be generated in normal and pathological circumstances[12], and some of the low-molecular-weight hydroxyproline and hydroxylysine peptides found in cell and organ cultures might be derived from these derivatives and therefore do not reflect collagen turnover, but rather some other cellular activity.

Free proline and lysine and polypeptide-bound forms of each, as well as three isomers of hydroxyproline, were exposed to several different reaction conditions (listed in Table 1), which contained or could generate superoxide anion, hydrogen peroxide or hydroxyl-free radicals[12].

The reaction products were identified using the following techniques: high-voltage electrophoresis[13], thin-layer chromatography[14], chemical derivatization and partitioning by solvent extraction followed by chromatophore generation (including characterization of the spectral absorption pattern of standards and the derivatives)[15], nitrous acid resistance[16], and behaviour on the amino acid analyser, including the reaction product absorption ratios at 440 and 570 nm and co-chromatography with known standards in at least two different elution conditions (Fig. 1).

The products of the reactions involving proline include at least four different hydroxyproline isomers—*trans*-3-hydroxy-

TR, trace. *trans*-3-hyp, *trans*-3-hydroxyproline; *trans*-4-hyp, *trans*-4-hydroxyproline; *cis*-3-hyp, *cis*-3-hydroxyproline; *cis*-4-hyp, *cis*-4-hydroxyproline; 5-hylys, 5-hydroxylysine.

* Data were determined by amino acid analyses without hydrolysis (free forms) or after hydrolysis in 6 M HCl (polypeptide forms). The presence of the metal ions did not interfere with the analyses. The values represent the moles of product formed per mole of proline or lysine (or *cis*-4 or *trans*-4) remaining at the end of the reaction ×100. Overall recovery of proline/lysine was less than 10%. The values represent averages of two to six determinations.

† Standard conditions were: 20 μM substrate, 0.2 mM ascorbate, 10 μM $FeSO_4 \cdot 7H_2O$, 1.0 mM H_2O_2, all in 0.1 M NaH_2PO_4, *p*H 4.4, at 37 °C for 1 h, followed by reduction with 1 mM $NaBH_4$ at *p*H 8.0.

‡ These metals with proline gave no reaction; with lysine, 50% of Fe^{2+}.

proline, *trans*-4-hydroxyproline, *cis*-3-hydroxyproline and *cis*-4-hydroxyproline. No differences were noted when D- or L-proline was used in free form. When free proline was the substrate, the relative amounts of each of these isomers produced were nearly equal in the conditions used for most of the experiments. However, with peptide-linked proline, there were significant changes in the distribution of the isomers produced. For example, free proline yields approximately equal amounts of *trans*-3-hydroxyproline and *trans*-4-hydroxyproline, whereas peptide-bound proline is predominantly converted to *trans*-4-hydroxyproline (Table 1). The proline sequence in peptide linkage also affected its relative reactivity and, interestingly, the configuration which is normally hydroxylated in collagen—Pro-Gly—was approximately five times more hydroxylated on a molar basis of starting substrate concentration than Gly-Pro or Gly-Pro-Ala. The proline or lysine recovered at the end of the reaction was less than 10% of the starting material. In addition to the products listed in Table 1, other products were noted and of particular interest was a substance which eluted from the amino acid analyser 7 min before *trans*-4-hydroxyproline, which we have tentatively identified as 4-ketoproline[17]. This material was separated from *trans*-4-hydroxyproline on the amino acid analyser by adjustment of the *p*H of the first buffer to 2.68 (Fig. 1). Several other products, similar in chromatographic properties on the amino acid analyser to the several isomers of the 3,4-dihydroxyprolines, were detected, but not studied further[17,18].

The reaction products generated with free lysine as substrate included 5-hydroxylysine and a second substance which eluted 10 min later, which has not been identified (Fig. 1). With lysine as substrate in polypeptide form, the major product was 5-hydroxylysine.

We suspect that 3- and 4-ketoproline are intermediates in the reaction. The 3-keto form apparently reduces readily in the presence of ascorbate as *trans*-3-hydroxyproline consistently appeared without the addition of sodium borohydride. The 4-keto form was variably present in the initial reaction conditions, but could be quantitatively eliminated by the addition of the sodium borohydride. The 4-keto intermediate was also noted when free *cis*-4-hydroxyproline was used as substrate.

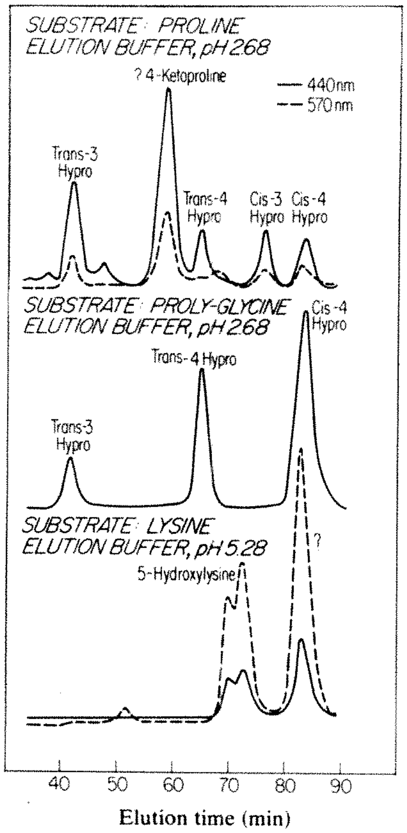

Fig. 1 Elution patterns of reaction products on the amino acid analyser of non-enzymatic hydroxylations of free proline (upper tracing), polypeptide-bound proline which was hydrolysed to free amino acids and then treated with nitrous acid (middle tracing) and free lysine (lower tracing). The solid tracing is the absorbance at 440 nm, the dotted tracing that at 570 nm. The pH 2.68 buffer was 0.18 M in Na^+, the pH 5.28 buffer was 0.35 M in Na^+. The identification of the eluting material by means other than co-chromatography with standards is detailed in the text. The two peaks with ? have not been characterized, but that with proline is probably 4-ketoproline.

When this reaction mixture was reduced, *trans*-4-hydroxyproline was generated. The experiments with hydroxyl radical scavengers, coupled with the fact that no hydroxylations occurred in the absence of added oxygen derivatives, indicate that some form of a reduced oxygen derivative is essential for the hydroxylation reaction to occur. The dependence of the reaction on the presence of metal ions is consistent with a reaction mechanism involving hydroxyl radicals, although the precise nature of the reactants in such mixtures is not understood[19].

Reduced oxygen derivatives have been reported in widely differing circumstances in nature. Of particular interest to matrix biology is the finding that a major effect of these oxygen radicals is to alter extracellular macromolecules. For example, covalent cross-linking via dityrosines in sea urchin fertilization membranes[20], marine mussel byssal fibres[21], collagen[22], elastin[23] and resilin[24] have been reported. Depolymerization of hyaluronic acid has been observed by viscometry following exposure to oxygen radicals[25]. Recently, it has been shown that plasma exposed to superoxide becomes chemotactic for neutrophils[26]; our data suggest that the chemotactic response of fibroblasts and monocytes to hydroxyproline-containing peptides[27] may occur *in vivo* in the absence of collagen breakdown at, for example, sites of inflammation where reduced oxygen derivatives, which we have now shown can hydroxylate non-collagenous peptides, are being produced[12,19,26].

The present data indicate that hydroxyproline- and/or hydroxylysine-containing peptides could be produced *in vivo* by a nonenzymatic reaction involving reduced oxygen derivatives. If this is supported by further studies, then some of the isomers or hydroxyproline which are generated, such as the *cis*-4-hydroxyproline, may be true biosynthetic products. Because *cis*-4-L-hydroxyproline is an analogue of L-proline and effective inhibitor of stable collagen triple-helix formation[28], its production *in vivo* would provide a novel mechanism for regulating net collagen production and add to the growing list of biological effects of oxygen radicals[29].

Biosynthetic labelling of platelet activating factor from radioactive acetate by stimulated platelets

H. Chap*, G. Mauco*, M. F. Simon*, J. Benveniste† & L. Douste-Blazy*

* INSERM Unité 101, Hôpital Purpan, 31059 Toulouse, France
† INSERM Unité 200, 32 rue des Carnets, 92140 Clamart Paris, France

Platelet activating factor (PAF-acether) is a chemical mediator released by basophils in *in vitro* and *in vivo* conditions of immunological challenge[1–5]. PAF-acether induces aggregation and secretion of platelets from different species[3,6,7] and could thus be implicated in various immunological forms of tissue injury[8,9]. Other sources have been described for this mediator, including macrophages[10] and platelets[11]. As the amounts of PAF-acether released in the latter case are sufficient to support the platelet aggregation[11] and as platelet aggregation by PAF-acether does not require ADP secretion or thromboxane biosynthesis[12], PAF-acether was proposed as the mediator of the putative third pathway of platelet aggregation[11]. Structural analysis of PAF-acether by lipases indicated that it could be a glycerophospholipid devoid of an ester linkage at the 1-position and bearing a fatty acid esterified at the 2-position[13]. This has provided the first evidence for a phospholipid displaying the properties of a powerful chemical mediator. Based on several

0028-0836/81/040312—03$01.00

lines of evidence, 1-*O*-alkyl-2-acetyl-*sn*-glyceryl-3-phosphorylcholine (1-alkyl-2-acetyl-GPC) was recently proposed as the chemical structure of the mediator, hence the term PAF-acether[14,15]. As PAF-acether synthesis occurs rather early in activated platelets, one of the most efficient pathways of PAF-acether formation could involve a rapid acetylation of the corresponding lysoderivative (1-alkyl-GPC). We now present evidence that platelets activated by ionophore A23187 are able to incorporate acetate into a mixture of 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC; the former supports the biological activity of PAF-acether.

Rabbit blood was drawn on to EDTA (5 mM) by intracardiac puncture and washed platelets were prepared according to Ardlie *et al.*[16]. Final suspension (10^9 platelets ml^{-1}) was in Tyrode's buffer (*p*H 7.35) containing 1 mM $MgCl_2$, 1.25 mM $CaCl_2$ and 0.35% (w/v) fat-free bovine serum albumin (Sigma). Platelets were incubated at 37 °C for 10 min under stirring in the presence of 250 $\mu Ci\ ml^{-1}$ ^3H-acetate (12 Ci $mmol^{-1}$, CEA) and 2.5 μM A23187 (Lilly). Lipids were extracted according to Bligh and Dyer[17]. The lower chloroformic phase was washed three times with methanol/water (1:1 by vol.) to remove excess free acetate. An aliquot of the lipid extract from both control and A23187-treated platelets was subjected to TLC on silicagel F 254 precoated plates (Merck) using chloroform/methanol/water (70:35:7 by vol.) as a solvent. The chromatogram was divided into 17 bands which were directly scraped into scintillation vials containing 10 ml of Picofluor (Packard) and radioactivity was determined by scintillation counting. Figure 1 shows that A23187 induced the appearance of a radioactive lipid migrating very close to sphingomyelin. This chromatographic behaviour is identical to that previously reported for PAF-acether[11].

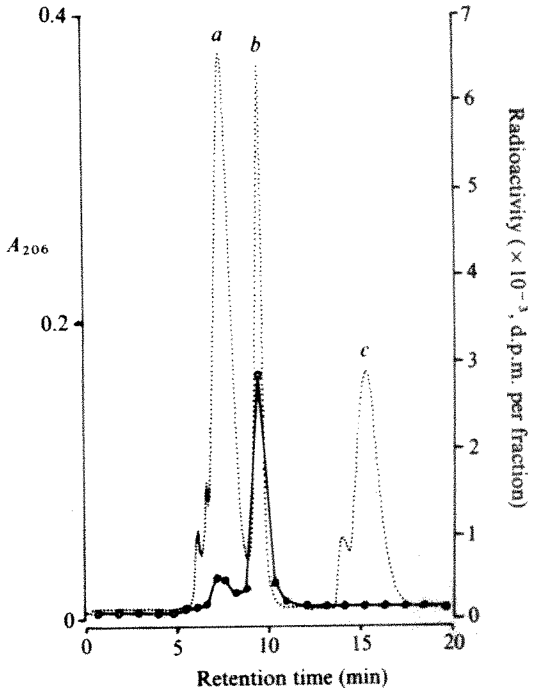

Fig. 2 Identification by HPLC of acetic acid as the hydrosoluble compound released by phospholipase A_2 treatment of purified ^3H-acetate-labelled platelet phospholipid. Preparation of ^3H-acetate-labelled platelet phospholipids has been reported in the text. An aliquot (40,000 d.p.m.) was incubated at 37 °C for 15 min with 5 IU *N. naja* phospholipase A_2 as previously reported[13]. After partition according to Bligh and Dyer[17], to 80 μl of the aqueous upper layer were added 5 μl of pure formic acid (*a*), 5 μl acetic acid (*b*) and 10 μl propionic acid (*c*). The mixture was then subjected to HPLC using a column of RP 18–10 μm (25 × 0.46 cm). Elution was performed according to Farinotti *et al.*[19] at a flow rate of 0.5 ml min^{-1} and 0.5-ml fractions were collected. Carrier acids were detected by absorbance at 206 nm (......) and radioactivity (———) was determined by liquid scintillation counting.

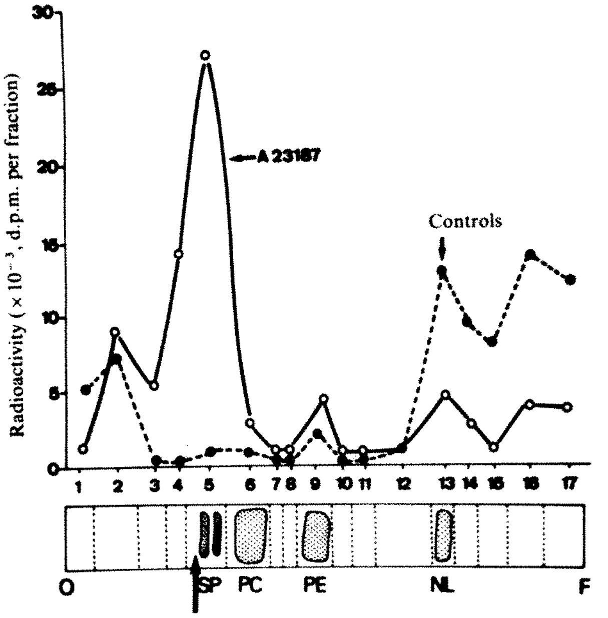

Fig. 1 Distribution of radioactivity after TLC of ^3H-acetate-labelled lipids from platelets. The lipid extracts from control (●) and A23187-treated (○) platelets were chromatographed as described in the text. The lower part of the graph represents the position of major, iodine-stainable lipids and the localization of the different bands scraped into scintillation vials. Each point represents the radioactivity measured in the corresponding band. Results are representative of four identical experiments. O, origin; SP, sphingomyelin; PC, phosphatidylcholine; PE, phosphatidylethanolamine; NL neutral lipids; F, solvent front. The arrow indicates the position of a pure standard of PAF-acether.

To characterize it further, the newly formed radioactive compound was then purified from a similar lipid extract by two steps of HPLC with a Lichrosorb Si 60/5 column (25 cm × 0.9 cm) at a flow rate of 5 ml min^{-1}. Using acetonitrile/methanol/water (60:30:10 by vol.) as a first solvent, a radioactive peak was eluted at 23 min. The pooled fractions (which corresponded to PAF-acether on TLC) were rechromatographed with hexane/propanol 2/water (39:52:9 by vol.). In the latter system, a radioactive peak was detected at 30 min and was clearly separated from other UV-detectable lipids. On TLC, the purified compound exhibited the same R_F as previously observed and it co-migrated with 1-alkyl-2-[^3H]acetyl-GPC and 1-acyl-2-[^3H]acetyl-GPC (see Table 1 legend for their synthesis).

The biological activity of the purified compound was checked on rabbit platelets suspended in Tyrode's buffer (*p*H 7.35) containing gelatin (0.25%, w/v) as previously described[3]. The compound displayed a strong aggregating activity, which still occurred in the presence of creatine phosphate/creatine phosphokinase (4 mM and 10 U ml^{-1}, respectively) or when using platelets incubated for 15 min with 1 mM aspirin before washing (in these conditions, platelets became unresponsive to 10 μM sodium arachidonate).

These results strongly suggest that stimulated platelets synthesize radioactive PAF-acether from labelled acetate. Further biochemical identification was performed by subjecting the purified compound to various treatments. After base-catalysed methanolysis[18] followed by neutralization with HCl and phase partition according to Bligh and Dyer[17], over 90% of the radioactivity was found in the aqueous upper layer. The same result was obtained on incubation with *Naja naja* phospholipase A_2 in previously reported conditions[13]. In these conditions, it was verified by HPLC[19] that the aqueous radioactivity coincided with free acetic acid (Fig. 2). These data confirm that acetic acid was esterified in the 2-position of the isolated phospholipid. However, incubation of the compound

Table 1 Percentage of hydrosoluble radioactivity after lipase treatment of ^{3}H-acetate-labelled phospholipids

	No. of experiments	Controls	Lipase	*P*
Platelet ^{3}H-phospholipid	6	16.2±7.1	60.0±9.6	<0.001
1-acyl-2-[^{3}H]acetyl-GPC	5	16.2±8.0	79.5±4.9	<0.001
1-alkyl-2-[^{3}H]acetyl-GPC	6	29.4±9.7	30.9±8.6	NS

The ^{3}H-acetate-labelled phospholipid isopolar to PAF-acether was purified from a platelet lipid extract as described in the text. 1-Acyl-GPC was obtained by phospholipase A_2 treatment (*Crotalus adamanteus*) of phosphatidylcholine isolated from egg[26] and then purified by TLC. This and synthetic 1-hexadecyl-*rac*-glyceryl-3-phosphorylcholine (Medmark) were acetylated as described by Demopoulos *et al.*[14] in chloroform containing ^{3}H-acetic anhydride (Amersham) diluted with cold anhydride to a specific radioactivity of 1 mCi μmol^{-1}. The two products were then purified by HPLC. Lipase treatment was performed at 37 °C for 60 min in 0.01 M Tris-HCl buffer (*p*H 7.4) containing 0.15 M NaCl and 0.01 M $CaCl_2$. The incubation medium contained in 0.25 ml : 0.02 ml of labelled phospholipid in ethanol (20,000–40,000 d.p.m.) and 0.025 ml of either lipase from *R. arrhizus* (Boehringer) suspended in 3.2 M $(NH_4)_2SO_4$ or 3.2 M $(NH_4)_2SO_4$ in the control tubes. Lipids were then partitioned according to Bligh and Dyer[17] and an aliquot of both lower (organic) and upper (aqueous) phase was determined for radioactivity by liquid scintillation counting using Picofluor (Packard). Results (mean ±1 s.d.) represent the percentage of radioactivity recovered in the upper phase. *P*, probability of significance according to Student's *t*-test. NS, not significant.

with 4 M HCl at room temperature for 3 h (ref. 5) did not modify its phase partition, excluding the occurrence of a vinyl-ether linkage at the 1-position of the phospholipid.

More striking results were obtained following treatment of the radiolabelled compound by lipases. As shown in Table 1, 60% of the radioactivity was water soluble after incubation with lipase from *Rhizopus arrhizus*. This value was close to 80% when incubating 1-acyl-2-[^{3}H]acetyl-GPC, whereas no change in phase partition occurred with 1-hexadecyl-2-[^{3}H]acetyl-GPC. Identical behaviour was obtained when using a lipase with high phospholipase A_1 activity purified from guinea pig pancreas (donated by J. Fauvel and M. J. Bonnefis[20]). These results indicate that the radioactive phospholipid that we isolated from A23187-stimulated platelets could correspond to a mixture of 1-acyl-2-acetyl-GPC and 1-alkyl-2-acetyl-GPC, the former being converted to hydrosoluble 2-acetyl-GPC through lipase hydrolysis. Indeed, TLC results have shown that the water-soluble compound released by lipase treatment of the ^{3}H-labelled platelets was the same as that obtained from 1-acyl-2-[^{3}H]acetyl-GPC. It remained at the origin and was clearly separated from PAF-acether and from free acetate, the latter migrating with the solvent front. In contrast the chromatographic behaviour of 1-alkyl-2-acetyl-GPC was unchanged after lipase treatment, thereby illustrating the specificity of this enzyme towards the ester bond at the 1-position of phosphoglycerides[21]. However, the lower organic phase contained all the original biological activity after such treatment, confirming previous data obtained on PAF-acether from pig leukocytes[13]. We therefore conclude that only 1-alkyl-2-acetyl-GPC supports the PAF-acether activity released by A23187-stimulated platelets. This agrees with the finding that the 1-acyl derivative exhibits a much lower activity than the 1-alkyl derivative[14,15].

The present study is an attempt to characterize the biochemical pathways of PAF-acether synthesis in a living cell. More recent results indicate that a similar incorporation of radiolabelled acetate occurs in stimulated murine macrophages[22]. However, several aspects of acetate incorporation in platelet PAF-acether remain unclear: (1) Are the concentrations of acetate used (20 μM) relevant to available intracellular acetate? Our study does not provide quantitative information; we simply expected the radioactive precursor to label the intracellular pool of acetate, the precise amount of which is unknown. (2) Is the acetylation reaction an enzymatic process involving, for instance, acetylcoenzyme A as an intermediate? This should be the object of further studies. (3) What is the origin of the phospholipid acceptors? 1-alkyl-GPC is released from hog leukocytes[23] and various other cell sources[24], including platelets, but we know of no accurate published report on the putative precursor 1-alkyl-2-acyl-GPC in these cells. The 1-alkyl- and 1-acyl-lysophospholipids could then act as acetyl acceptors for acetate, leading to the formation of a molecule with high or low activity. This would agree with the suppression of PAF-acether synthesis by bromophenacyl bromide, a phospholipase A_2 inhibitor[25]. However, further studies are necessary to characterize the mechanism and the specificity of acetate incorporation into these phospholipids.

This work was supported by INSERM (CRL 78.5.148.3). We thank Dr L. McGregor for correcting the manuscript.

Effects of ATP and vanadate on calcium efflux from barnacle muscle fibres

Mark T. Nelson & Mordecai P. Blaustein

Calcium ions carry the inward current during depolarization of barnacle muscle fibres and are involved in the contraction process[1]. Intracellular ionized calcium ($[Ca^{2+}]_i$) in barnacle muscle, as in other cells, is kept at a very low concentration, against a large electrochemical gradient[2,3]. This large gradient is maintained by Ca^{2+} extrusion mechanisms. When $[Ca^{2+}]_i$ is below the contraction threshold[4], Ca^{2+} efflux from giant barnacle muscle fibres is, largely, both ATP dependent and external Na^+(Na_o^+) dependent (see also refs 5,6). When $[Ca^{2+}]_i$ is raised to the level expected during muscle contraction (2–5 μM)[7], most of the Ca^{2+} efflux from perfused fibres is Na_o dependent; as in squid axons[8], this Na_o^+-dependent Ca^{2+} efflux is ATP independent. Orthovanadate is an inhibitor of ($Na^+ + K^+$) ATPase[9] and the red cell Ca^{2+}-ATPase[10]. We report here that vanadate inhibits ATP-promoted, Na_o^+-dependent Ca^{2+} efflux from barnacle muscle fibres perfused with low $[Ca^{2+}]_i$ (0.2–0.5 μM), but has little effect on the Na_o^+-dependent, ATP-independent Ca^{2+} efflux from fibres with a high $[Ca^{2+}]_i$ (2–

0028–0836/81/040314—03$01.00

5 μM). Nevertheless, ATP depletion or vanadate treatment of high $[Ca^{2+}]_i$ fibres causes an approximately 50-fold increase of Ca^{2+} efflux into Ca^{2+}-containing lithium seawater. These results demonstrate that both vanadate and ATP affect Ca^{2+} extrusion, including the Na_o^+-dependent Ca^{2+} efflux (Na–Ca exchange), in barnacle muscle.

The intracellular solute composition of giant muscle fibres from the barnacle, *Balanus nubilus*, was controlled by internal perfusion[11]. Intracellular $[Ca^{2+}]$ was maintained with Ca-EGTA buffers containing 2 or 8 mM EGTA and appropriate concentrations of $CaCl_2$ (see figure legends). The perfusion fluids also contained caffeine, and the mitochondrial uncoupler, carbonylcyanide *p*-trifluoromethoxyphenyl hydrazone (FCCP), to minimize Ca^{2+} sequestration in sarcoplasmic reticulum and mitochondria, respectively. Caffeine and FCCP do not directly affect Ca^{2+} efflux from internally perfused barnacle muscle fibres (unpublished data). ATP levels are controlled with a regenerating system consisting of phosphoenolpyruvate and phosphokinase. Perfused fibres do not contract even when $[Ca^{2+}]_i$ is raised above the normal contraction threshold (~0.9 μM)[4]. Thus, Ca^{2+} efflux measurements can be made on fibres containing Ca^{2+} levels that would normally be expected to cause contractures (>1 μM)[7].

As in squid axons[8], Na_o^+-dependent Ca^{2+} efflux from barnacle muscle fibres is promoted by ATP when $[Ca^{2+}]_i < 1$ μM (ref. 5). Ca efflux from ATP-depleted fibres perfused with 0.2–0.5 μM $[Ca^{2+}]_i$ was ~0.3 pmol cm^{-2} s^{-1} ($n = 3$) and insensitive to the removal of external Na^+. Similarly, Ca^{2+} efflux from ATP-fuelled, vanadate-treated fibres perfused with 0.2–0.5 μM $[Ca^{2+}]_i$ was ~0.2 pmol cm^{-2} s^{-1} ($n = 3$) and was insensitive to the removal of external Na^+. However, as shown in Fig. 1, in a representative fibre perfused with ATP and 0.2 μM $[Ca^{2+}]_i$, Ca^{2+} efflux was about 0.75 pmol cm^{-2} s^{-1}. This efflux declined to about 0.35 pmol cm^{-2} s^{-1} when external Na^+ was replaced by Tris. When 1 mM vanadate was added to the perfusion fluid, Ca^{2+} efflux into Na^+ seawater fell to ~0.2 pmol cm^{-2} s^{-1}. These data demonstrate that Ca^{2+} efflux from fibres containing low $[Ca^{2+}]_i$ is Na_o^+ dependent, and can be inhibited by vanadate.

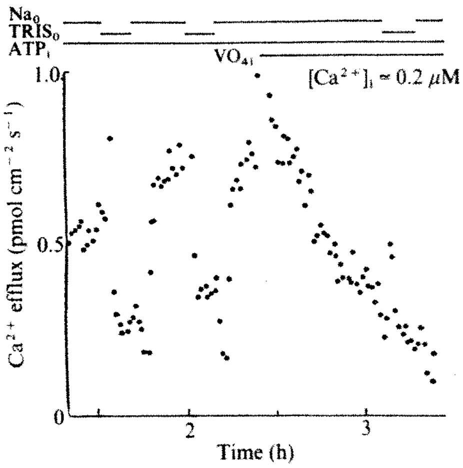

Fig. 1 Effects of external Na^+ and Tris, and internal vanadate on $^{45}Ca^{2+}$ efflux from a fibre perfused with low $[Ca^{2+}]_i$. The composition of the perfusion fluid was: 189 mM K glutamate, 10 mM Na glutamate, 38 mM KCl, 375 mM sucrose, 8 mM $MgCl_2$, 8 mM EGTA, 4.1 mM $CaCl_2$ ($[Ca^{2+}]_i \simeq 0.2$ μM), 3mM Na_2 ATP (Sigma), 3 mM phosphoenolpyruvate (Sigma), 8 μg ml^{-1} pyruvate kinase, and 40 mM HEPES. The perfusion fluids were buffered to *p*H 7.3 with Tris base. A Ca-EGTA stability constant of 7.6×10^6 M^{-1} was used to calculate free calcium concentrations ($[Ca^{2+}]_i$). The composition of the standard external solution (Na_o^+) was (in mmol l^{-1}): 456 NaCl, 6 Tris, 10 KCl, 11 $CaCl_2$ and 32 $MgSO_4$. All external solutions were buffered to *p*H 7.8 at 20°C with maleic acid. Osmolalaties of all internal and external solutions were 930–980 mosmol kg^{-1}. Tris or Li^+ (see Figs 2 and 3) was substituted isosmotically for Na^+ in the Na-free seawaters (indicated by Tris of Lio in the bars at the tops of the figures). Internal perfusion with ^{45}Ca, 2 mM caffeine, and 25 μM FCCP was begun 80 min before the data shown here were obtained. After 150 min of perfusion, 1 mM vanadate was added to the perfusion fluid. Resting potential, −56 mV. Temperature, 16°C. Fibre diameter, 1.4 mm.

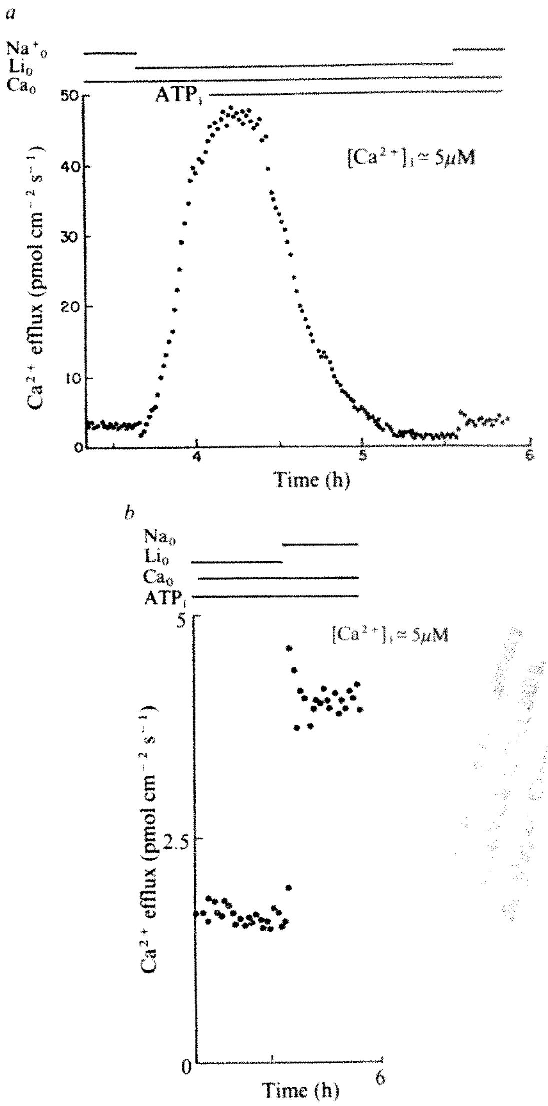

Fig. 2 *a*, Effects of external Na^+ and Li^+, and internal ATP on $^{45}Ca^{2+}$ efflux from a barnacle muscle fibre perfused with high $[Ca^{2+}]_i$. *b*, Effects of external Na^+ and Li^+ on $^{45}Ca^{2+}$ efflux from the same fibre in the presence of ATP (last part of Fig. 2*a* expanded). Internal perfusion with fluid containing $^{45}Ca^{2+}$, 2 mM caffeine, 25 μM FCCP, 2 mM EGTA and 1.95 mM Ca ($[Ca^{2+}]_i \approx 5$ μM) was begun 200 min before data shown here were obtained. After 250 min of perfusion, 2 mM ATP and an ATP-regenerating system were added to the perfusion fluid. The fibre was exposed to 456 mM Na^+ seawater, except during the periods indicated, when the seawater contained 456 mM Li^+. Resting potential, −47 mV. Temperature, 16 °C. Fibre diameter, 1.4 mm.

In fibres containing a high $[Ca^{2+}]_i$, bathed in Ca^{2+}-free media, Li^+ and Tris (and choline) could be used interchangeably as external Na^+ replacements (compare with Fig. 2). However, in fibres with a low $[Ca^{2+}]_i$, Li^+ seems to substitute partially for external Na^+ in supporting Ca^{2+} efflux[12]. Therefore, Tris was used to replace Na^+ in fibres with a low $[Ca^{2+}]_i$ (Fig. 1).

In squid axons containing high $[Ca^{2+}]_i$ (>2 μM), most of the Ca^{2+} efflux is Na_o^+ dependent, but ATP independent[8]. In addition, in high $[Ca^{2+}]_i$, ATP-depleted axons[8], the replacement of external Na^+ by Li^+ increases Ca^{2+} efflux two- to fourfold. This Li_o^+-stimulated efflux is also completely dependent on external Ca^{2+}. Ca^{2+} efflux from perfused barnacle muscle fibres exhibits similar properties. Namely, when ATP-depleted fibres are perfused with high $[Ca^{2+}]_i$, the replacement of external Na^+ by Li^+ increases Ca^{2+} efflux about 10-fold (from ~5 to ~50 pmol

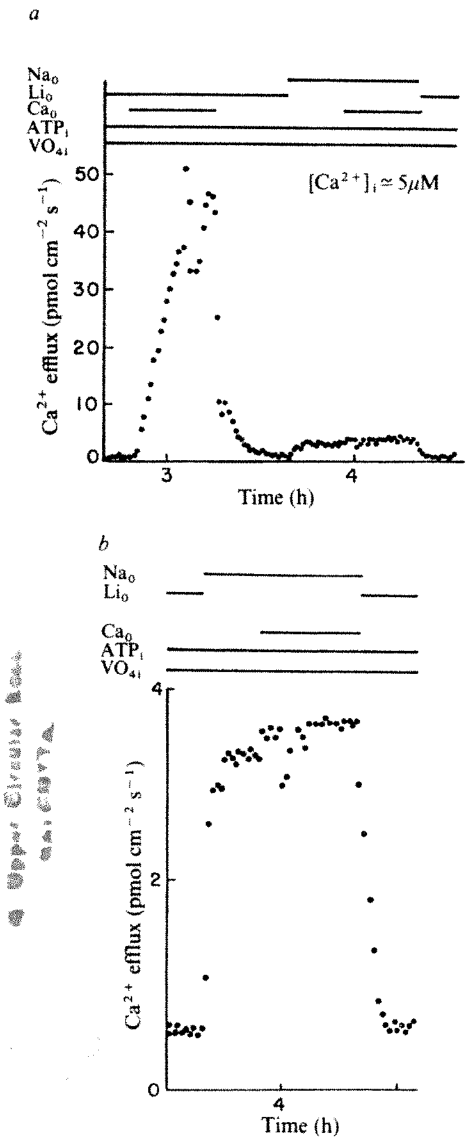

Fig. 3 *a* and *b*, Effects of external Na^+, Li^+, and Ca^{2+} on $^{45}Ca^{2+}$ efflux from an ATP-fuelled fibre perfused with high $[Ca^{2+}]_i$. The end tail of the experiment of *a* is shown on an expanded scale in *b*. Internal perfusion with $^{45}Ca^{2+}$, 3 mM ATP and an ATP-regenerating system, 1.2 mM vanadate, 2 mM caffeine, 8 mM EGTA and 7.8 mM Ca^{2+} ($[Ca^{2+}]_i \simeq 5\ \mu M$) was begun 160 and 210 min before data shown in *a* and *b*, respectively, were obtained. The fibre was bathed in 456 mM Na^+, except for the periods noted, when the seawater contained 456 mM Li^+. The seawater also contained 11 mM Ca^{2+}, except for the periods indicated, when Mg^{2+} replaced Ca^{2+} in the seawater. Resting potential, −45 mV. Temperature, 16 °C. Fibre diameter, 1.5 mm.

cm^{-2} s^{-1}; see Fig. 2*a*). This Li_o^+-stimulated efflux is also entirely Ca_o^{2+} dependent—the removal of Ca_o^{2+} reduces Ca^{2+} efflux into Li^+ seawater (Li SW) to ~1 pmol cm^{-2} s^{-1} (not shown). Moreover, the addition of ATP to the perfusate reduces $Li_o^+ + Ca_o^{2+}$-dependent Ca^{2+} efflux (Fig. 2*a*), and the subsequent replacement of Li_o^+ by Na_o^+ increases Ca^{2+} efflux to about the level seen in the absence of ATP (~4 pmol cm^{-2} s^{-1}; Fig. 2*a*, *b*).

Vanadate mimics the effect of ATP depletion in ATP-fuelled fibres perfused with high $[Ca^{2+}]_i$: it promotes a large Ca^{2+} efflux in Li SW (Fig. 3*a*: compare with Fig. 2*a*). Li_o^{2+}-stimulated Ca^{2+} efflux from vanadate-treated, ATP-fuelled fibres, like Li_o^{2+}-stimulated Ca^{2+} efflux from ATP-depleted fibres, is completely dependent on Ca_o^{2+} (Fig. 3*a*).

Figure 3*a*, *b* also shows that Ca^{2+} efflux from vanadate-treated, high $[Ca^{2+}]_i$ fibres can be promoted by Na_o^+ in the absence of Ca_o^{2+}. In summary, the data from Figs 1 and 3*a* demonstrate that the Na_o^+-dependent Ca^{2+} efflux (presumably Na^+–Ca^{2+} exchange) is blocked by vanadate when it is ATP dependent (in low $[Ca^{2+}]_i$ fibres), but not when it is ATP independent (in high $[Ca^{2+}]_i$ fibres)[11]. Clearly, vanadate cannot be used to distinguish Na_o^+-dependent from Na_o^+-independent Ca^{2+} efflux (contrast with ref. 13).

Resting barnacle muscle fibres have a $[Ca^{2+}]_i$ of about 0.05–0.2 μM (ref. 14). The threshold for contraction is about 0.5–0.9 μM (ref. 4), and maximal isometric force is developed with a 10-fold higher $[Ca^{2+}]_i$ (ref. 7). Our data demonstrate that the Ca^{2+} efflux is Na_o^+-dependent throughout the normal physiological range of $[Ca^{2+}]_i$ values for these fibres. When $[Ca^{2+}]_i$ is below the contraction threshold (< ~0.5 μM)[4], the Ca^{2+} efflux is largely ATP dependent and vanadate sensitive. A substantial fraction of this efflux (~60%) depends on Na_o^+ when $[Ca^{2+}]_i \simeq$ 0.2 μM (Fig. 1). At the $[Ca^{2+}]_i$ levels expected at the peak of contraction (~5 μM)[7], about 90% of the Ca^{2+} efflux is Na_o^+ dependent; but this (Na_o^+-dependent) efflux is neither ATP dependent nor vanadate sensitive.

The mechanism responsible for the residual Ca^{2+} efflux into Na^+-free media is uncertain. This efflux could, in part, be a passive Ca^{2+} and Ca-EGTA leak. However, Ca^{2+} efflux from ATP-fuelled fibres into Na^+-free media was greater than Ca^{2+} efflux from ATP-depleted or vanadate-treated fibres (even with external Na^+ present; compare with Fig. 1). This difference in efflux may represent an ATP-dependent, vanadate-sensitive 'uncoupled' Ca^{2+} pump[13]. Alternatively, this efflux may simply represent an exchange that is activated by other monovalent cations (for example, K^+, Li^+, choline or Tris)[12] and/or by the residual external Na^+ located in the spaces enclosed by surface membrane invaginations.

Our experiments do not show how ATP affects Na^+–Ca^{2+} exchange. However, as vanadate inhibits a number of ATPases[15], our data may infer that the influence of ATP on Na_o^+-dependent Ca^{2+} efflux involves a phosphorylation step. This is consistent with evidence that the non-hydrolysable β–γ methylene analogue of ATP cannot substitute for ATP in promoting Ca^{2+} efflux from the squid axons[16]. Unfortunately, ATP hydrolysis possibly associated with Na^+–Ca^{2+} exchange would be difficult to detect in barnacle muscle fibres which contain many ATPases.

Our data are consistent with the view[8] that ATP increases the affinity of the Na^+–Ca^{2+} exchange system for external Na^+ and/or internal Ca^{2+}. Moreover, the effects of ATP and vanadate on the Ca^{2+} efflux in high $[Ca^{2+}]_i$ fibres may indicate that ATP increases the Na^+/Li^+ selectivity ratio of the carriers, thereby inhibiting $Li_o^+ + Ca_o^{2+}$-dependent Ca^{2+} efflux. Regardless of the uncertainties, our data demonstrate that Na^+ ions, probably acting via an Na^+–Ca^{2+} exchange mechanism, are important for regulating Ca^{2+} in barnacle muscle fibres in physiological conditions.

We thank Dr E. Santiago for technical assistance, Dr L. Reuss for a supply of orthovanadate, and Mrs B. Brooks for preparing the typescript. This research was supported by MDAA, NINCDS, and NSF. M.T.N. was supported by an NIH training grant.

Co-release of enkephalin and catecholamines from cultured adrenal chromaffin cells

Bruce G. Livett, Deanne M. Dean, Larry G. Whelan, Sidney Udenfriend* & Jean Rossier*†

Division of Neurology, The Montreal General Hospital and McGill University, Montreal, Quebec, Canada H3G 1A4
* Roche Institute of Molecular Biology, Nutley, New Jersey 07110

The opioid peptides Leu-enkephalin and Met-enkephalin[1,2] are stored intraneuronally in the brain[3] where they are thought to act as neurotransmitters and/or neuromodulators[4]. Evidence for their release from nerve terminals has come from biochemical and pharmacological studies *in vitro* with brain tissue slices[5,6] and synaptosomes[6]. Enkephalins also exist in the peripheral nervous system in nerve cell bodies and axon terminals in the gastrointestinal tract[7], sympathetic ganglia[8–11] and adrenal gland[12]. In the adrenal gland, high levels of enkephalins are present both in axon terminals of the splanchnic nerve[13] and in the adrenal medullary chromaffin cells[13–15] where they are stored together with the catecholamines in the chromaffin granules[14–16]. Stimulation of the adrenal gland *in vivo*[15,17] or the perfused gland *in vitro*[14] causes release of catecholamines and enkephalins into the adrenal vein. However, it is not clear whether the origin of the released enkephalins is the adrenal medullary chromaffin cells or the enkephalin-containing splanchnic nerve terminals that innervate the medulla. We now show that enkephalin and catecholamines are released together from primary cultures of bovine adrenal medullary chromaffin cells by nicotine in a Ca^{2+}-dependent manner.

Primary cultures of bovine adrenal medullary chromaffin cells provide a useful experimental system for investigating the release of catecholamines uncomplicated by diffusion barriers present in intact tissue. For example, this cell culture system has been used to characterize the pharmacological release of catecholamines from the cells by nicotinic agonists[18], to investigate the role of substance P[18,19], somatostatin[19] and enkephalins[20] as modulators of these nicotinic receptors, and to demonstrate the presence of Leu- and Met-enkephalin in high concentrations in the processes and terminal varicosities that characterize these adrenal paraneurones[21]. For the present study, primary cell cultures of adrenal medullary cells were established as monolayers on collagen-coated plastic tissue culture dishes[19] (for further details see Fig. 1 legend). After 8 days in culture, the cells were processed for immunohistochemical localization of Leu-enkephalin as previously described[21]. Preimmune rabbit serum, rabbit anti-Leu-enkephalin serum (R164B) preabsorbed with Met-enkephalin and fluorescein-conjugated goat anti-rabbit serum used in this study were obtained from Dr R. P. Elde. The specificity of the Leu-enkephalin antiserum has been characterized by radioimmunoassay and immunofluorescence[21]. Strong immunofluorescence specific for leu-enkephalin (Fig. 1*b*) was observed in the perikarya and varicose processes of approximately 30% of the adrenal paraneurones whereas over 80% of the cells stained positively for catecholamines (Fig. 1*c*) by the glyoxylic or formaldehyde–glutaraldehyde techniques[18,21]. The immunoreactive Leu-enkephalin had a fine granular disposition within the cytoplasm and processes and exhibited an increasing proximal to distal ratio of fluorescence consistent with synthesis in the perikarya with subsequent transport, processing and storage in the terminals[21].

Catecholamines are normally released from the adrenal gland *in vivo* following activation of acetylcholine (ACh) receptors on the chromaffin cells by ACh released from splanchnic nerve terminals innervating the medulla. In a similar manner, pharmacological studies on bovine adrenal paraneurones have shown that ^{3}H-noradrenaline taken up and stored in reserpine-sensitive sites can be released from the cells by activation of nicotinic (but not muscarinic) ACh receptors[19]. The results in Table 1 show that in the presence of nicotine (ED$_{50}$ 5 × 10^{-6} M) the cells released 13.2 ± 1.6% (n = 5) of their endogenous total catecholamines over a 5-min period. Nicotine produced a preferential release of endogenous noradrenaline (20.9 ± 1.4%) over adrenaline (10.4 ± 0.8%). It also released enkephalins from the cells, and the fraction of the cellular Leu-enkephalin released (8.2 ± 1.3%) was similar to that of the endogenous adrenaline released. The release of both catecholamines and Leu-enkephalin by nicotine was Ca^{2+} dependent (Table 1). Although Met-enkephalin and enkephalin congeners and precursors contained in the chromaffin granules[14–16] are also released[15,22], the combination of immunoassay gel filtration and HPLC methods[22,23] used in our study were highly selective for Leu-enkephalin (see Table 1 legend).

Table 1 Calcium-dependent release of Leu-enkephalin and catecholamines from adrenal paraneurones

	% Cellular content released		
Secretory stimulus	Noradrenaline	Adrenaline	Leu-enkephalin
Nicotine 5 × 10^{-6} M	1.4 ± 0.7	1.0 ± 0.2	ND
Nicotine 5 × 10^{-6} M + Ca^{2+}, 2.2 mM	20.9* ± 1.4	10.4† ± 0.8	8.2*† ± 1.3

The release studies were carried out on 10 culture plates (6 days old) each containing 1 × 10^6 chromaffin cells grown in the presence of Bacitracin (see Fig. 1 legend) in 1 ml medium. Five plates served as controls (nicotine but no Ca^{2+}) and the other five contained nicotine and 2.2 mM Ca^{2+}. Each plate was washed at 37 °C for 15 min in 1.0 ml of a HEPES-buffered Krebs–Ringer saline (KRH) containing 0.2% bovine serum albumen[19] and the plates were then incubated in the release experiments for three successive 5-min intervals in 1 ml of KRH medium alone (0–5 min), KRH medium containing nicotine (5–10 min); KRH medium alone, 'washout' sample (10–15 min). At the end of each 5-min period, the incubation media were removed from the cells, placed on ice and the new incubation medium pre-equilibrated to 37 °C added to the cells. A 100-μl aliquot of the medium removed from the cells was acidified with 25 μl 2 M perchloric acid for catecholamine estimation and the remaining 900 μl acidified with 900 μl 2 M acetic acid for subsequent extraction, chromatography and analysis of Leu-enkephalin. After 15 min the cells were scraped off the plate in 0.5 ml of ice-cold KRH with a rubber policeman and the extract acidified as above for assay of catecholamines and Leu-enkephalin. Assay of endogenous catecholamines: Endogenous catecholamines (both within the cells and released into the media) were assayed by the two-wavelength differential spectrofluorimetric procedure[25] of Renzini *et al*[26]. Noradrenaline and adrenaline levels were obtained by reference to standards after solving simultaneous equations for fluorescence of the samples at 410 and 455 nm with a program (written by Mr Serge La Fontaine) for a digital PDP 11/40 computer. The variability of triplicate assays of the same sample was ±5%. These day-6 cultures contained 7.6 ± 0.8 (n = 10) μg adrenaline per 10^6 cells and 2.9 ± 0.5 (n = 10) μg noradrenaline per 10^6 cells (molar ratio adrenaline : noradrenaline = 2.4). Assay of endogenous Leu-enkephalin: The freeze-dried extracts of cells and media were reconstituted in 10 mM sodium phosphate buffer pH 7.5, 145 mM NaCl supplemented with thiomersal 0.01%, gelatine 0.1% and crystalline bovine serum albumen 0.01%. The extracts were assayed by a radioimmunoassay using a C-terminal-directed Leu-enkephalin antiserum. The characteristics of the C-terminal Leu^5-enkephalin antiserum (RB 92) have been described elsewhere[23]. This antiserum has a cross-reactivity of 3% with Met^5-enkephalin, and is quite specific for the C-terminus of Leu-enkephalin. In terms of molar ratio it has a cross-reactivity of 3% with Met-enkephalin[23] and <1/10,000 with Leu-enkephalin-Arg^6 and Met-enkephalin Arg^6. Note that although the radioimmunoassay is highly selective for Leu-enkephalin, Met-enkephalin is generally present in amounts several times greater than Leu-enkephalin, and is also released[15] and will therefore necessarily be detected in the radioimmunoassay. However, the Leu^5-enkephalin immunoreactivity in the cell extracts and in the media was further characterized by gel filtration and HPLC and was found to correspond to authentic Leu^5-enkephalin. The amount of endogenous catecholamines and Leu-enkephalin contained in the cells at the beginning of each experiment was estimated for each culture plate by summing the amounts in the media at the three time periods and adding it to that remaining in the cells at 15 min. The release of endogenous catecholamines and Leu-enkephalin from the cells into the medium during the 5-min stimulation period is expressed as a percentage of the total content in the cells at the beginning of the experiment. The results give the mean ± s.e.m. (n = 5) where the percentage of catecholamines and Leu-enkephalin released by nicotine stimulation has been compared by Students t-test. ND, not detected.

* $P < 0.001$, † not significant at $P < 0.2$.

A characteristic feature of the nicotinic receptor response is that it shows activation at low levels of agonist (10^{-7}–10^{-5} M nicotine) and inhibition at higher levels (> 10^{-4} M). In accord

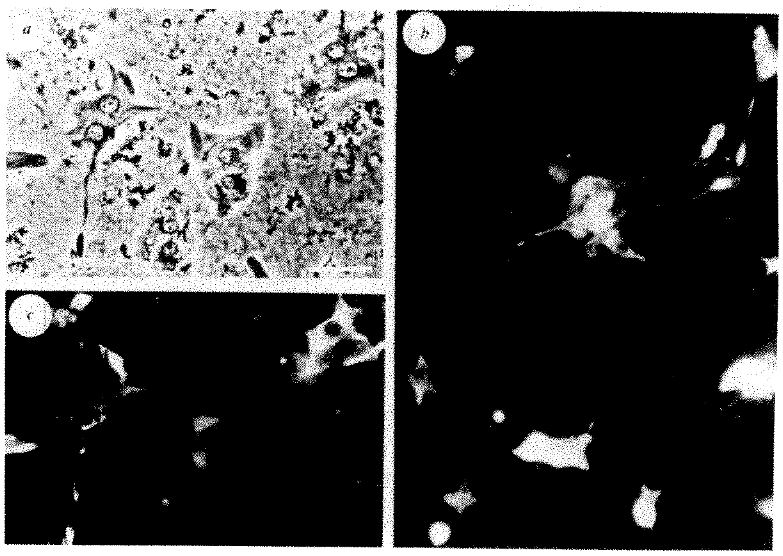

Fig. 1 Histochemical localization of Leu-enkephalin and catecholamines in the perikarya and varicose processes of bovine adrenal paraneurones maintained in cell culture for 6 days, *a*, Phase: background material is serum protein and collagen substrate precipitated by Bouin's fixative. *b*, Same field as *a*; Leu-enkephalin immunofluorescence. *c*, Catecholamine fluorescence. Bars represent 50 μm in *a*, *b*, 100 μm in *c*. Chromaffin cells were isolated from bovine adrenal medullae by retrograde perfusion with Collagenase (Sigma type 1; 0.5 mg ml^{-1})[27] and DNase (Sigma type 1; 13 μg ml^{-1}) in a Ca^{2+}- and Mg^{2+}-free Locke's buffer[28] and purified by fractionation on a self-generating gradient of Percoll (Pharmacia) as described previously[19,29]. By this procedure 195 × 10^6 chromaffin cells of density 1.060.01 g ml^{-1} were obtained from three adrenal glands (wet weight of medullae 25.8 g) with an adrenaline : norrenaline ratio of 3 : 1. The cells were plated in a medium consisting of 80% Eagle's minimal essential medium (MEM) (Gibco), 10% human placental serum (heat-inactivated), 2% 9-day chick embryo extract (50% in balanced salt solution), 600 mg% glucose, cytosine arabinoside (10^{-5} M), 5-fluorodeoxyuridine (10^{-5} M), uridine (10^{-5} M), penicillin (200 mg ml^{-1}) and streptomycin (100 mg ml^{-1})[30], on collagen-coated plastic[31] tissue culture dishes (Corning, 35 mm, 10^6 chromaffin cells) or Aclar 33C plastic 'hats' (Allied Chemical 15 mm, 5 × 10^5 chromaffin cells), and incubated in a humid atmosphere at 36 °C for 6 days before use. The media were replaced at days 2 and 4; and on days 5 and 6 Bacitracin (Sigma) was added to a final concentration of 5 × 10^{-5} M. Immunofluorescence staining of the cells (*b*) with the anti-Leu-enkephalin serum (R164B, 1/90) was shown to be specific by its total inhibition when preabsorbed with synthetic Leu-enkephalin (Peninsula)[21]. Furthermore, cultures incubated with preimmune serum or with the fluorescent conjugate alone showed no specific fluorescence[21]. The cells also contained high concentrations of catecholamine in their perikarya and varicose terminals as demonstrated by the formaldehyde–glutaraldehyde ('Faglu')[32] fluorescence histochemical technique. The final preparations were observed unmounted (for immunofluorescence, in 0.1 M bicarbonate-buffered glycerol; for catecholamine, dry) by incident fluorescence illumination with ×10 or ×20 dry Fluortar (Wild-Leitz) objectives using a Leitz Ortholux-II fluorescence microscope fitted with a Ploem incident illuminator and dichroic mirror primary and secondary filters optimal for fluorescein isothiocyanate or for catecholamine fluorescence. The results were recorded on Tri-X (Kodak) film rated at 400ASA. Exposure times were in the range 5–10 s.

with this general property, the dose–response curve for release of endogenous catecholamines and enkephalins by nicotine (Fig. 2) showed similar responses with inhibition at high concentrations of agonist. At day 6, the adrenal paraneurones contained 699 ± 51 ($n = 7$) pg Leu-enkephalin per 10^6 cells and 20.7 ± 1.7 ($n = 7$) μg catecholamines per 10^6 cells: the molar ratio of catecholamines to Leu-enkephalin released by 5 × 10^{-5} M nicotine (105 × 10^3) was similar to that present in the cells (94 × 10^3).

A recent study[17] showing that Met-enkephalin circulates in human plasma as the intact pentapeptide and that its concentration in the adrenal vein is twice that in the internal jugular or in the peripheral circulation, raises the possibility that enkephalins are secreted together with catecholamines from the adrenal medulla. This is strongly supported by the parallel release of catecholamines and enkephalins recently demonstrated in perfused dog adrenal[15] and by the present study. Further, the close correspondence of release of adrenaline and Leu-enkephalin (Table 1), and the previous immunohistochemical evidence[13] for co-storage of noradrenaline with Met-enkephalin in adrenal medullary gland cells may be of physiological significance. There is increasing evidence that amines and peptides may co-exist not only in adrenal chromaffin cells but also in several nekonal systems[24]. The present demonstration that amines and peptides are released simultaneously from adrenal chromaffin cells in response to a stimulus raises the possibility of co-secretion of catecholamines and enkephalins from adrenergic neurones and the question of the role of this co-secretion.

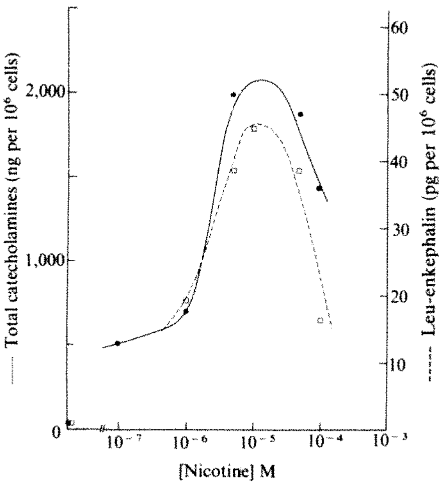

Fig. 2 Dose–response curves for release of endogenous catecholamines and Leu-enkephalin by nicotine. Adrenal paraneurones cultured on 14 Aclar hats were equilibrated for 15 min in KRH medium (containing 2.2 mM Ca^{2+} and 5 × 10^{-5} M Bacitracin), and this medium was then replaced by the same medium but containing the concentrations of nicotine indicated. At each concentration of agonist, two hats containing 5 × 10^5 cells per hat were pooled for analysis. After 5 min at 37 °C, the media were removed, acidified and chilled on ice and the cells collected for analysis of endogenous catecholamines and Leu-enkephalin as described in Table 1 legend.

This study was supported in part by a grant to B.G.L. from the Canadian MRC. J.R. was supported by the Institute National de la Santé et de la Recherche Medicale (France) and D.M.D. by a pre-doctoral fellowship from the Muscular Dystrophy Association of Canada. We thank Mr Joe Donahue for photography, Mrs Gwen Landrigan for typing the manuscript, and Dr R. P. Elde for providing the antisera used for the immunofluorescence studies.

Note added in proof: We have recently shown that Leu- and Met-enkephalin are co-stored within adrenaline (but not within noradrenaline) cells in the bovine adrenal medulla (B.G.L., R. Day, R. P. Elde and P. R. C. Howe, unpublished). A 'preliminary note' by S. M. Stine, H.-Y. T. Yang and E. Costa (*Neuropharmacology* **19**, 683–685 [1980]) indicates that Met-enkephalin-like immunoreactive material is released from isolated bovine chromaffin cells both spontaneously and in response to high concentrations of K^+ (56 mM) and acetylcholine (10^{-4} M).

Photolabelling of cholera toxin subunits during membrane penetration

Bernadine J. Wisnieski & John S. Bramhall*

Department of Microbiology and The Molecular Biology Institute, University of California, Los Angeles, California 90024

There has been much speculation about the mechanism by which cholera toxin exerts its effect on the cytoplasmic side of the membranes with which it interacts[1–4]. After the pentamer of B subunits (5B) binds to membrane receptors, particularly the monosialylganglioside GM_1, the disulphide-linked dimer A_1SSA_2 (which together with 5B constitutes the complete toxin) is thought to penetrate the membrane, perhaps through a channel formed by 5B and become reduced so that A_1SH units reach the cytoplasm and stimulate adenylate cyclase. Evidence for this mechanism is circumstantial[1,4,5]. If it is correct, a compound which will specifically label intramembranous sections of the toxin should label the channel-forming B subunits but not the channel-contained A_1 subunit. We have tested this prediction with a photoreactive glycolipid compound[6,7] and have obtained the opposite result. Therefore, we propose that only the A_1 subunit enters the membrane and we provide here data on the kinetics of that process.

The experimental protocol described is a direct and nonperturbing method for studying the dynamics of membrane penetration by proteins and other molecules. For simplicity, we used the Newcastle disease virus (NDV) system, earlier characterized with the photoreactive glycolipid probe[6], as a membrane target for cholera toxin because the viral envelope contains only three proteins, designated HN, F and M (ref. 8); surface neuraminidase activity resident in the HN protein makes NDV especially rich in GM_1 (ref. 8). The glycolipid probe 12-(4-azido-2-nitrophenoxy)-stearoyl[1-^{14}C]glucosamine (12APS-GlcN) is unique in that it will spontaneously insert into any membrane, and studies with a spin-labelled (nitroxide) counterpart suggest that the glucosamine moiety restricts it to the surface monolayer for an appreciable time after insertion[9]. The photoreactive group of 12APS-GlcN is located on the stearic acid chain of the amphiphilic compound. It reacts with vicinal compounds only when samples are exposed to UV light. Photolabelling is relatively nonspecific[7]. The probe labels coliphage $M13(f_1)$ coat protein only after incorporation into the bilayer of artificial vesicles[7]. Further, and most significantly, it labels only those residues of the protein which reside within the outer monolayer (ref. 10 and unpublished data). Chowdry and Westheimer[11] have reviewed membrane photolabelling studies. We have previously shown that cholera toxin can be photolabelled after binding to NDV charged with probe[12,13]. Here we analyse the kinetics of specific subunit insertion into the membrane.

Figure 1 shows the separation of proteins derived from cholera toxin, NDV and NDV with bound cholera toxin. The difference between the amount of toxin bound to NDV and the total toxin present (60 μg per sample) can be estimated by comparing lanes 1 and 3 and lanes 4 and 5. Typically, 3–5 μg of the toxin bound to NDV in the conditions used. Next to each stained gel the corresponding fluorogram shows proteins radiolabelled by the photoreactive probe (Fig. 1). Irradiation for 15 s allowed as much labelling of membrane proteins as irradiation for 6 min (data not shown); thus we conclude that most of the probe was photoactivated. Gel bands designated VP represent viral proteins whose photolabelling has been described elsewhere[6]. About 15–25% of the protein in band

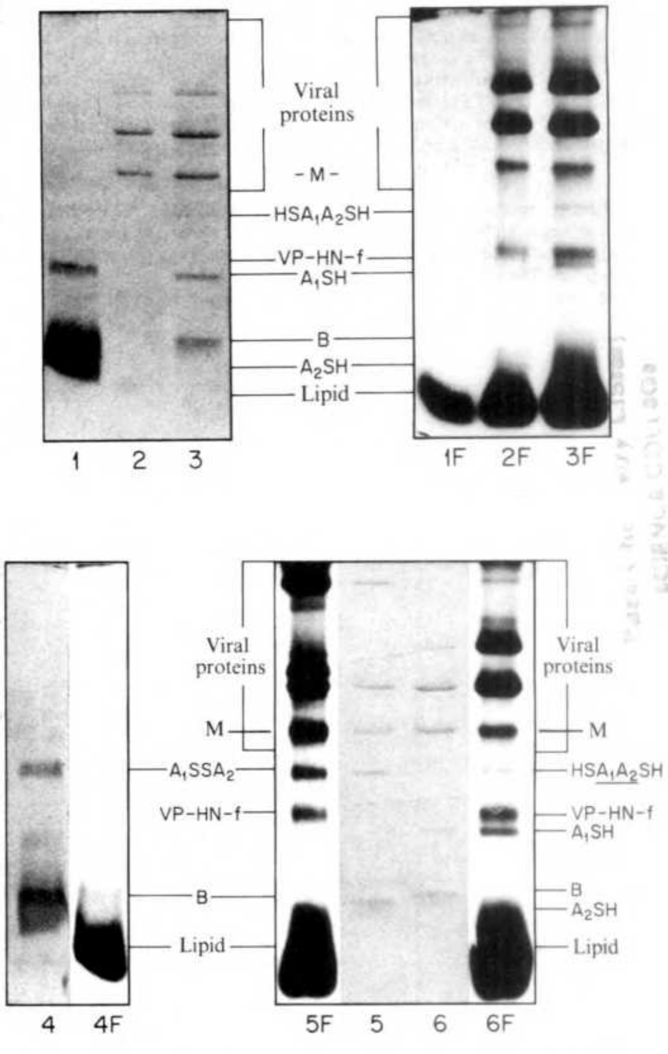

Fig. 1 Radiolabelling of NDV and cholera toxin proteins with the photoreactive probe 12APS-GlcN. Stained gel lanes are 1–6; corresponding fluorogram lanes are 1F–6F. Unreduced samples are in lanes 4 and 5. Lanes 1 and 4 contain cholera toxin (60 μg) labelled in solution and acid precipitated; lane 2 contains NDV (30 μg protein) labelled in suspension and pelleted. Lanes 3, 5, and 6 contain cholera toxin labelled after attachment to NDV for 1 min at 37 °C. Each sample was irradiated at 360 nm for 15 s. The amount of probe (50 mCi mmol^{-1}) per sample was 4×10^{-2} μCi. Total equilibration time with probe was 16 min at 37 °C for toxin alone and for NDV alone, and 15 min for NDV to which toxin was added 1 min before irradiation. Procedures as described in Table 1 legend.

Experiments were carried out under red safety lights until completion of electrophoresis to avoid activation of probe in unirradiated controls. Cholera toxin, purified[14] and stored at 6 mg ml^{-1} in 0.1 M sodium phosphate buffer, *p*H 7, was thawed and diluted to 1 mg ml^{-1} with 5 mM sodium phosphate-buffered saline containing 1 mM EDTA, *p*H 7.4 (PBSE). Two aliquots (0.6 ml) were spun at 149,000*g* for 30 min to remove any aggregates. The supernatant was used throughout. NDV strain HP-16, isolated as described elsewhere[6], was diluted to 450 μg protein per 9.4 ml PBS. The photoreactive probe 12APS-GlcN (50 mCi mmol^{-1}), synthesized as described elsewhere[15], was diluted to 90,000 c.p.m. per 10 μl of ethanol. In tube A, 150 μl of probe was dried and 50 μl of ethanol added and in tube B, 40 μl of probe was dried and 13 μl of ethanol added. The NDV suspension (9.4 ml) was added to tube A and 240 μl of toxin solution plus 2.5 ml PBSE added to tube B. Both tubes were incubated at 37 °C for 15 min. During this time, toxin solution was dispensed in 60-μl portions into 11 borosilicate tubes (6 × 50 mm), then 0.6 ml of NDV from tube A was added to each of these tubes, which were incubated for periods of time from 0.5 to 15 min before irradiation for 15 s at 366 nm with a mineral lamp (UV-Products, San Gabriel, California). Usually two samples were irradiated at each time point to provide reduced and non-reduced samples for gels. One unirradiated sample provided a control for background radioactivity. Two samples (0.6 ml) of NDV from tube A were incubated for an additional 15 min at 0 °C and at 37 °C before irradiation. Another two 0.6 ml samples of NDV were cooled to 0 °C before being added to two small tubes, each of which contained 60 μl of chilled toxin solution. One of these was irradiated after 1 min at 0 °C, the other after 15 min at 0 °C. The contents of tube B were divided into four 0.6-ml samples which were incubated at 0 °C for 1 min, 0 °C (15 min), 37 °C (1 min) and 37 °C for 15 min before irradiation. The entire experiment was repeated to provide a duplicate set of samples for analysis. Each time, 60-μl portions of toxin solution were added to 0.6 ml of PBSE and incubated for 30–60 min at 37 °C and centrifuged to determine how much toxin aggregated and could be pelleted without acid precipitation. This routine check was performed because it was found that commercial lyophilized toxin did not give reproducible results when used as a substitute for freshly isolated toxin (probably because it proved to be extremely difficult to completely solubilize). All samples were pelleted at 149,000*g* for 30 min on a Beckman SW50.1 rotor in buckets fitted with 0.7 ml adaptors. To each sample containing toxin with probe alone (from tube B), 50% trichloracetic acid (60 μl) was added after irradiation and the samples cooled to 0 °C before centrifugation. Pellets were boiled for 2 min in 40 μl of reducing or non-reducing SDS-buffer[16]. Electrophoresis and fluorography were carried out as described elsewhere[13]. Gel slices were oxidized to $^{14}CO_2$, which was collected and counted[6]. Top, data from non-reduced samples; bottom, reduced samples. Columns designated NDV alone and toxin alone refer to samples incubated independently with probe for 15 min at 37 °C, before irradiation. The sample of toxin alone (60 μg) was acid precipitated. The other columns represent components of toxin which pelleted with virus, estimated to be 5% of the 60 μg added. VP, viral protein; HN-f, HN-fragment. The $HS\underline{A_1A_2}SH$ peptide is the reduced but uncleaved $\underline{A_1A_2}$ peptide. Normally A_1SSA_2 completely reduces to A_1SH and A_2SH; however, in rapidly isolated cholera toxin preparations, not all the linear $\underline{A_1A_2}$ peptide is nicked between the two cysteines which form the disulphide bridge between A_1 and A_2.

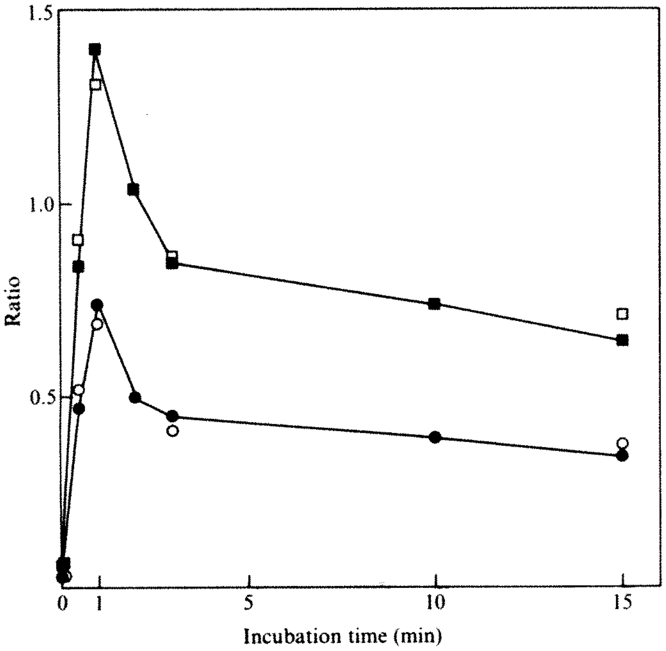

Fig. 2 The kinetics of photoreactive labelling of cholera toxin A subunits. Open symbols, ratios calculated from Table 1 (top); solid symbols, ratios calculated from Table 1 (bottom). Zero time points represent ratios calculated from 0°, 15′ samples in Table 1. Solid symbols, ratio of radiolabel in $A_1SH + HS\underline{A_1A_2}SH$ (unnicked) to radiolabel in viral protein M (●) and HN-f (■). Open symbols, ratio of radiolabel in A_1SSA_2 (nicked plus unnicked) to radiolabel in viral protein M (○) and HN-f (□). The ratio of radiolabel in HN-f to radiolabel in M was relatively constant (average 0.51; range 0.47–0.57).

A_1SSA_2 represents $\underline{A_1A_2}$ linear peptide which was not proteolytically cleaved during toxin purification[12] (the underlining of A_1A_2 is meant to distinguish this linear (uncleaved) peptide from the cleaved peptide A_1A_2). The rest of the band represents peptide which was cleaved between the disulphide bridge into discrete A_1 and A_2 subunits. The B subunit contains an internal disulphide bond and migrates with a larger apparent molecular weight when reduced. Reduced toxin samples show a faint band representing the reduced, but uncleaved, linear peptide $HS\underline{A_1A_2}SH$ (ref. 12), as well as A_1SH and B. The A_2SH subunit does not stain effectively. It migrates ahead of B and can be detected when ^{125}I-labelled toxin is electrophoresed[12]. In the fluorograms shown, the A_2SH peptide could not be resolved with any confidence from the diffuse band of radiolabelled lipids.

Other samples, including a series irradiated at defined times after the addition of toxin to NDV, were similarly electrophoresed. Bands representing viral proteins VP-M and VP-HN-fragment and toxin subunits (except A_2SH) were cut from stained gels after fluorography (because VP-HN-fragment does not stain (Fig. 1)), and oxidized to $^{14}CO_2$ which was trapped and counted. The level of radioactivity in the B subunit was not significantly above background in conditions tested (Fig. 1 and ref. 13). As previously demonstrated[6,13], unirradiated samples did not contain any radiolabelled proteins. Radioactivities of the pertinent bands are shown in Table 1. The labelling of A_1 plus A_2, that is, the net radioactivity associated with unreduced A_1SSA_2 (cleaved plus uncleaved), is expressed as a function of time and temperature of incubation with NDV before the 15 s irradiation. To standardize the data between gel lanes, raw data were later expressed as ratios within a particular lane. Radiolabelling of the two viral proteins chosen for ratio calculations did not vary with time or temperature or the presence of reducing agent, and therefore accurately reflect the amount of sample in each gel lane.

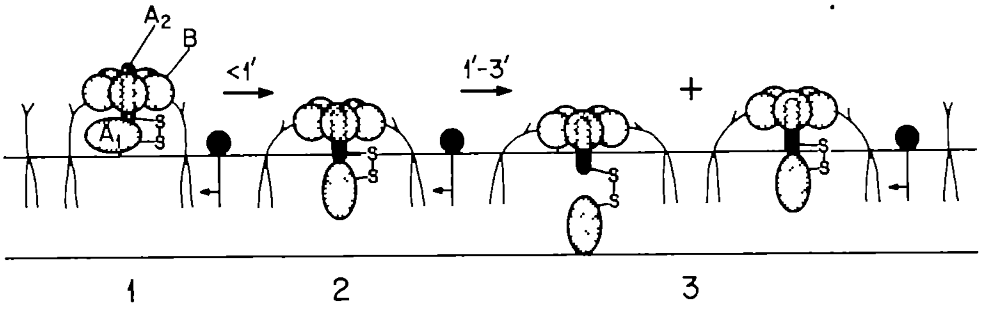

Fig. 3 Transmembrane kinetics of the active A_1 subunit of cholera toxin. Step 1, B subunits bind to ganglioside receptors (forked structures) Within 1 min of binding at 37 °C, A_1 insertion into the outer monolayer of the membrane is complete (Step 2). Within 2 min of insertion, A_1 equilibrates between the outer and inner monolayers (Step 3) The equilibrium achieved is undoubtedly a dynamic one, however, relative to the kinetics of the photolabelling reaction, the position of each A_1 is fixed. The small arrow represents the photoreactive group of 12APS–GlcN.

Data in Table 1 indicate that the A subunit of toxin can enter the vicinity of photogenerated reactive groups within seconds of binding to the viral membrane. To assess whether the radioactivity in the A_1SSA_2 band was due to labelling of A_1, A_2, or both, the ratios of counts in this band to the counts in both VP-M and VP-HN-f were plotted as a function of incubation time at 37 °C with NDV (Fig. 2, open symbols). The counts in A_1SH and in uncleaved $\overline{HSA_1A_2SH}$ were summed and expressed as a ratio to counts in $\overline{VP\text{-}M}$, and to counts in VP-HN-f (Fig. 2, solid symbols). Surprisingly, Fig. 2 shows that the ratios obtained as a function of time using total A_1SSA_2 (unreduced) counts and the ratios obtained using a formula in which 75–85% of A_2 is not included (due to reduction and dissociation of the cleaved fraction of A_1SSA_2 molecules) are not significantly different. From this we conclude that the majority of the radiolabel associated with the A_1SSA_2 band (unreduced) and the $\underline{SHA_1A_2SH}$ (reduced, uncleaved) is actually attached to the A_1 subunit of the toxin and not the A_2 portion.

The most striking feature of the data presented in Table 1 and in Fig. 2 is that the A component of toxin, more specifically the A_1 portion (from the rationale above), becomes increasingly accessible to photolabel within the first minute of incubation at 37 °C with NDV. During the next 2 min of incubation, radiolabelling of A_1 decreases by roughly 40% (34–41%). Between 3 and 15 min of incubation, very little change occurs. The accessibility of A_1 to probe after 15 min is 50% (46–54%) of that observed at 1 min. The rapid penetration and labelling of A_1 resemble that of complement component C9 on addition to vesicles containing C5b-8 (refs 17, 18 and unpublished data). The ratio of label in uncleaved toxin (HSA_1A_2SH) to label in A_1SH (calculated from data in Table 1) undergoes a slight increase with time; the significance of this remains to be determined. The kinetics of labelling of the A_1 subunit was verified qualitatively by exposing X-ray film to gels for various time periods before development. The first A_1-containing bands to produce silver grains in the film emulsion were always from the very early incubation times. Little or no labelling of any toxin subunit occurred when toxin and NDV were incubated together at 0 °C before irradiation, regardless of incubation time, even though NDV bound the same amount of toxin at this temperature as at 37 °C and displayed no change in its own labelling profile.

Values for the extent of labelling of the viral proteins and of the bound cholera toxin A_1 subunit (at the 1 min time point) were all at the level of 4 mol%. A similar value was obtained with M13 coat protein in vesicles[7]. This strongly implies that within 1 min of toxin addition and binding, most of the A_1 associated with virus entered the membrane envelope. If we assume that only 10% or 1% of the virally bound A_1 entered the membrane, the calculated level of A_1-specific labelling needs to be increased to 40 and 400 mol%, respectively, an unlikely occurrence unless an equivalent level of preference of probe for A_1 is proposed. Thus, we propose that most of the A_1 associating with virus actually penetrates the bilayer. We believe this to be the first such demonstration.

Our data are incompatible with the Gill[1] model for toxin entry because if the B pentamer formed a transmembrane channel, we would expect to label B but not A (which would be protected from the probe by residues of the B channel). The reverse was actually observed, and the detected entry of the enzymatically active A_1 subunit was found to be temperature-dependent, occurring at 37 °C (a temperature compatible with physiological activity), but not at 0 °C (a temperature compatible with binding but not activity).

Explanation of the kinetic data shown in Fig. 2 must answer two questions: (1) where does 50% of the A_1 entering the membrane go and (2) why does only 50% of the entering A_1 leave? One proposal (see Fig. 3), is based on the assumption that the probe remains restricted to the outer monolayer. This is a reasonable assumption because, as previously mentioned, all available data are consistent with an asymmetric distribution of such a compound (refs 9, 10 and unpublished data). Within 1 min of toxin binding, the A_1 subunit penetrates the outer monolayer of the membrane (step 1). The kinetics of A_1 entry between 0 and 1 min would reflect the kinetics of toxin binding to receptor[19] and subunit penetration. Between 1 and 3 min, the rapid decrease in A_1 labelling suggests that about half of the A_1 molecules (or one half of each molecule) leave the vicinity of probe within 2 min of entry (step 2). We visualize this as an equilibration of A_1 between the outer and inner monolayers until roughly one half is in each monolayer. The calculated half-time for the A_1 equilibration process (decrease in labelling) is of the order of 10–20 s. This time factor is not unreasonable for a diffusion-limited process in a viscous medium. At any time after 3 min, only 50% of the A_1 that entered the membrane remains accessible to probe, indicating very little change in A_1 distribution after 3 min (step 3).

By use of photoreactive probes to investigate the dynamics of toxin translocation in other systems, we can start to examine the specific roles of membrane composition, fluidity and asymmetry on protein traversal through membranes.

The magnitude of signal amplification by ligand-induced receptor clustering

Charles DeLisi

Laboratory of Theoretical Biology, National Cancer Institute,
National Institutes of Health, Bethesda, Maryland 20205

Lateral mobility of plasma-membrane proteins is now documented for a variety of cell systems. Evidence is accumulating that the molecular clustering allowed by such mobility may be important in the transduction of information at the cell surface[1–7]. Moreover, in a wide variety of systems, only a very small fraction of receptors need to be bound to induce a response[8,9], such as in the mast cell/basophil system where receptor clusters as small as dimers can induce a response[10] and only three or four such dimers are necessary for local degranulation[11]. As receptors are mobile, some clustering is expected even in the absence of ligand. As an approximate indication of the numbers involved, a consideration of constraints on translational entropy by spontaneous pair formation predicts[12] about 100 pairs on average for a cell with 500,000 receptors (typical of mast cells[13]), if a pair is defined as two receptors whose peripheries are within 5 Å. This estimate need not present a problem as it can be reduced by several orders of magnitude by postulating orientational requirements, repulsive potentials and/or more stringent constraints on tanslational entropy. Moreover, some cell preparations do show a slow Ca^{2+}-dependent background release[2] and this may, in fact, reflect spontaneous clustering and suggest that the control of activity is not stringent for those cells. An alternative view of the regulation of activity, however, which may have broad implications, is that receptors must be in proximity for some minimum amount of time for the transmission of biological information. This residency requirement may, for example, reflect the time required for the initiation of Ca^{2+} flow[14] or for receptors to change conformation[15] or for the pair to bind an integral membrane protein[16]. Whatever the origin, the quantitative predictions of the idea, which I develop here, suggest, for biologically relevant parameter values, an exceedingly sensitive control mechanism that can amplify the probability of an event by a factor of 10^{20} or more.

An estimate of the probability that a pair, having formed, will be active t s later is easily made if the pair separation times are exponentially distributed. Thus, if t_- is the mean time for a pair to separate by diffusion to some distance Δ beyond which it cannot transmit a signal, the fraction of pairs remaining within Δ for t s after pair formation is $\exp(-t/t_-)$. The fraction that remains within Δ long enough to transmit a signal is approximately

$$\nu_0 = \exp(-t_D/t_-) \tag{1}$$

where t_D is the minimum time the perimeters must be within Δ for transduction of a signal.

When receptors are cross-linked by ligand, pair separation will depend not just on diffusion but on the time required to break the ligand–receptor bond. If k_1 and k_{-1} are the reactive forward and reverse rate constants for ligand–receptor interaction respectively, then the effective rate constant for pair dissociation is[17,18]

$$k_r = \frac{k_- k_{-1}}{k_1 + k_-} \tag{2}$$

and the effective dissociation time, t_r, is

$$t_r = 1/k_r \tag{3}$$

In equation (2), the diffusive reverse rate constant, k_-, is related to the diffusive dissociation time by

$$k_- = 1/t_- \tag{4}$$

For diffusion-limited reactions ($k_1 \gg k_-$), equation (2) becomes

$$k_r = k_-/K_0$$

where

$$K_0 \equiv k_1/k_{-1} \tag{5}$$

is the intrinisic equilibrium constant of a ligand site for a receptor site. The ligand-induced amplification (A) of the transduction probability is defined as the ratio of the probability of transduction in the presence of ligand to that in its absence. Thus

$$A = \exp\left[-\frac{t_D}{t_-}\left(\frac{1}{K_0} - 1\right)\right] \tag{6}$$

Note that equation (6) is the ratio of two probabilities, each probability being obtained by division by the actual number of pairs. Hence the actual number of pairs does not enter equation (6). Had a different definition of amplification been adopted in terms of an increase in numbers of pairs (and not just their duration), the amplification would be somewhat larger than estimated below, by perhaps two orders of magnitude. It will become evident that the distinction between the two definitions is neither qualitatively nor quantitatively important. Equation (6) was chosen because of its relative simplicity.

K_0 will be large even if binding is weak. For example, a binding free-energy change of 5.5 kcal corresponds to an intrinisic equilibrium constant of 10^4 at room temperature. A plot of ammplification as a function of the ratio t_D/t_- for $K_0 = 10^4$ rises exponentially, reaching 10^{10} at a ratio of 25 and 10^{32} at a ratio of 75 (Fig. 1). Thus the transduction probability can be changed from essentially zero in the absence of ligand (for example, $\simeq 10^{-10}$ at $t_D/t_- = 25$) to close to one in its presence. The large amplifications are consequences of very low levels of spontaneous signal transmission in the absence of ligand.

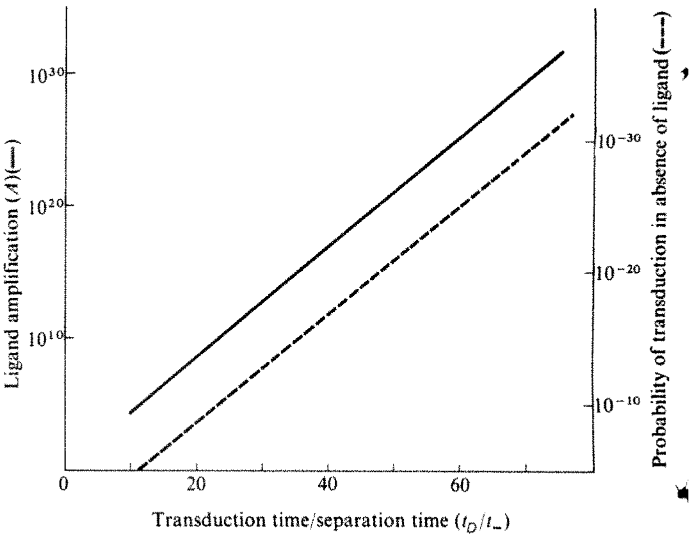

Fig. 1 Probability of transduction in the absence of ligand (– – –) and the amplification achieved (———) with a low-affinity ligand having an intrinsic equilibrium constant for the receptor of $K_0 = 10^4$.

Table 1 Mean time for a receptor pair to separate to a distance Δ

Δ(Å)	95	100	105	110	120	130
t_-(s)	1.3×10^{-6}	$5{\cdot}3\times10^{-6}$	1.2×10^{-5}	1.7×10^{-5}	4.3×10^{-5}	7.4×10^{-5}

Diffusion coefficient $= 3\times10^{-10}\,\text{cm}^2\,\text{s}^{-1}$, distance of closest approach = 90 Å.

How reasonable is the range of ratios for $t_D//t_-$ shown in Fig. 1? Transduction times are expected to be very rapid. For example, conformational changes in proteins in solution generally occur in $10^{-2}-10^{-3}$ s (ref. 19), though such changes might take somewhat longer in a membrane. Consequently, if transduction requires a conformational change, t_D would be of the order of milliseconds or longer. Similarly, experiments in which the flow of Ca^{2+} into a cell was followed indicate that uptake is 90% complete within 30 s, suggesting a time constant of seconds or less. Thus a transduction times of about 10^{-3} s would seem to be a reasonable lower bound. Amplification would then, according to Fig. 1, require diffusive dissociation times of $\leqslant 10^{-4}$ s.

The diffusive dissociation time can be estimated as follows. Consider circular receptor disks of diameter s with the plane of the disks coinciding with the plane of the membrane. The coordinate origin is fixed at the centre of one of the disks. Then, if the centre of a second disk is at $s \leqslant \rho \leqslant s+\Delta$, the mean time $W(\rho)$ required for its first arrival at $s+\Delta$ satisfies[20]

$$D\nabla^2 W(\rho) = -1 \tag{7}$$

where D is the sum of the diffusion coefficients of the disks. The solution to equation (7) subject to the boundary conditions

$$W(s+\Delta) = 0$$

$$\left(\frac{\mathrm{d}W}{\mathrm{d}\rho}\right)_{\rho=s} = 0$$

is

$$W(\rho) = \frac{(s+\Delta)^2 - s^2}{4D} + \frac{s^2}{2D}\ln\,(s/(s+\Delta)) \tag{8}$$

The mean time for a particle in the active region to escape is obtained by averaging equation (8) over all distances between s and $s+\Delta$. Thus,

$$t_- = \frac{2}{(s+\Delta)^2 - s^2}\int_s^{s+\Delta} \rho W(\rho)\,\mathrm{d}\rho \tag{9}$$

Diffusive dissociation times were calculated according to equation (9) as a function of Δ (Table 1), using a receptor diameter of 90 Å and a diffusion coefficient of $3\times10^{-10}\,\text{cm}^2\,\text{s}^{-1}$, numbers typical of the mast cell system[21,22]. The calculation is not of course intended to be precise, but is presented here only to provide perspective for evaluating the plausibility of the range of ratios in Fig. 1.

The above analysis assumes that when receptors are cross-linked, they are always within the active radius. However, this assumption is not compatible with molecular flexibility. Suppose, for example, that the doubly bound ligand were fully flexible and its maximum extension exceeded Δ. Then within the framework of the residency-time requirement, the ligand would not be sensed by the cell and the amplification would be one. The reason is that if the ligand is so flexible that it does not affect the diffusion of one receptor relative to its partner, the time to escape from the active region will not be changed; only the rate of entry into the region will change. A fully flexible molecule is, however, unrealistic.

For molecules in solution, some fluctuation in distances between groups is expected, even if the intervening chain is short. However, when both groups are constrained to lie on a cell surface as a result of bonding to receptors, the ability of the intervening backbone bonds to rotate is severely restricted—a fact easily verified by examination of molecular models. The chain is then effectively frozen in whatever configuration it was in when the second bond formed. From this point of view, the distances between reactive groups on a ligand, averaged over the collection of multiply bound ligands, will reflect the distribution of distances between groups when the ligand is free, even though the distance between groups on any particular molecule does not fluctuate. But only that fraction of multiply bound ligands having configurations constraining the peripheries of the receptors to be within Δ will be recognized. Thus the reduction in the concentration of active pairs, at a fixed ligand concentration, will be the main effect of flexibility and the amplification factor given by equation (6) remains essentially unchanged. Experiments using stiff chains or using flexible chains whose dimensions have been determined independently, for example by energy transfer, may elucidate the validity of these remarks.

Finally, note that the form of equation (6) is not necessarily limited to systems that rely on clustering. For example, if the step subsequent to binding were a conformational change, then t_- could be interpreted as the natural lifetime of the active conformation in the absence of ligand. In the presence of ligand, the lifetime would be k_r, the dissociation time of the ligand. The amplification would then be $\exp[k_r - k_-)t_D] \simeq \exp(k_r t_D)$, and the fraction of receptors remaining active for t_D, $\exp(-k_r t_D)$. As long as $k_r t_D$ is much less than one, changes in k_r will not affect the fraction of bound ligands that are active. As $k_r t_D$ becomes greater than one, however, activity should drop rapidly. Somewhat similar considerations[23] were used to explain the precipitous drop in cyclic AMP production as the affinity of hyponeurophyseal hormones for their receptors decreased, while the total bound concentration remained constant.

In conclusion, the molecular complex mediating information transfer, whether it be a receptor cluster or a particular receptor conformation, is assumed to be present at all times, but intrinsically unstable with a decay time that is short compared with the time required for information transfer. Signals in these circumstances are too low to be distinguished from background noise. Ligands, by stabilizing an active complex so that its decay time exceeds the time required for information transfer, selectively amplify particular signals. Numerical estimates indicate that such amplification can be very large.

I thank Drs Henry Metzger and Alan Perelson for reading and commenting on the manuscript.

Evidence for a divided genome in bean golden mosaic virus, a geminivirus

S. Haber, M. Ikegami, N. B. Bajet & Robert M. Goodman

Department of Plant Pathology, University of Illinois, Urbana, Illinois 61801

Geminiviruses[1,2], a recently discovered group of plant viruses, are the only viruses containing circular single-stranded DNA (ssDNA) found in eukaryotic organisms. Their ssDNA, which is less than half the size (molecular weight (M_r) 7–8 × 10^5) (refs 3–6) of that of other ssDNA viruses[7,8], is the smallest yet found in autonomously replicating viruses. Geminivirus DNA is encapsidated in paired isometric particles whose monomer units measure ~18 nm. This unique capsid morphology was accounted for by an early hypothesis of a functionally divided genome. Among the RNA plant viruses, there are several groups that carry necessary genetic information on more than one nucleic acid species. In the case of geminiviruses, two nucleic acid components were postulated to be carried in each paired particle[9,10]. Analyses of the physical composition of geminiviruses showed, however, that there is only one DNA molecule in each paired particle[6,11,12]. We have now investigated the DNA of a geminivirus using restriction endonucleases and a biological assay of infectivity and report here evidence for a divided genome in bean golden mosaic virus (BGMV). Two different nucleotide sequences are found and both seem to be required for infectivity.

BGMV was maintained by sap transmission in *Phaseolus vulgaris* L. ('Top Crop') kept in simulated humid tropical conditions in a growth chamber[11,13] and purified as described elsewhere[13,14]. Viral DNA labelled with ^{32}P *in vivo* was obtained by collecting systemically infected trifoliolate leaves from plants 5 days after inoculation of primary leaves and feeding with ^{32}P-orthophosphate (1 mCi per leaf) through the cut ends of petioles. The leaves were then maintained for 4 days in a Petri dish by feeding a balanced inorganic salt solution through the petioles.

BGMV DNA is resolved by polyacrylamide gel electrophoresis in 7 M urea into two components which comprise a covalently closed circular molecule (M_r 8 × 10^5) and a slightly shorter linear molecule[5]; previous evidence suggests that the linear molecule is derived from (or possibly is a precursor of) the circular form[11]. We separated ^{32}P-labelled circular and linear molecules by gel electrophoresis and recovered the DNA by electro-elution[15] from excised gel slices. The DNA was then digested separately with restriction endonucleases *Hha*I and *Hae*III which have sequence-specific activity on the ssDNA of bacterial viruses[16,17]. DNA from ΦX174 digested with *Hae*III was used as a standard.

Digestion of linear or circular BGMV DNA with *Hha*I yielded fragments of the same size and relative electrophoretic mobility (data not shown), confirming our previous conclusion that circular and linear forms of BGMV DNA contain the same nucleotide sequences[11]. Calculation of the length of each BGMV DNA fragment present in complete *Hha*I digests of circular BGMV DNA revealed that the total length of these fragments (5,380 nucleotides) was about twice that expected (2,510 nucleotides) from electron-microscopic measurements of the DNA (ref. 5) (Table 1).

We also used a virus-specific double-stranded (ds) DNA, which we consider to be a replication intermediate, isolated from ^{32}P-labelled, BGMV-infected leaves. This contains the complementary strand to viral DNA and both strands are of

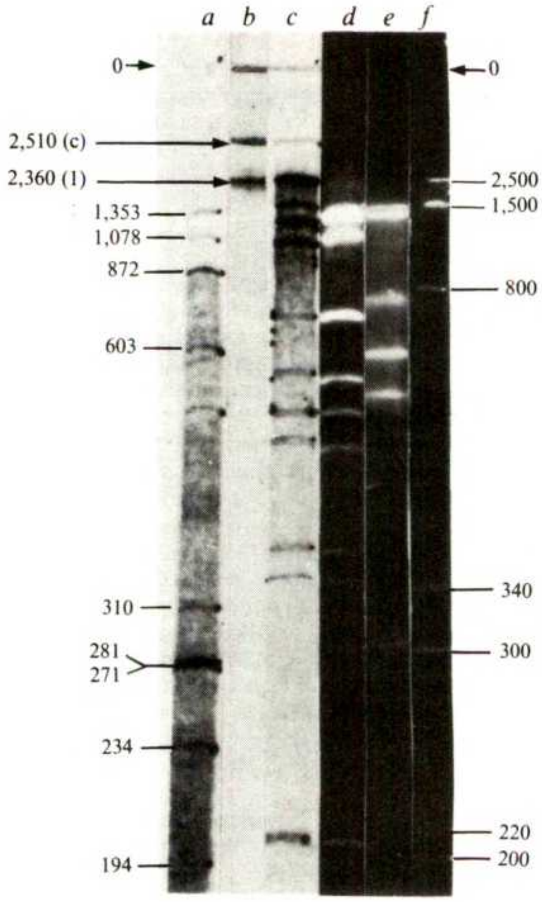

Fig. 1 Analysis of BGMV DNA by restriction endonucleases. *a*, 6 μg of ΦX174 viral ssDNA was incubated with 70 units of *Hae*III for 16 h at 37 °C in 50 mM Tris-HCl, *p*H 7.5 (120 μl), 5 mM $MgCl_2$ and 0.5 mM dithiothreitol. *b*, 4 μg of BGMV viral DNA was incubated as in *a*, but without restriction enzyme: c, circular DNA; l, linear DNA. *c*, 4 μg of BGMV viral DNA was incubated with 120 units of *Hha*I for 16 h at 37 °C in 50 mM Tris-HCl (*p*H 8.0, 500 μl) and 5 mM $MgCl_2$. *d*, 5,000 c.p.m. of ^{32}P-BGMV dsDNA, with 5 μg of ΦX174 RF DNA as carrier, was incubated with 20 units of *Hha*I as in *c*. *e*, 5,000 c.p.m. of ^{32}P-BGMV dsDNA with 5 μg of ΦX174 RF DNA as carrier was incubated with 20 units of *Hae*III as in *b*. *f*, 2,000 c.p.m. of ^{32}P-M13 RF DNA, prepared by the procedure of Messing (unpublished protocol), with 5 μg of ΦX174 RF DNA as carrier, was incubated as in *e*. After incubation, samples were phenol/chloroform extracted and the DNA ethanol-precipitated[15], then redissolved in 10 μl of sterile distilled water. Immediately before application to 4% polyacrylamide (acrylamide/bisacrylamide, 22:1) 7 M urea slab gels (0.75 mm × 13 cm × 14 cm)[15], each sample was added to 6 μl of a solution containing 50% sucrose, 30% urea, 0.2% xylene cyanol, 0.2% bromophenol blue and heated at 90 °C for 1 min. The electrophoresis buffer was 50 mM Tris-borate (*p*H 8.3), 1 mM EDTA. Electrophoresis was at 200 V until the xylene cyanol dye reached the bottom of the gel. Gels *a*, *b* and *c* were stained in the dark for 30 min with 0.005% Stains-All in 50% formamide, then destained in distilled water under light. For autoradiography, X-ray film (DuPont Cronex) was exposed to dried gels (*d*, *e* and *f*) in intensifying screen cassettes at −80 °C for ~4 d before developing. Arrows indicate the positions of restriction fragments from *Hae*III digests of ΦX174 viral DNA (left) and *Hha*I digests of M13 RF DNA (right); the numbers indicate approximate number of nucleotides (ΦX174) or nucleotide pairs (M13) of the fragments. Interpolated values for BGMV viral and dsDNA restriction fragments are given in Table 1. The top of the gel is indicated by the arrow labelled 0.

0028-0836/81/040324—03$01.00

Table 1 Restriction fragment sizes of ΦX174 ssDNA, BGMV ssDNA, BGMV dsDNA and M13 RF DNA shown in Fig. 1, in order of increasing electrophoretic mobility

DNA	Treatment	Fragment sizes (nucleotides or nucleotide pairs)	Remarks
ΦX174 ss	*Hae*III	1,353; 1,078; 872; 603; 310; 281; 271; 234; 194*	Sizes of these fragments were computed from the nucleotide sequence given in ref. 18
BGMV ss	Untreated	2,510 (circular); 2,360 (linear)	Sizes based on electron microscope measurements[5]
BGMV ss	*Hha*I	(2,510)†; (2,360); (1,650); 1,230; 1,050; (950); 660; 570; 520; 475; 365; 335; 175	Sizes based on interpolation using ΦX174 ssDNA *Hae*III fragments as standards. Sum of length of fragments in complete digests is 5,380 nucleotides
BGMV ds	*Hha*I	1,350; 1,030; 650; 520; 460; 420; 340; 320	Sizes based on M13 RF DNA *Hae*III fragments as standards. Sum of fragment lengths is 5,280 nucleotide pairs
BGMV ds	*Hae*III	1,480; 1,380; 750; 585; 510; 290	Sizes based on M13 RF DNA *Hae*III fragments as standards. Sum of fragment lengths is 4,995 nucleotide pairs
M13 ds	*Hae*III	2,500; 1,500; 800; 340; 300; 220; 200	Sizes of these fragments are from values given in a laboratory protocol (J. Messing, unpublished)

* Fragments 118 and 72 nucleotides long run off the gel in conditions used in our experiments (see Fig. 1 legend). Identity of these fragments was verified by comparison with *Hae*III restriction products of ΦX174 RF DNA. Other fragments in Fig. 1*a*, some of which occur as discrete bands, are due to the presence of ~20% by weight linear ssDNA in the ΦX174 ssDNA preparation.

† Values in parentheses are for DNA fragments produced by incomplete digestion of the substrate, as indicated by their absence in digests of BGMV dsDNA by the same enzyme, and by results of prolonged incubation of ssDNA with larger amounts of enzyme (not shown).

approximately unit length in relation to the circular viral DNA (M.I. and R.M.G., unpublished). The fragments produced by *Hha*I digestion of BGMV dsDNA corresponded exactly in number and size to those produced by complete *Hha*I digestion of circular viral ssDNA (Fig. 1).

Digestion of BGMV dsDNA with *Hae*III yielded six fragments with a total length of 4,995 nucleotide pairs (Table 1), confirming the results obtained with *Hha*I.

Attempts to analyse BGMV ssDNA by digestion with *Hae*III were not successful. *Hae*III digestion yields the same number and sizes of fragments from ΦX174 ssDNA as are found in *Hae*III digests of ΦX174 replicative form (RF) DNA[16]. The *Hae*III restriction fragments of circular BGMV viral DNA, however, were very small (20–100 nucleotides) and did not form discrete bands (data not shown). The nucleotide ratio of ^{32}P-labelled BGMV DNA is 32% A:33% T:22% G:13% C (unpublished results); thus it is unlikely that the *Hae*III recognition sequence (5′GG↓CC3′) is as numerous in such a small DNA (with G+C = 35%) as the restriction analysis suggested. Results with BGMV dsDNA confirm this. We cannot explain the apparently anomalous behaviour of *Hae*III with BGMV ssDNA.

These results indicated that BGMV may contain a divided genome with ssDNA components of the same physical size but different nucleotide sequence. The same result could be expected, however, if two related but distinct strains of the virus were present. We tested the divided genome hypothesis by investigating the dilution kinetics of infection by BGMV DNA in bean cell protoplasts. Protoplasts were prepared from leaf mesophyll cells of healthy beans (N.B.B and R.M.G., unpublished results), inoculated with different amounts of BGMV DNA, and infected cells scored after 24 h by immunofluorescence. The slope of the infectivity dilution plot (Fig. 2) was closer to two than one.

Part of the initial evidence that led to the discovery of divided genomes in other plant virus groups were infectivity dilution curves whose slopes deviated significantly from unity[19,20]. Our results now indicate that BGMV and possibly other geminiviruses may also contain a divided genome. This result extends to ssDNA viruses the interesting prevalence of divided genomes among the plant viruses and we believe it is the first example of a divided genome in a DNA virus. We conclude that the BGMV DNA genome is encapsidated in paired particles of two classes which, according to all present evidence, differ only in the sequence of the circular DNA molecule they contain. If this hypothesis is correct, the infectivity dilution kinetics of the virus particles should also approach a value of two; unfortunately, we have not found an experimentally useful local lesion host for BGMV and attempts to infect protoplasts by inoculation with whole virus have been unsuccessful.

This discovery is expected to complicate further studies on the molecular biology of BGMV. To sequence or map gene functions on BGMV DNA, we must be able to resolve two DNA

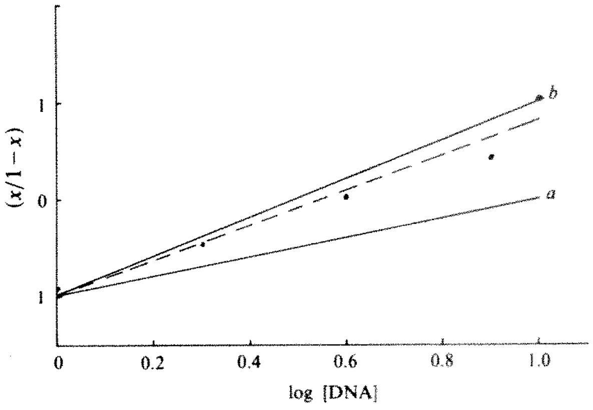

Fig. 2 Relationship between concentration of BGMV DNA in the inoculum and proportion of inoculated bean cell protoplasts infected. Plots shown are data from one (expt. 3) of five separate experiments (---) and theoretical plots (—) for *a*, one-hit and *b*, two-hit kinetics. Protoplasts were isolated from the mesophyll of Top Crop bean leaves and inoculated with various amounts of DNA (data are in μg ml^{-1}). Infected cells were scored by an indirect fluorescent-antibody method using anti-BGMV rabbit serum and fluorescein-labelled anti-rabbit γ-globulin goat serum. Data were corrected for the number of living cells determined by phenosaffranin staining[21] and then transformed to logit values[22] ($\log x/(1-x)$) where x is the proportion of living cells infected. The logit transformation was used to correct for the decreased availability of infectable cells at higher DNA concentrations. Data from five experiments were plotted and the lines drawn by linear regression analysis. The slopes, correlation coefficients (r) and the probability level (P) at which r values are significant are shown below:

Expt	1	2	3	4	5
Slope	1.99	1.71	1.71	1.78	1.78
r	0.97	0.96	0.98	0.99	0.97
P	0.01	0.05	0.01	0.01	0.01

species which are indistinguishable by size but differ in nucleotide sequence. Perhaps the best approach would be to find restriction endonucleases that will digest at one site in only one of the two sequences and then to clone that sequence out of a mixture of the two using recombinant DNA techniques.

We acknowledge the collaboration and advice of Dr K. S. Browning, and thank Drs C. L. Niblett and R. W. Blakesley for discussions and Dr P. D. Shaw for comments on an earlier draft. Research was supported by a grant (7800549) from the USDA Competitive Research Grants Office and from the Illinois Agricultural Experiment Station (project 68-366).

Bacterial plasmids serve as model systems for studying the regulation of DNA replication[1]. Elucidation of the molecular mechanisms involved in plasmid DNA synthesis requires the development of efficient cell-free plasmid replication systems. Such *in vitro* systems have previously only been described for Col E1-type plasmids[2,3] and for the R6K plasmid[4,5]. Here we report that extracts of *Escherichia coli* can carry out the complete replication of miniplasmids derived from the antibiotic-resistance plasmid R1. This R1 replication system differs from the previously described ColE1 and R6K systems in its strict dependence on DNA-directed protein synthesis. We believe this to be the first report of the functional coupling of the three fundamental reactions of genetic information transfer (transcription, translation and replication) in a cell-free system.

Table 1 Requirements of the system

Omissions	dCMP incorporated (pmol)
None	94.9
$MgCl_2$	0.8
dTTP	5.1
ATP	2.1
CTP, GTP, UTP	3.5
Creatine phosphate	1.0
Cyclic AMP	36.7
Amino acids	40.3

Extract was prepared from C600 (pKN177) and supplemented with exogenous pKN177 DNA (30 μg ml^{-1}). The complete system is the standard reaction mixture described in Fig. 1 legend with an additional 0.5 mM of each of the 20 amino acids. [α-^{32}P]dCTP (1,000 c.p.m. pmol^{-1}) was used as radioactive label. Reaction mixtures (25 μl) were incubated in duplicate at 30 °C for 60 min.

To develop an *in vitro* replication system for the R1 plasmid, we used the mini-R1 plasmids pKN177 and pKN182, which had been spontaneously generated from the R1 Cop mutant pKN104 (ref. 6). Plasmid pKN182 has a molecular weight of 3.9×10^6 and carries only the replication region of the parent plasmid, whereas pKN177, having a molecular weight of $\sim 9 \times 10^6$, also contains the ampicillin-resistance gene of R1. The Cop phenotype is caused by a single base substitution in the replication region[7], which prevents the expression of a *trans*-acting

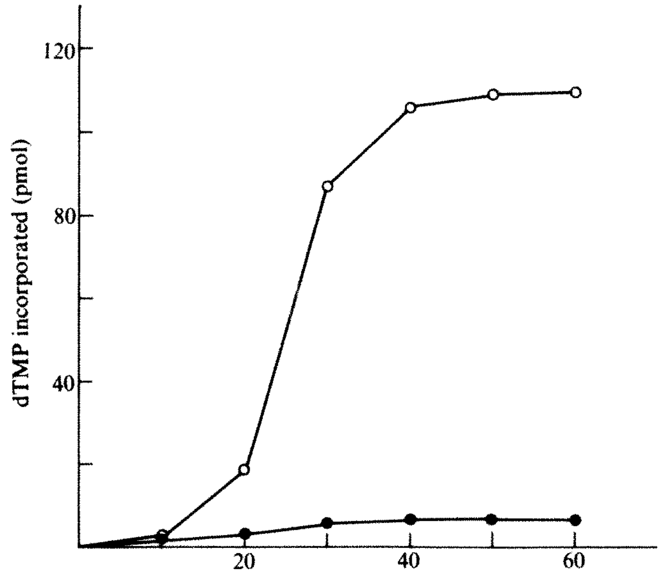

Fig. 1 Kinetics of pKN177 DNA synthesis. A cell-free extract was prepared from *E. coli* C600 (pKN177) by the freeze–thaw method[8] in the presence of 1 mM EDTA and 1 mM dithiothreitol. Standard reaction mixtures contained final concentrations of 50 mM HEPES *p*H 8.0, 100 mM KCl, 11 mM magnesium acetate, 15 mM creatine phosphate, 0.1 mg ml^{-1} creatine kinase, 2 mM ATP, 0.4 mM each of CTP, GTP and UTP, 0.05 mM NAD, 0.05 mM cyclic AMP and 0.025 mM each of dATP, dCTP, dGTP and ^{3}H-dTTP (500 c.p.m. pmol^{-1}). Reaction mixtures (500 μl) containing 250 μl extract (7.5 mg protein) were incubated at 30 °C without (●) or with (○) addition of exogenous pKN177 DNA (30 μg ml^{-1}). At the times indicated, 25-μl samples were removed and assayed for acid-insoluble radioactivity.

0028-0836/81/040326—03$01.00

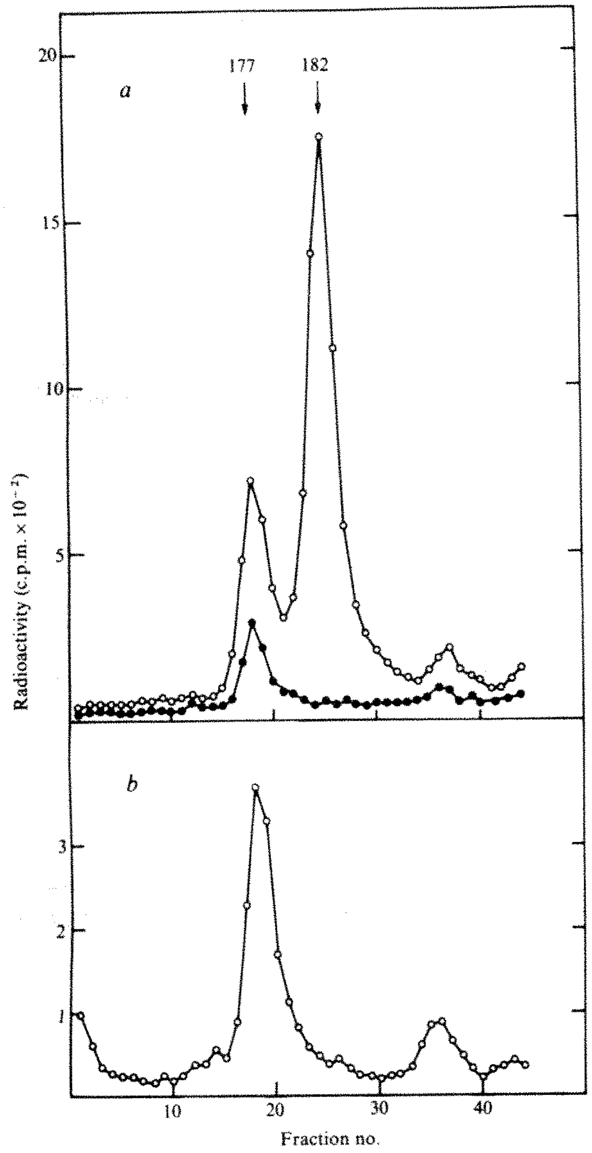

Fig. 2 Alkaline CsCl gradient centrifugation of *in vitro* synthesized DNA. Extracts were incubated for 60 min at 30 °C in standard reaction mixtures (150 µl) without or with addition of exogenous plasmid DNA (30 µg ml^{-1}). Reactions were stopped by addition of EDTA (50 mM) and the DNA was purified by gel filtration through a Sepharose 6B solumn. Aliquots were layered on preformed 4.2-ml alkaline CsCl gradients (density 1.2–1.4 g ml^{-1} in 0.2 M NaOH) and centrifuged for 35 min in a Beckman SW 50.1 rotor at 5 °C. Fractions (100 µl) were collected from the bottom of the tubes and assayed for radioactivity. Centrifugation is from right to left. The arrows indicate the positions of supercoiled pKN177 and pKN182 DNA, respectively. *a*, C600 (pKN177) extract incubated without (●) or with (○) addition of pKN182 DNA; *b*, C600 extract incubated with addition of pKN177 DNA.

negative control function[6]. Due to their reduced size and increased copy number (~25 copies per chromosome), these mini-R1 plasmids offer experimental advantages for setting up an *in vitro* system for R1 DNA replication.

Plasmid DNA synthesis was first studied in extracts from the plasmid-carrying *E. coli* strain C600 (pKN177) with the assumption that mini-R1 replication may require a plasmid-coded replication protein. We found that extracts prepared by freeze–thaw lysis of lysozyme-treated cells can catalyse a low but significant amount of dTMP incorporation into endogenous plasmid DNA. Furthermore, a marked stimulation of DNA synthesis was observed on addition of exogenous pKN177 DNA. The kinetics of dTMP incorporation with or without addition of plasmid DNA is shown in Fig. 1. It can be seen that there is a lag period of 10 min before the onset of DNA synthesis and that the incorporation levels off after 40 min of incubation. Addition of pKN177 DNA stimulates the total incorporation

Table 2 Replication capacity of extracts prepared from plasmid-carrying and plasmid-free strains

	Plasmid DNA added		
Source of extract	None	pKN177	ColE1
C600 (pKN177)	14.8	138.1	182.9
C600	0.0	9.5	163.5

Standard reaction mixtures (25 µl) included ^{3}H-dTTP (500 c.p.m. pmol^{-1}) and 0.5 mM of each of the 20 amino acids. Exogenous pKN177 DNA (30 µg ml^{-1}) or ColE1 DNA (50 µg ml^{-1}) were added as indicated. Incubations were performed in duplicate at 30 °C for 60 min. Values shown are dTMP incorporated (pmol).

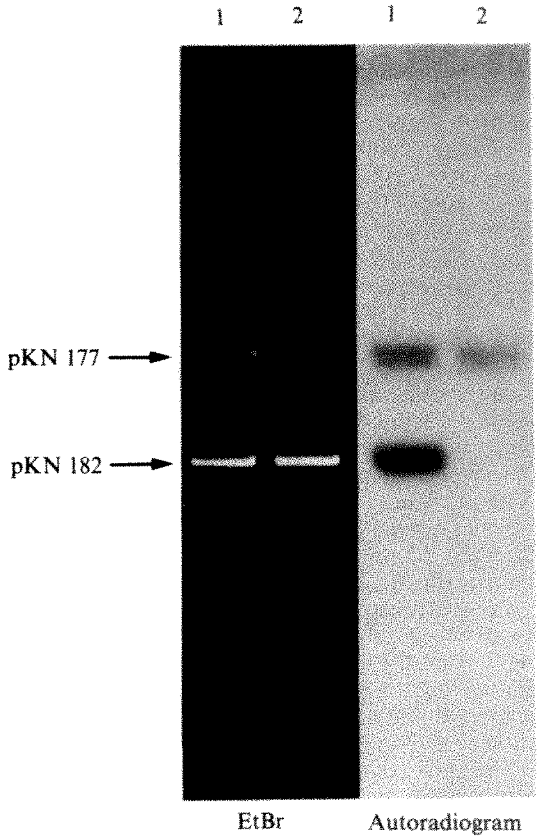

Fig. 3 Effect of rifampicin on plasmid DNA replication. Extract from C600 (pKN177) was incubated for 60 min at 30 °C in standard reaction mixtures (150 µl) containing [α-^{32}P]-dCTP (1,000 c.p.m. pmol^{-1}) plus exogenous pKN182 DNA (30 µg ml^{-1}) without or with addition of rifampicin (25 µg ml^{-1}). The reactions were stopped with EDTA and the DNA was purified as described in Fig. 2 legend. Aliquots of the untreated control (lane 1) and of the rifampicin-treated sample (lane 2) were electrophoresed in a 1.0% agarose gel for 3.5 h at 100 V. The gel was stained with ethidium bromide and autoradiographed. The arrows indicate the positions of supercoiled pKN177 and pKN182 DNA, respectively.

~15-fold. The optimal concentration of exogenous plasmid DNA is about 3 nM; higher concentrations of pKN177 DNA are inhibitory. Similar results were obtained with pKN182 DNA (data not shown).

The requirements of the system (supplemented with exogenous pKN177 DNA) are summarized in Table 1. It was found that the magnesium ion concentration is of critical importance. Optimal dTMP incorporation requires 9–11 mM MgCl$_2$, whereas almost no DNA synthesis can be detected at 5 or 15 mM MgCl$_2$. In addition, the system requires not only deoxynucleoside triphosphates but also all four ribonucleoside triphosphates and is strictly dependent on an ATP-regenerating system. A variable degree of stimulation, depending on the extract preparation, was noted on adding cyclic AMP and/or an amino acid mixture. The replicative capacity for mini-R1 DNA is lost if the extract is prepared in the absence of dithiothreitol.

Having optimized the reaction conditions, we investigated whether exogenous pKN177 DNA can also replicate in extracts from *E. coli* cells that do not carry any plasmid. It was found that extracts from plasmid-free cells can catalyse a significant amount of DNA synthesis when supplemented with pKN177 DNA (Table 2). However, the replicative capacity for pKN177 DNA of such extracts is an order of magnitude lower than that of extracts from cells carrying this plasmid. In comparison, exogenous ColE1 DNA is replicated by both types of extracts with similar efficiency.

To characterize the reaction product, the *in vitro* synthesized DNA was analysed by alkaline CsCl gradient centrifugation (Fig. 2). To distinguish between endogenous and exogenous DNA, extracts from C600 (pKN177) were supplemented with pKN182 DNA. Comparison of the two superimposed gradients shown in Fig. 2*a* indicates that the exogenously added pKN182 DNA not only functions as template for its own replication but also stimulates the synthesis of the endogenous pKN177 DNA. This stimulation is R1 specific as it was consistently observed on addition of mini-R1 plasmids but not on addition of ColE1 DNA (data not shown).

The incorporated label is found in two peaks of fast-sedimenting DNA, corresponding to closed-circular monomers of pKN177 and pKN182. Only a minor fraction of the label sediments in the position of open-circular DNA. Similarly, the reaction product of pKN177 DNA replication in extracts from plasmid-free cells consists predominantly of supercoiled monomeric plasmid DNA (Fig. 2*b*). No peak of labelled DNA fragments sediments more slowly than unit-length single strands, as would be expected for material derived from replicative intermediates[4,8]. These results indicate that the *in vitro* system carries out the complete replication of both endogenous and exogenous mini-R1 DNA without detectable accumulation of partially replicated molecules.

The effects of various antibiotics on mini-R1 replication *in vitro* are shown in Table 3. As expected for semi-conservative DNA replication, the incorporation of dTMP is entirely blocked by inhibitors of DNA gyrase (novobiocin and oxolinic acid)[9,10]. An unexpected finding is the complete inhibition of mini-R1 replication by antibiotics which interfere with different stages of protein synthesis (chloramphenicol, puromycin, streptomycin and tetracycline). Plasmid replication evidently is coupled tightly to translation, because DNA synthesis stops within 10 min of the addition of chloramphenicol (data not shown). Plasmid DNA synthesis is also strongly affected by rifampicin, a specific inhibitor of RNA polymerase. The residual rifampicin-resistant incorporation observed with extracts from plasmid-carrying (but not plasmid-free) cells is probably due to the presence of endogenous plasmid-specific RNA.

The inhibitory effect of rifampicin on plasmid replication in an extract containing endogenous pKN177 DNA and exogenous pKN182 DNA was further analysed by agarose gel electrophoresis of the reaction products (Fig. 3). Comparison of the ethidium bromide-stained gel with the autoradiogram shows that the ^{32}P-label is incorporated exclusively into supercoiled plasmid DNA. Interestingly, only the endogenous pKN177 DNA but not the exogenous pKN182 DNA can function as a template for rifampicin-resistant DNA replication.

Table 3 Effects of antibiotics on pKN177 DNA synthesis

Addition (μg ml^{-1})	Source of extract C600 (pKN177)	C600
None	101.7	13.8
Novobiocin (25)	1.6	0.2
Oxolinic acid (50)	2.4	0.3
Chloramphenicol (100)	1.1	0.3
Puromycin (100)	1.5	0.2
Streptomycin (100)	1.6	–
Tetracycline (100)	1.4	—
Rifampicin (25)	14.9	0.1

Standard reaction mixtures (25 μl) were supplemented with exogenous pKN177 DNA (30 μg ml^{-1}) and 0.5 mM of each of the 20 amino acids. ^{3}H-dTTP (500 c.p.m. pmol^{-1}) was used as radioactive label. Incubations were performed in duplicate at 30 °C for 60 min. Values shown are dTMP incorporated (pmol).

The data presented here demonstrate that mini-R1 replication *in vitro* requires both transcription and translation. A requirement for *de novo* RNA and protein synthesis has previously been observed *in vivo* for the uncontrolled replication of a runaway-replication mutant of R1 (ref. 11). It was postulated that the translation product is an R1-specific initiator protein that is not re-usable. Indirect evidence that R1 carries a gene essential for autonomous replication has been presented by Kollek *et al.*[12]. This gene is considered analogous to the *rep A* gene of the closely related R100 plasmid[13]. Evidently, mini-R1 replication *in vitro* is also strictly dependent on the plasmid DNA-directed synthesis of an essential replication protein. The R1-specific stimulation of endogenous plasmid replication by addition of exogenous mini-R1 DNA can thus be explained by assuming that the presumptive *rep A* gene product is a *trans*-acting protein. The transcription requirement would then reflect the synthesis of a messenger RNA for this protein. On the other hand, the differential effect of rifampicin on endogenous and exogenous plasmid DNA synthesis (see Fig. 3) indicates that a *cis*-acting RNA associated with the template DNA may also be involved in R1 DNA replication.

Results similar to those presented here for pKN177 and pKN182 have also been obtained for other mini-R1 plasmids (R.D., unpublished data). The plasmids tested include pKN1562 the copy control of which corresponds to the parent R1 plasmid[14]. Therefore, this *in vitro* system is not restricted to a particular type of Cop mutant and should prove useful for a detailed analysis of R1 replication control.

We thank Dr Søren Molin for supplying the plasmids pKN177 and pKN182 and for helpful suggestions, and Dr Heinz Schuster for providing support and laboratory facilities. R.D. was supported by a short-term fellowship from EMBO and a grant from the Danish MRC.

Highly conserved lipoprotein assembly in teleost and amphibian yolk-platelet crystals

R. H. Lange

Institute for Anatomy and Cytobiology, University of Giessen,
Aulweg 123, D-6300 Giessen, FRG

Ohlendorf *et al.*[1] have reported that yolk-platelet crystals in the frog, *Xenopus laevis*, were orthorhombic (space group $P2_122_1$) and consisted of elongated asymmetric units (~$5.5\times11.5\times25$ nm). The presence of an orthorhombic lattice in amphibian yolk platelets fulfilling the symmetry requirements of crystals had been missed in earlier structural interpretations[2,3]. A comparative study of teleost, urodele and anuran yolk-platelet crystals performed in our laboratory has shown the widespread occurrence among equatic vertebrates of an orthorhombic lattice with unit-cell sides similar to those of *Xenopus*. However, we report here that the space group ($P2_12_12_1$) and certain features of the macromolecular complex are at variance with those reported for *Xenopus*[1].

The material studied consisted of the amphibians *Rana temporaria* (gastrula) and *Triturus* sp.[4] (uncleaved, two-cell and blastula stages) and the teleost *Pelvicachromis pulcher*[5] (Cichlidae; immature and mature eggs). Thin-sectioned specimens were fixed (1% glutaraldehyde/1% OsO_4/0.1 M phosphate buffer) and subjected to two very different embedding procedures (epoxy-resin and glutaraldhyde–urea[6]). On applying electron diffraction and tilting, the presence of an orthorhombic lattice was confirmed in all three cases. This was achieved by establishing the presence of symmetry *mmm* for the reciprocal orthorhombic lattice in each case. Moreover, the unit-cell sides *a*, *b*, *c* were almost identical among the three species studied and—falling in the range derived by Ohlendorf *et al.*[1,7] for wet and lyophilized platelets—were also very close to those of *X. laevis* (Fig. 1 legend). This observation supports our view that we are dealing with much the same structure in teleost and amphibian yolk platelets and that our data are also relevant to the findings in *Xenopus*[1,7]. The evolutionarily conservative behaviour of the molecular assembly is underlined by the very similar appearance of 12 indexed diffraction patterns (for [100], [010], [001], see Fig. 1) as well as seven identified crystal projections (electron images) in the three species studied.

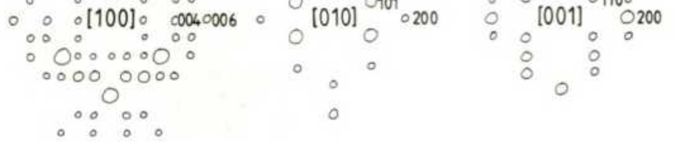

Fig. 1 Electron diffraction patterns (tracings) obtained in *Triturus* sp. when the crystals were oriented as indicated. In the other two species studied, only changes in the intensities of single reflections were noted. The means of unit-cell lengths as determined from such patterns in the three species had the following rangers (in parentheses the X-ray data from *X. laevis* for dried[7] and wet[1] preparations are given for comparison): $a=8.3\ldots9.1$ ($7.9\ldots8.9$) nm; $b=15.8\ldots17.7$ ($15.8\ldots17.2$) nm; $c=16.6\ldots19.3$ ($17.6\ldots19.6$) nm; the lower limit of our data refers to epoxy-resin embedding following dehydration in acetone, the upper limit to glutaraldehyde–urea embedding in the partly hydrated state.

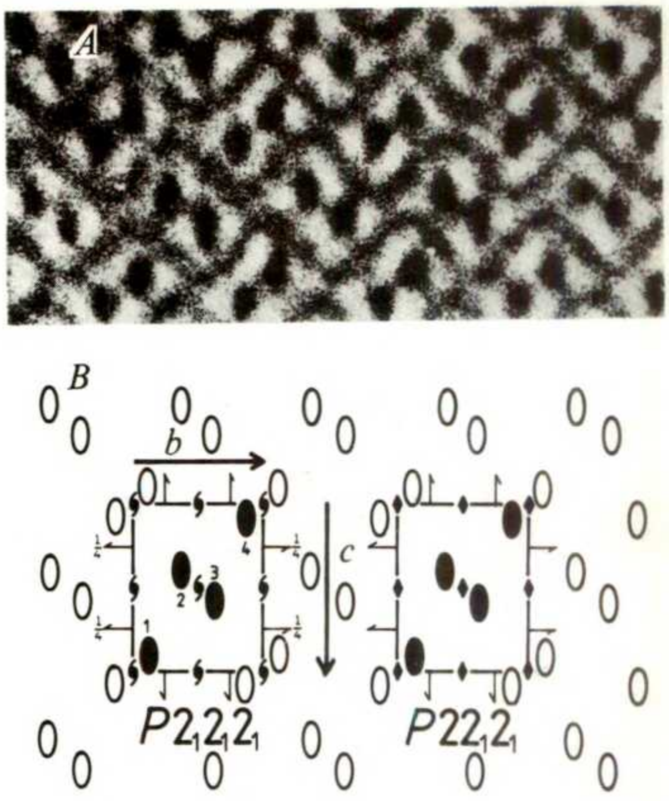

Fig. 2 Electon micrograph of a teleost yolk-platelet crystal viewed along the short axis *a* of the unit cell (*A*) and tracings of the same [100] projection (*B*) made approximately to the same scale. Orientation and size of the unit cell have been unequivocally defined by corresponding diffraction patterns; the cell may, however, be displaced. The footprint-like pattern shown can only be interpreted by assuming 2_1-screw-axes parallel to the unit-cell sides *b* and *c*. Note that these two screw-axes have unique positions in this projection, there are no alternative positions for them. If the primitive orthorhombic lattice has been correctly assigned then only two space group interpretations are possible[11] ($P2_12_12_1$ and $P22_12_1$, but not $P2_122_1$); these interpretations are illustrated in *B*. $P22_12_1$ implies a 2-fold symmetry axis (⧫) perpendicular to the plane of the paper in the middle of each pair of dark elliptic bodies and thus a location of these bodies in the same height along this axis; $P2_12_12_1$ has a 2-fold screw-axis (❟) at this site, implying that the height of neighbouring dense bodies differs by $a/2$, which is in fact shown to be the case (Fig. 3). *A* is a high-power enlargement of a raw electron micrograph originally recorded on 35-mm film at magnification ×25,000 and shows a certain degree of distortion due to sectioning. Dense particles (probably phosvitin complexes, see text) are numbered in the same way as in Fig. 3*B*. International symbols[11]; $b\sim16.5$ nm.

The absence of reflections (100, 300, 010, 030, 050, 001, 003, 005, 007) in the electron diffraction patterns suggests the presence of 2-fold screw-axes parallel to all three unit-cell sides, that is, space group $P2_12_12_1$. Conclusive proof for the space group, however, can be obtained in this case from the mass distribution in electron micrographs (Figs 2, 3). The most revealing projection with respect to molecular arrangement is the previously unstudied projection along the *a* axis ([100], Fig. 2), the second most revealing that along the *c* axis ([001], Fig. 3). It is evident from Figs 2 and 3 that there are four asymmetric

0028–0836/81/040329—02$01.00

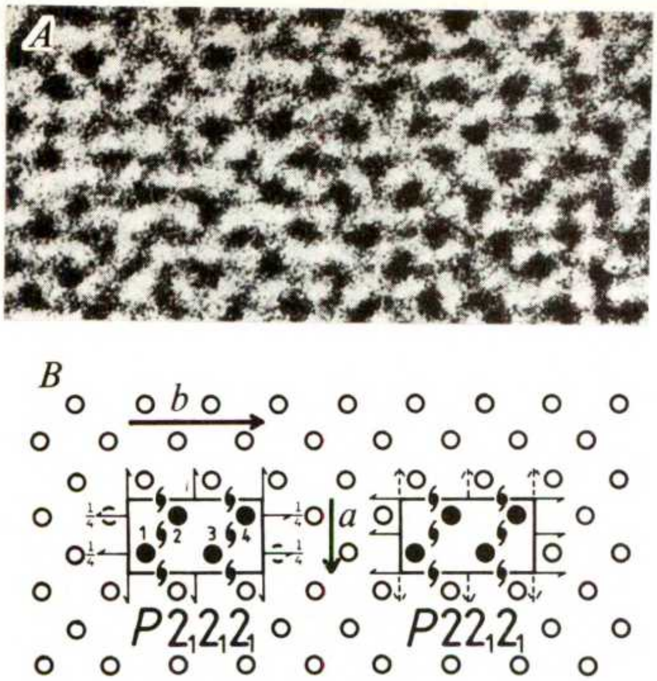

Fig. 3 Electron micrograph of a newt platelet crystal viewed along the *c* axis (*A*) and schematic tracing of the same [001] projection (*B*) made approximately to the same scale. It can be seen that only a screw diad (space group $P2_12_12_1$) and not a rotation diad (space group $P22_12_1$) parallel to unit-cell side *a* correctly describes the matter distribution. Note that positioning of these additional symmetry elements is not deliberate for geometrical reasons[11]. The rotation diad not consistent with the observed mass distribution is shown dashed on the right half of *B*. Compare *A* with the negatively stained preparation in Fig. 1 of the report by Ohlendorf *et al.*[1]. For further details see Fig. 2 legend.

units per unit cell, as in *X. laevis*[1]. There is no evidence that the complex exceeds the length of the *b* axis[1]; however, this point awaits confirmation by further analysis, as does the positioning of a local 2-fold axis[1] of the dimeric structure[8].

To explain the discrepancies between the findings in *X. laevis*[1,7] and our amphibian and teleost data, we should consider the methods used. As shown by investigations using negative staining techniques in electron microscopy of protein molecules[9], there is commonly an overlap of negative and positive staining of such preparations. Such overlap is inevitable and must be considerable when a highly anionic protein like the phosvitin moiety[8] of the yolk-platelet subunit is stained with a cationic dye containing uranyl ions[1]. The dark spots in the positively stained crystals in [100] and [001] projection (Figs 2, 3)—unrecognizable in unstained sections but quite evident in sections stained with uranyl acetate at low *p*H (3.5)—give the most probable location of the phosvitin moiety[2]; in contrast to previous views[2], however, it accommodates both phosvitin molecules of the dimeric complex[8]. This significant part of the complex may largely have escaped representation in the negatively stained preparations of *X. laevis* platelets[1]. In fact, the negatively stained preparation (Fig. 1 of ref. 1) is almost identical to the [001] projection (Fig. 3) in the three species studied here following positive staining of crystal sections with uranyl acetate and lead citrate. In a negatively stained preparation, the space occupied by stain is interpreted as being void of the macromolecule under study; this makes it very unlikely that the results of the three-dimensional reconstruction of the amphibian lipovitellin–phosvitin complex[1] is reliable.

The procedure used in the present study yields results comparable with X-ray data of protein crystals[10], except that it produces a reduction in length of some 10% (due partly to dehydration, especially for epoxy-resin embedding), various degrees of distortion (due to sectioning) and a resolution limit between 1.5 and 2 nm. All our findings were reproduced—and most of our work was indeed done—using glutaraldehyde–urea embedding in the partially hydrated state[6]. The original authors of this procedure have proved that the extremely lipid-rich myelin sheath does not lose its natural birefringence and dimensions when subjected to this embedding method[6]. This implies that the material studied in our laboratory has been preserved as adequately as possible. The sectioning process, furthermore, precludes the bias produced by splitting isolated platelets along preferential planes[1] and thus makes all crystal projections available with the same probability.

I conclude that teleost and amphibian yolk platelets are quite similar assemblies of lipoprotein complexes (orthorhombic, $P2_12_12_1$, almost identical unit-cell lengths for all species studied so far) and, therefore, contain a macromolecular constituent of highly conserved tertiary structure. Space group $P2_122_1$ and the three-dimensional shape of the asymmetric unit as described in isolated yolk platelets of *X. laevis*[1] do not agree with observations made on our comparative material.

I thank Professor S. Haussühl for crystallographic advice, Mr G. Magdowski for technical assistance and the Deutsche Forschungsgemeinschaft for support.

Corrigenda

In the letter 'West Antarctic ice sheet fluctuations in the Antarctic Peninsula area' by D. E. Sugden and C. M. Clapperton, *Nature* **286,** 378–381 (1980), the correction factor of ~750 radiocarbon years for Antarctic Peninsula shells was added to rather than subtracted from the Holocene ^{14}C dates of 6,930 ± 60 and 7,200 ± 50 yr BP for the outer and inner fractions of SRR-1500. The adjusted dates should be 6,180 and 6,450 radiocarbon years BP respectively. The discussion concerning the possibility of an ice-free George VI Sound in the Holocene thus refers to conditions 6,000–6,500 radiocarbon years ago and not ~8,000 years ago. This change does not affect the conclusions of the paper.

In the letter 'Selective killing of mycoplasmas from contaminated mammalian cells in cell cultures' by Marcus *et al.*, *Nature* **285,** 659–661 (1980), the footnote to Table 2 should refer to a 400-W lamp, not 40-W as published.

Erratum

In the letter 'Expression of H-2, lamin and SV40T and TASA on differentiation of transformed murine teratocarcinoma cells' by Knowles *et al.*, *Nature* **288,** 615–618 (1980), two lines were omitted from the bottom of the left-hand column on page 617; it should read:

...... differentiates seems to express the H–2D^b private specificity. It has been observed that somatic cell hybrids between F9 and differentiated cells can ......

BOOK REVIEWS

. . . and when the cupboard is bare?

Kenneth E. Boulding

The Lean Years: Politics in the Age of Scarcity. By R. Barnet. Pp.349. (Simon and Schuster: 1980.) $12.95. To be published in the UK, in April, by Abacus, pbk £2.50. *Energy: From Opulence to Sufficiency.* By J. H. Krenz. Pp.264. (Hemisphere/Holt, Rinehart & Winston: 1980.) $24.95, £15.50.

THESE two books have a somewhat similar theme, but are about as different in style and approach as two books could be. The Krenz volume has a somewhat narrower scope, dealing primarily with energy, whereas that by Barnet takes materials into account; the basic theme of adaptation to the exhaustion of non-renewable resources is common to them both. The book by Krenz is sober, well documented, is based solidly on the best available quantitative information, and presents a rounded picture, even though the author is not afraid to express value judgments on such matters as the future of nuclear energy. The Barnet volume is sparkling, anecdotal in style, rarely presents a complete, well-rounded picture, and is constantly engaged in implied, not too explicit value judgments.

Krenz begins with a clear general consideration of the energy crisis and energy conservation, goes on to a thoughtful discussion of environmental and resource constraints, analyses the situation in regard to fossil fuels, then has a key chapter on more effective energy utilization, which is a better way of describing "conservation". There follows a discussion of "Nuclear Energy: A Faustian Bargain?" which expresses the anxieties and ambiguities involved without dismissing them. Then there is an excellent section on alternative sources of energy, which is both sober and sobering to the over-optimistic. The book concludes with a discussion of the need for a new ethic to deal with the probability of a more austere future.

The Barnet book starts with a rather uneven discussion of the "Post-Petroleum World", and continues with a section on "Guns, Butter and Oil: Changing the Face of Power", which also deals with minerals, food and water, and relates increasing scarcity to what he calls "the new international military order", particularly in the Third World. He concludes with a section entitled "The Global Factory: The Planning of Scarcity", in which he foresees a world employment crisis resulting from the disruption of traditional agriculture and the population explosion. This last chapter ends with a rather vague plea for decentralization without any clear indication as to how to achieve it. Here, Barnet sees little reason for optimism, and what emerges is the general feeling that bad boys will continue to be bad because whoever stops them will be worse. It is, indeed, a gloomy end to liberal hopes.

In terms of suggested solutions to the problem, Krenz, as befits the somewhat narrower scope of his book, lays great stress on the value of conservation and the large technical potential which is latent in conservation practices, in just getting more in terms of human values out of the same input of energy. There are estimates which suggest that we can maintain much the same style of life that we do now with 25 per cent of our current energy input, or with a bit of luck and technical change, maybe 50 per cent. This, in a sense, is a common task which must be shared widely. Barnet, on the other hand, leans towards conspiracy theories of what is the matter with us, does not lay so much stress on conservation, and ends up arguing for a rather vague kind of decentralization as a way of saving us from the concentrated power either of large corporations or of socialist states.

The contrast between the two books illustrates at least one of the virtues of quantified data. The Krenz book, even though it is somewhat abstracted from reality, does give us an overall picture of the proportions of the problem, which the qualitative anecdotal approach of Barnet does not really permit. There is a basic difference, perhaps, between the scientific and the journalistic approach.

Both books would be improved by a little more economics. Although neither of the authors is an economist, Krenz recognizes the importance of economic considerations, though he is perhaps a little over-impressed with purely physical concepts of efficiency. From the human point of view, the only significant concepts of efficiency are those which involve human values. Thus, a process can be highly inefficient in terms of transformation into a particular form of energy, and even highly inefficient according to second law efficiency, that is, transformation of the availability of energy for work. But if the energy output is important by human standards and the input is low-valued, the process can be very efficient in human valuation terms. Thus, the rise of electric power, especially after about 1910, was inefficient by some physical standards but was extremely efficient in terms of human valuations. In commodity output at least, as measured by gross national product, per unit of energy input increased sharply in those decades, largely because of the greater convenience of subdivisibility of electricity as compared to alternative means of transporting energy. Both volumes neglect the problem of energy transport, which is most important from the point of view of human valuations. Energy when and where and in the form in which we want it almost invariably involves its transportation.

Energy: From Opulence to Sufficiency by Krenz can be strongly recommended to those who want an overall survey of the technological problems of energy in fairly non-technical language. The Barnet volume, *The Lean Years,* would appeal to those who enjoy liberal–radical rhetoric, who like to think that everything that is wrong with us is somebody else's fault or the result of a defective political structure of society, which no doubt it often is. Neither book, however, really comes to grips with the way in which decision making and the great network of social interaction actually move us towards overall betterment or worsening. But this, no doubt, is too much to ask. ☐

Kenneth E. Boulding is Distinguished Professor of Economics Emeritus and Director of the Program of Research on General Social and Economic Dynamics at the Institute of Behavioral Science, University of Colorado, Boulder.

Jerrold Krenz — sober and thoughtful

Richard Barnet — sparkling and anecdotal

Progress and prospects in tumour virology

Peter W. J. Rigby

DNA Tumor Viruses. Molecular Biology of Tumor Viruses, Part 2, 2nd Edn. Edited by J. Tooze. Pp.945. (Cold Spring Harbor Laboratory: 1980.) $65, $78 outside USA.

THE first edition of this monograph on the molecular biology of tumour viruses was both timely and influential. It was timely because its publication, in 1973, coincided with the advent of techniques for the physical mapping of viral genomes and it was influential because it acted as an invaluable source for the many molecular biologists, including myself, who began working on tumour viruses in the hope that they would, in conjunction with the new techniques, provide insights into the mechanisms of eukaryotic gene regulation. This second edition thus had much to live up to and it has, in general, succeeded most admirably.

Like its predecessor, the book is a compilation of chapters written by a variety of authors and brought together under the editorship of John Tooze. In his preface Tooze admits to some of the problems that bedevilled the preparation of the book; in particular, it proved impossible to persuade so many authors to produce their material at exactly the same time. While many of these problems have clearly been resolved, there remain cases where it is apparent that closely related chapters were written, or finally revised, at quite different times and there are thus inconsistencies of fact or interpretation. These deficiencies are, however, more than compensated by the book's strengths. It aims successfully at a wide audience, being written in a clear, didactic style quite approachable by final-year undergraduates, yet it is also sufficiently comprehensive and penetrative to be of great value to established workers in the field.

The first section comprises six chapters concerned with the smallest DNA tumour viruses, the papovaviruses and papillomaviruses. Viruses of the former class are now understood in considerable detail which is reflected in separate chapters on genomic organization, the lytic cycle, cellular transformation and genetics. Each of these contributions was written by different authors which leads to some unevenness of approach due principally, one suspects, to the writing having been done at different times. This shows particularly in the treatment of the middle T-antigen of polyoma and of the cellular 53K protein found in SV40-transformed cells. I particularly enjoyed the chapter by Nick Acheson on the lytic cycle of SV40 and polyoma. This deals in some detail with experimental problems and gives the reader an excellent feel for the certainties and uncertainties of the area. The chapters on human papovaviruses and on papillomaviruses are quite different in content, being necessarily much more biological in approach. However, the molecular biology of the human papovavirus BK is dealt with poorly; its DNA sequence, which appears in one of the appendices, is hardly discussed.

Adenoviruses are covered in three chapters, two written by Jane Flint alone, the other by her in collaboration with Tom Broker. That one author was involved in all three chapters shows clearly in a much more uniform approach and consistent treatment. The chapter on lytic infection is truly excellent, being both comprehensive and detailed yet clearly written and easy to follow. It also deals superbly with some of the less-known regions of tumour virus research, including an outstanding discussion of adenovirus assembly.

The chapter on herpes simplex viruses, by Patricia Spear and Bernard Roizman, is by far the largest in the book and is also the least satisfactory. It would have been much more appropriate for a specialized review. In many places the textual discussions would have benefited from the provision of appropriate diagrams while, conversely, it is the only chapter to use extensive figures of primary experimental data. These are discussed in a style so condensed that it will be impenetrable to all but experts. The chapter is also somewhat unbalanced. It deals too superficially with herpes genetics and is too heavily biased towards the work and opinions of the authors.

The final pages are occupied by six appendices giving the DNA sequences of SV40, polyoma and BK, and of the transforming segments of adenovirus types 5, 7 and 12. Also presented are lists of restriction sites, maps of mRNAs and putative protein sequences. This section represents an excellent innovation and will be of the greatest value. I have only one criticism of this section, albeit a severe one. The sequence of SV40 has recently been modified by the addition of an extra, small restriction fragment. While this is referred to in the introduction to the appendix, the sequence used does not include it. It would have been worth correcting this, even at the price of a slight delay in publication.

This book is as timely as its predecessor, detailing the results of one phase of the work and setting the scene for the studies that are to come. It will, therefore, be as influential. I fully share the editor's regret that the increased size of the book has necessitated a significant increase in price and sincerely hope that a paperback edition will be forthcoming so as to put the book within the reach of the many students who ought to own a copy. Economics notwithstanding, this book is mandatory reading for those wishing to obtain a general view of tumour virology, for those wishing to become involved in this most exciting area of research and for those currently involved in it. The editor and the authors are to be congratulated on undertaking so well what must have seemed to them an almost impossible task. I can only hope, on behalf of all in the field, that in five years time they will have the courage to attempt a third edition. □

Just beyond the pale

Paul Davies

Gravity, Particles, and Astrophysics. By Paul S. Wesson. Pp.188. (Reidel: 1980.) Dfl.65, $34.

COSMOLOGY and astrophysics attract an enormous number of speculative theories, not all proposed by cranks, but many of them written somewhat tongue-in-cheek. Paul Wesson is a man with an encyclopaedic knowledge of those grey areas somewhere between the canonical models of orthodoxy, and the manifestly absurd, that manage to slip into the reputable journals. His previous book, *Cosmology and Geophysics* (Adam Hilger, 1978), dealt lucidly with a variety of "variable G" theories, in which the Newtonian gravitational G is assumed to vary with time. It is a theme continued and updated in this latest work, but accompanied by a range of other, similar, conjectures: particle creation, anomalous redshifts, tired light and cosmic numerology, for example.

The author's subjects range ambitiously from the planets to the primaeval furnace. Scarcely an unorthodox idea escapes attention somewhere. The professional cosmologist will be alternately delighted and dismayed to see many half-forgotten theories receiving an airing. From the Lyttleton–Bondi cosmology to modern gauge theories of gravity, Wesson gets around to them all in some context or other.

Like it or not, many of these unusual theories have been extensively, even infuriatingly, discussed in the scientific literature for years. Some of them, such as the so-called big number coincidences or the varying *G* theories, have occupied the attentions of eminent physicists and astronomers. One should not blame the author for attempting a comprehensive presentation of such issues just because they command only minority support.

My real criticism of this book is that it reads rather like a shopping list. In his enthusiasm for including everything, the author has only managed to achieve a compendium of speculations, and not a coherent discussion. References are so liberally used that the text becomes impossible to read in some parts. On one page I counted one hundred such interjections. This is fine in a reference source for non-standard cosmology and astrophysics, but will not satisfy the demand by conservative "straight thinkers" to know something of the work of their more adventurous-minded colleagues.

Of course, a subject does not become respectable merely by quoting a vast array of big names. Even Einstein patronized some odd theories. Nor should one be persuaded that all unconventional ideas are in some mysterious way consistent with each other. This book is written in a style that leads one to believe there is a sort of grand, coherent theory of unconventional physics and cosmology existing alongside the more publicized one. It gives the impression of two sciences: the one to which most professionals subscribe, and another, almost the same in its predictions, but with subtle differences. Wesson is fair in drawing attention to some of the shortcomings of the latter, but clearly believes that his several hundred "grey area" references are probing closer to the truth than many of us would be prepared to acknowledge. □

Paul Davies is Professor of Theoretical Physics at the University of Newcastle upon Tyne.

Agricultural prognoses

Kenneth Blaxter

Britain's Future in Farming. Edited by Sir Frank Engledow and Leonard Amey. Pp.164. (Geographical Publications: Berkhamsted, Herts, UK, 1980.) £9.

THE farming industry accounts for less than 3% of the labour force in the United Kingdom and contributes about the same percentage to its gross domestic product. Yet it is the most obvious of our industries since it occupies the major part of our countryside and produces most of the food we consume. The industry has much changed with time; it is now capital intensive and heavily dependent in some of its sectors on sophisticated inputs from other parts of the economy. These changes are relatively recent and, as the authors of this book state, "a highly urbanized economy with a romantic view of the countryside has yet to come to terms with the unpicturesque aspects of an intensive and efficient agriculture". Questions necessarily arise about the future of farming, in turn inevitably implying questions about the policy to be adopted and the goals to be sought; these considerations are basic to this volume.

The book is the result of four years of study by a group of 15 people knowledgeable about farming, food provision, forestry, agricultural science, banking, and the social and political history of land use. None of the chapters is assigned to an author, but the discerning can detect where initial responsibility rested for written styles are revealing. There is thus a collective responsibility and this at times seems to have engendered some collective irresponsibility. Surely some of the statements made cannot have been agreed by all. Is it reasonable to suppose that all agreed "that the Ministry of Agriculture [MAFF] should resume its role in education and research and subsume the Agricultural Research Council [ARC]"? Or that security of tenure for farmers should be withdrawn forthwith? Such statements in the text do not appear in the conclusions with which no doubt all agreed. The first becomes transformed to a plea for better integration and a suggestion that attention should be drawn to the relationship of MAFF and ARC, while the second does not appear at all.

A few provocative statements, however, do not detract from the overall thesis and, on the contrary, perhaps enhance what is a sensible account of the problems related to the management of our resources of land. It should do much to show that the interests of agricultural and urban communities in reality have much in common and that certain broad principles related to land use may well be sufficient to provide a basis on which to develop policies to meet new eventualities. The conclusions and recommendations are admittedly detailed — there are 28 of them — but the whole tenor of the book relates to the theme that the source of renewable land must be preserved, that the pressures upon it whether direct or indirect must be reduced and farming practices themselves should be designed to provide a flexibility to accommodate inevitable and continued change. □

Sir Kenneth Blaxter is Director of the Rowett Research Institute, Aberdeen.

Practical vacua

John Yarwood

A User's Guide to Vacuum Technology. By John F. O'Hanlon. Pp.402. (Wiley-Interscience: 1980.) £13.35, $31.20.

JOHN O'Hanlon is a member of the research staff at IBM in the USA. As a result this book is really up-to-date. He has written the most useful and thoughtful account of vacuum technology which has appeared in recent years, and one which will be of value to the student, technician, engineer, scientist and technical manager. As would be expected from an author with such a background, the book (according to his preface) emphasizes "the operation and selection of equipment for processes used in semiconductor, optics, and related technologies". But he does himself an injustice — this book is much wider in scope than such a statement would appear to indicate.

SI units are used throughout, with the exception that pumping speed (now called "volume rate of flow" — not a good term although scientifically accurate) is given in l/s or m³/h, depending on the type of pump, and the diameters of the top flanges of diffusion pumps are given in inches. The section on essential gas theory covers gas properties, kinetic theory, basic relevant formulae (without proofs), gas flow and the measurement of pumping speed (where the work of the International Standards Organization has not been acknowledged; all the credit seems to go to the USA). Succeeding chapters are up-to-date, apposite accounts of real value, dealing with a wide range of equipment — gauges, pumps, analysers — and associated topics.

The book is rounded off with six appendices and, overall, can be recommended as a most useful and comprehensive volume.

John Yarwood was formerly Head of Physics at the Polytechnic of Central London, and is the editor of Vacuum.

UV photobiology

Philip C. Hanawalt

Biological Effects of Ultraviolet Radiation. By Walter Harm. Pp.216. (Cambridge University Press: 1980.) Hbk £15, $29.95; pbk £4.95, $9.95.

WE HAVE long appreciated the essential role that light plays in the maintenance of life forms on our planet through the processes of photosynthesis. In recent years, however, we have become increasingly aware of the deleterious effects of the shorter wavelengths of light in the Sun's spectrum. We have learned that ultraviolet light (UV) damages the precious DNA, resulting in mutations, the death of cells and sometimes malignant transformation. The latter effect would be intolerably frequent were it not for cellular enzymes that constantly monitor the DNA to identify and repair the lesions that UV inflicts. This is dramatically illustrated by the rare hereditary disease, xeroderma pigmentosum, in which DNA repair deficiency renders the victims exquisitely sensitive to sunlight-induced skin tumours.

Biological effects of UV was an excellent choice of topic for this first volume in a new series sponsored by the International Union of Pure and Applied Biophysics, since UV is both an important biophysical probe for DNA repair systems and an environmental hazard of some concern. The books in this series are meant to serve as specialized texts for advanced students in particular fields of biophysics. The author, Walter Harm, was one of the pioneers in the field of UV photobiology and he was therefore in a good position to provide the kind of historical perspective that could bring the subject to life and excite students. Unfortunately this monograph doesn't really gain much vitality as it plods ponderously through the details of classical bacterial UV photobiology.

Without first surveying the range of interesting biological effects, the first chapter launches into electronic excitation and the practical nuts-and-bolts details of experimental UV photobiology. Chapter 2 carries on with more practical advice for the researcher, including some useful numerical examples to illustrate important points. A carefully detailed consideration of UV interactions with biologically important molecules is followed by a not-so-useful chapter on classical target theory and survival curve shapes. (The word "multihitlike" was a new one to me.) I would have preferred more discussion of why shoulders on survival curves may be explained by existence of repair systems. The terms excision-repair and post-replication repair are introduced but not defined until three chapters later.

The subject of enzymatic photoreactivation is treated in great detail, reflecting the recent research interests of the author. In contrast, the discussion of dark repair systems is incomplete and contains a number of inaccuracies, such as a reference to sequential action of the *uvrA* and *recA* systems (p.107). The book is nearly devoid of discussion of our current understanding of the enzymology of dark repair and its genetic control. Yet this is perhaps one of the most exciting areas of research in UV photobiology.

The predominant emphasis in the text is on UV inactivation of bacteria and their phage, even in the chapter on solar UV radiation effects. Sunlight effects on human skin are relegated to less than two pages followed by a brief chapter on UV carcinogenesis and an even shorter one on sensitized UV effects on DNA.

I must say that I would find it difficult to teach a course using this book as a text but I find it quite useful as a reference work. It does provide a comprehensive treatment of the now classical studies on UV effects in prokaryotes. It might have been more aptly titled *Microbial Effects of UV Radiation*; as Dr Harm emphasizes, much of our understanding in UV photobiology and DNA repair has been based upon the solid foundation of early studies with simple prokaryotes.

Philip C. Hanawalt is Professor of Biology and Dermatology at Stanford University, and Director of the Graduate Program in Biophysics.

Social science and the stomach

John Yudkin

Consuming Passions: The Anthropology of Eating. By Peter Farb and George Armelagos. Pp.279. (Houghton Mifflin: 1980.) $12.95.

THE past 25 years have seen not only a rapid growth in research in nutrition, but the increasing recognition that nutrition is as much a social as an experimental science. Its wide span is encompassed in the short definition of nutrition as the study of the relationship between people and their food. Thus, there are now fewer academics who consider nutrition to be a section of biochemistry or of physiology, and few among the growing number of university departments of nutrition that do not include in their courses relevant aspects of social nutrition from economics, sociology, anthropology and psychology.

This book will certainly be of interest to nutritionists and dietitians, as well as to anthropologists, but its appeal is very much more general since it contains a mass of fascinating information. Its wide range is best indicated from this quotation near the end of the work: "The thesis of this book has been that to know what, where, how, when and with whom people eat is to know the character of their society". For example, you will learn from the book that "cannibal" is derived from "Carib" (as in "Caribbean") and that a "companion" is the person with whom you eat bread; that among the people of Trobriand it is unseemly for couples to eat together before marriage, just as it is (was?) for unmarried Western couples to sleep together; that cultural customs such as not eating pork or the reverence of the Hindu for cattle often have a biological or ecological basis.

The authors deal first with the evolution of human dietary patterns, how they have adapted to the availability of local foods, and the differences called for, and met, at different phases of the life of the individual. There follows a description and suggested explanation for the myths and religious concepts that influence eating behaviour, and the rules that different people have adopted towards food in their relationships with family, clan and strangers. There is considerable discussion of food preferences and avoidances, and the development of national cuisines.

It would be pleasing to be able to say that this book had achieved a synthesis between those aspects of eating that belong to the social sciences and those that belong to the natural sciences. The fact is, however, that until recently at any rate most people who have become professionally interested in nutrition have come through the separated and narrowly confined and demarcated pathways of these two groups of disciplines. It is understandable then — but a great pity — that the data on the nutrient content of foods have not been properly checked.

It is not true that one person may "burn calories ten times faster" than another "of the same age, sex and physical proportions". It is misleading, too, to worry about the fact that a portion of canned peas contains 100 times as much salt as do fresh peas, when in absolute terms this would still be about one-fiftieth of the amount taken in a day; more importantly, it ignores the fact that people add very much more salt when cooking vegetables than that present in the canned peas. The plausible suggestion that pica usually has a nutritional significance — for example, that eating clay provides minerals lacking in the diet — has been repeatedly disproven.

One last grumble is that the authors have adopted the somewhat hysterical current concern about the safety of modern food processing. For example, they say categorically that food colours are carcinogenic, a statement that, of all countries, is highly unlikely to be true in America with its rigid food laws that are especially sensitive about suspected carcinogenicity of food additives.

Nevertheless, for the general reader this is a book that is well and clearly written (except for the use of "human" as a noun!) and is full of interesting facts about what and why we eat what we do. For the specialist reader, too, there is a host of references. If, therefore, you are dubious about the theories of Claude Levi-Strauss on attitudes and behaviour towards food, you will be directed to the writings of several other authors, some of whom agree and some of whom disagree with his views. □

John Yudkin is Emeritus Professor of Nutrition at London University.

CORRESPONDENCE

Continued from page 218

provisions of the First Amendment of the Constitution by permitting the teaching of evolution. This, the suit says, disparages the religion of creationists and in itself amounts to the teaching of a religion — the religion of secular humanism.

The charges in the suit focus on the *Science Framework for California Public Schools, Kindergarten and Grades One through Twelve*, published by the California State Department of Education in 1978. Dr Richard Lemmon and I served on the committee that wrote this publication, a task that took about three years. It involved a steady battle with creationists who resisted the inclusion of statements concerning evolution. On some occasions, we obtained their consent, only to have them change their minds. For example, a statement that "Darwinian evolution is a cornerstone of modern biology" was first permitted, then deleted.

The final document says:

> Living organisms have universal properties, including derivation of energy from outside sources, and reproduction. Evolutionary studies indicate that these organisms are naturally selected from generation to generation, producing descendants with different characteristics and producing variability among populations of living species. The process has been going on so long that it has produced all the groups and kinds of plants and animals now living as well as others that have become extinct.
>
> . . . In addition to reproduction, another characteristic of life is change in its genetic material with passage of time. This process, termed evolution, takes place through changes in DNA. Changes in DNA molecules are produced by mutation, which includes replacement of some DNA bases by others, and recombination in which segments of DNA are added to or subtracted from genes. Duplication of genes sometimes also occurs. Most mutations are harmful and do not persist; they are eliminated by natural selection.
>
> Beneficial mutations occasionally take place and are responsible for the appearance of new characteristics. A third class is "neutral" or "near neutral" mutations.

The Creation Research Society (through Creation-Life Publishers) does not confine itself to matters of religion but also addresses scientific questions. A complaint by a parent in Livermore is that the publication *Dry Bones*, published by Creation-Life in 1979, is being used in lower grades of an elementary school. It contains a dialogue between children and their father, including:

> Q: "Did dinosaurs live when Noah lived, Dad?"
> A: "That's what I think. The way it looks, dinosaurs were drowned in the Flood, too."
> Q: "Did Noah have to take them on the Ark?"
> A: "He surely did". . .
> Q: "I guess[Darwin] thought fossils were proof for evolution."
> A: "No, Darwin said that fossils were 'perhaps the most obvious and serious objection' to his theory."
> A: ". . . Did your friend also tell you about scientists at Oak Ridge National Laboratories?"
> Q: "No, what about them, Dad?"
> A: "They used uranium dating on wood in rocks of the dinosaur group, and got ages of only thousands of years."

THOMAS H. JUKES

University of California, Berkeley

Genes and race

SIR — Some time ago you published a letter from me concerning the use made by the National Front of apparently "scientific" justification of racist arguments. I asked, through your columns, Professors Eysenck and Jensen publicly to dissociate themselves from the use made of their names in apparent support of these views.

I now wish to bring an analogous issue to the attention of readers of *Nature*. Ever since the publication in 1975 of E.O. Wilson's *Sociobiology: The New Synthesis*, the danger has been clear that in due course racists would deploy sociobiology in support of their views. The "New Right" in France has been doing so for some time, and now the breakaway journal from the National Front in Britain, *New Nation*, has done so too. Its first two issues, dated summer and autumn 1980, carry articles entitled: "Nationalism, racialism: products of our selfish genes" and "Science is championing our creed of Social Nationalism", authors respectively John Thornton Bannerman and Richard Verrall (the latter is also the author of a pamphlet entitled "Did Six Million Really Die?").

The first cited of these comes complete with a picture of "Richard Dawkins, author of *The Selfish Gene*", and cites him, Wilson, Maynard Smith and one Travers (presumably Trivers) amongst others. The final section of this article appears alongside an advertisement from "Nationalist Books" which includes such choice titles as ***Debunking the Genocide Myth*** and ***Anne Franck's diary — a hoax.*** Opponents of sociobiology, it is therefore scarcely surprising to note, are categorized as "Marxist" and "Jewish".

The concluding paragraph reads as follows:

> For us, as racial nationalists, this is an important vindication of our position. For it is increasingly clear that it isn't just "bad luck" that our genes don't permit us to live in a Marxist–Rousseauesque egalitarian communist utopian World State of universal altruism. It was an inevitable result of the way evolution works that our genes would not permit us so to live. What the evolutionary theoreticians have shown us is that, with the system of genetic inheritance shared by all vertebrates, the only type of social organization which can evolve, let alone work, is one based upon kinship, upon the ties of blood and of race. Nationalism is not only an integral part of our genetic inheritance, it is an inevitable end product of the evolutionary processes which shaped that inheritance.

May I suggest that it would be in the public interest that John Maynard Smith and Richard Dawkins should clearly dissociate themselves from the use of their names in support of this neo-Nazi balderdash.

Energetic consensus

SIR — It was disheartening to learn from your correspondent that the First European Bioenergetics Conference had shown a "general acceptance of the chemiosmotic concept of energy transduction" and that interest was now moving on from this assured base to the finer molecular details of the problem (*Nature* 4 December 1980, p.432). If there is such consensus on this matter there is very good reason to believe that it could be mistaken.

The chemiosmotic hypothesis is founded upon a very simple and invalidating illogicality: no evidence has ever been given that protons move into the bulk-phase during synthesis. Oxygen-pulse studies which supposedly support the hypothesis are carried out under entirely different experimental circumstances; and to have used the results of such studies to generalize upon the nature of proton movements in ATP synthesis was to introduce an inferential *non sequitur* into the energy transduction argument from the outset. The basic chemiosmotic equation:

$$\triangle p = \triangle\ \psi - Z \triangle p\mathrm{H} \qquad (1)$$

has no meaning if protons are not translocated to the bulk-phase.

We have attempted to state this view since 1974[1] and the accumulating experimental evidence we have obtained has led to the ϱ-zone interpretation of mitochondrial energy transduction in which the proton-motive force has been regarded as a localized and surface electrical force, with a minimal osmotic involvement:

$$\triangle p^{\varrho} \approx \triangle \psi^{\varrho} \qquad (2)$$

Recent experiments showing the generation of negative fixed charges on the inner membrane specifically associated with the energization process[2] have fulfilled the main prediction of the ϱ-zone interpretation and given a further compelling reason to suspect the adequacy of the chemiosmotic view; they also call into question our own formulation of the proton-motive force given in equation (2).

It now seems probable that during synthesis the proton-motive force should be regarded as a coulombic rather than a chemiosmotic force, and that its assessment should be made in terms of charge–charge relationships taking place in a surface region of variable dielectric. Some of the more recondite thermodynamic implications of such a system have already been anticipated by Ashcroft and Coster[3]; meanwhile an unsophisticated estimate of the intercharge distance, l, may be gained from the relationship:

$$W = \frac{q_1 q_2}{\varepsilon l} = 15\ \mathrm{kcal}\ (\triangle Gp)$$

and the speculative use of a now dubious chemiosmotic H^+/ATP stoichiometry of 3. Substituting the dielectric constants for the "limit" media ($\varepsilon_{aq} = 75$; $\varepsilon_{lipid} = 2$) intercharge distances of 0.9 and 33Å are obtained; the functional value may reasonably be expected to lie between these extremes and to be in accord with the requirements of the ϱ-zone interpretation.

ANNOUNCEMENTS

Awards

Drs J.-P. Mach and S. Carrel, (Lausanne Branch of the Ludwig Institute for Cancer Research) have received the 1980 Cancer Prize of the Swiss Cancer League.

The Charles Frederick Chandler Medal, presented by Columbia University for achievement in pure or applied chemistry has been awarded to **Frank H. Westheimer** (Morris Loeb Professor of Chemistry at Harvard University).

The NASA Group Achievement Award has been presented to **Dr Sam Gulkis** (JPL); **Dr David Jauncey** and **Dr Michael Batty** (CSIRO) for the development of a radio astrometric interferometer in the Southern Hemisphere.

The Council of The Institute of Physics has made the following awards for 1981; Bragg Medal and Prize to **G.E. Foxcroft** (Rugby School); Charles Chree Medal and Prize to **Dr K.A. Browning** (Meteorological Office Radar Research Laboratory, RSRE Malvern); Charles Vernon Boys Prize to **Dr P.N. Pusey** (Royal Signals and Radar Establishment, Malvern); Duddell Medal and Prize to **Dr B.A. Joyce** (Philips Research Laboratories, Redhill); Glazebrook Medal and Prize to **Dr G.H. Stafford** (Rutherford and Appleton Laboratories, Chilton); Guthrie Medal and Prize to **Dr J.C. Ward** (Physics Department, Macquarie University, Australia); Maxwell Medal and Prize to **Dr J.M. Kosterlitz** (Department of Mathematical Physics, Birmingham University); Thomas Young Medal and Prize to **N.J. Phillips** (Department of Physics, Loughborough University of Technology); Prize for the 1980 Graduateship Examination of the Institute to **James Cooke** (Dublin College of Technology).

The Council of the Royal Society invite nominations for the 1981 Royal Society Esso Energy Award which should be sent by 6 February 1981. The Award is given for outstanding contributions to the advance of science or engineering or technology leading to the more efficient mobilzation, use and conservation of energy resources, and consists of a gold medal and a prize of £1,000. Further information from: Dr R.W.J. Keay, The Royal Society, 6 Carlton House Terrace, London SW1, UK.

A fellowship in human anatomy, to be called the Wellcome-Franks Medical Fellowship, has been endowed at St Hugh's College, Oxford, by The Wellcome Foundation Limited. Enquiries to: Ron Champion, The Wellcome Foundation Ltd, 183 Euston Rd, London NW1, UK.

Environmental researchers and scientists — either from university or industry — are invited to compete for Chemviron's fifth 'Award' a $10,000 cash prize to be given in 1982. It is awarded for outstanding work in the area of physical–chemical treatment of potable and waste water, or of sludge resulting from treatment of such waters. Copies of the regulations can be obtained from Dr J. Melbourne, c/o Chemviron, Chaussee de Waterloo 1135, B-1180, Brussels, Belgium. Only entries originating in Europe will be accepted.

The Roussell Prize to be awarded in 1982, is given every two years to a chemist or a biochemist whose work on steroids in therapeutic medicine has been chosen as the most outstanding by an International Committee. Further information from: Professor J. Mathieu, Centre de Recherches, Roussel Uclaf, 102 route de Noisy, 93230 Romainville, France.

The Trustees of the Lady Tata Memorial Trust invite applications for awards for personal support for research on leukaemia, in the Academic Year beginning October, 1981. Candidates with programmes of research on any aspect of malignant disease which may throw light on problems of leukaemia will be eligible for consideration. Further information from: Secretary of the (European) Scientific Advisory Committee, Lady Tata Memorial Trust, MRC Leukaemia Unit, Royal Postgraduate Medical School, Du Cane Road, London W12, UK.

The Paul-Martini-Prize, was initiated by the Medizinisch Pharmazeutische Studiengesellschaft e.V. (Mainz) in association with the Deutsche Gesellschaft Für Medizinische Dokumentation, Informatik und Statistik e.V. to promote the development of scientific methods for evaluation in clinical pharmacological and therapeutical fields. Papers should be submitted by 28 April 1981 either in German or English with six copies to the Medizinisch Pharmazeutische Studiengesellschaft e.V. Bilhildisstr. 2, D 6500 Mainz.

The International Union Against Cancer, with funds provided by the Cancer Research Campaign (UK), will award fellowships for research on cancer to persons on the staff of universities, teaching hospitals, research laboratories or similar institutions. These enable investigators to work abroad to gain new experience in clinical or basic research laboratories or similar institutions. Application forms and additional information from: International Union Against Cancer, rue du Conseil-Général, 3, 1205 Geneva, Switzerland.

Meetings

9-10 February, **New Concepts in Drug and Nutrition Delivery Systems,** Paris (Roberts S. First, Inc. Avenue Marnix 19A, 1050 Brussels, Belgium).

9-13 February **Fundamentals of Microprocessors,** London (Bleasdale Computer Systems Ltd, Francis House, Francis St, London SW1, UK).

9-13 February, **Protein Structure and Function,** Lorne, Australia (Dr R.J. Simpson, St Vincent's School of Medical Research, Victoria Parade, Fitzroy, Victoria, Australia).

12 February, **4th Interdisciplinary Cancer Research Workshop,** New Orleans (Dr P. Politzer, Chemistry Dept, University of New Orleans, Louisianna).

15-17 February, **Proprioception, Posture and Emotion,** New South Wales (Dr D. Garlick, Committee in Postgraduate Education, PO Box 1, Kensington, New South Wales, Australia 2033).

8-15 February, **Immunoglobulin Idiotypes and their Expression,** Salt Lake City (ICN-UCLA Symposia, Molecular Biology Institute, University of California, Los Angeles, California 90024).

15-20 February, **Differentiation and Function of Hematopeitc Cell Surfaces,** Keystone (ICN-UCLA, Molecular Biology Institute, University of California, Los Angeles, California 90024).

20 February, **Ulcer Therapy,** Frankfurt (GDCh, Postfach 90440, D-6000 Frankfurt/M8, West Germany).

25-27 February, **Recombinant DNA Research,** San Francisco (Edward Ruffig, c/o Scherago Associates Inc, 1515 Broadway, New York 10036).

22 February — 1 March, **Mechanisms of Chemical Carcinogenesis,** Keystone (ICN-UCLA Symposia, Molecular Biology Institute, University of California, Los Angeles, California 90024).

1-8 March **Cellular Recognition,** Keystone (ICN-UCLA Symposia, Molecular Biology Institute, University of California, Los Angeles, California 90024).

4-7 March, **Chemical Indices and Mechanisms of Organ-directed Toxicology,** Barcelona (Secretariat, Toxicology 81, 142 Oxford Rd, Cowley, Oxford, UK).

8-21 March, **Basic Concepts and Techniques in Research on Biological Membranes,** Ibadan (Dr Enitan A. Bababunmi, Dept of Biochemistry, University of Ibadan, Nigeria).

9-11 March, **Drug Delivery System Development,** London (A.S. Goldberg, Powder Advisory Centre, PO Box 78 London NW11, UK).

10-13 March, **POWTECH '81.** Birmingham (Clive H.R. Hopkins, Green Dragon House, 64-70 High St, Croydon, Surrey, UK).

nature

29 January 1981

Madrid, Helsinki and exchanges

The reopening of the Madrid conference on the Helsinki agreements will bring very little joy to those directly concerned and little benefit to the rest of us. The proceedings so far have been one long wrangle, a measure of the extent to which East–West relations have deteriorated even since 1973, when the Final Act was signed at Helsinki. The weeks ahead are to be given over to proposals for the further elaboration of the Helsinki agreements (see page 343). For the reasons that have made the conference so far an occasion for the restatement of well-known positions, the second period is likely to see only a rehearsal of familiar opinions, known to be unacceptable to one or other of the states involved. Not much has changed since the proceedings at Madrid began. Sakharov is still in Gor'kii, for example. The replacement of President Carter by President Reagan will matter in the long run, but for the time being is likely to diminish American interest in the proceedings. The best that can be hoped for now is that the remainder of this conference will pass off without too much further damage being done.

One of the potential casualties is that provision of the Helsinki accords under which the Madrid conference itself is being held. Like many other international agreements (the Helsinki Final Act is not a treaty in the formal sense), signatories are invited to meet every so often to consider how things are working out. By comparison with Madrid, the meeting in Belgrade three years ago was more or less constructive. It accomplished little, but it did at least agree that there should be another meeting. The time is approaching in the proceedings at Madrid when people will be asking themselves whether they can properly wish on their successors in office another bout of frustration like the present. It will be unfortunate if they decide too quickly that that question should be left for decision through the normal diplomatic channels. That would assure that nothing like Madrid will happen again. That would be a misfortune.

Among international agreements, the Helsinki accords are a peculiar species. They correspond not to formal contracts among sovereign states to behave in specified ways but, rather, to the kinds of letters of intent that are signed by commercial companies which are persuaded that they have the basis for a deal but which have agreed that they may back off in certain unspecified circumstances. The Helsinki accords thus lie somewhere in between the promises to abstain from alcohol subscribed to by members of temperance movements throughout the world and the fine print on the back of air travel tickets which binds the airline which collects the money to convey the would-be traveller to his destination provided that it is able to do so. While the Helsinki agreements were being negotiated, scepticism about their potential value abounded. In many respects, they have not worked — people's freedom to move elsewhere, for example, is still constrained. On the other hand, the remarkable freedom of journalists to visit Poland in the past few turbulent months may owe something to Helsinki. And advance notification of military manoeuvres may have done something to calm anxiety in Central Europe in recent years. The vagueness of the agreements has also, as predicted, made scope for misunderstanding but also injustice — such as the repression of the Helsinki monitoring groups in the Soviet Union. But the accords exist and, like other international agreements, could be abandoned only by further souring East–West relations.

For the scientific community, what matters most is what the accords have to say about cooperation and exchanges of people. The first flurry of excitement after Helsinki has now been overtaken by events, the banishment of Sakharov to Gor'kii only one of the more obvious. To people in the West, it is intolerable but also mystifying that scientists should be treated like this. In the East, imprisonment, exile and repression are instruments of government entirely consistent with (and thus justifiable by) the old Tsarist feudal principles that a person belongs ultimately to the state. There is nothing in the Helsinki accords to ensure that the Soviet government will behave differently towards its citizens, but there are opportunities to demonstrate that, if it did, important benefits would accrue. This is why flat declarations such as that attributed to Dr Philip Handler during the first frustrating session at Madrid can serve very little purpose. What is needed, and what Western governments should be proposing in the weeks ahead, is a much more imaginative programme of scientific exchanges than those previously arranged. Case law (and common experience) suggests that busy people do not wish to visit unfamiliar places for months on end. Why not, then, shorter visits? And why should not the governments at Madrid commit themselves to the support of participation in run-of-the-mill scientific meetings that would bring in more people from Eastern Europe, not just the Soviet Union?

Naming names in British universities

The crunch is coming for British universities. Indeed, it may have come already. The British government's decision in December that a further £30 million should be taken from the budget of the University Grants Committee in the financial year beginning in April could easily precipitate the crisis that has been looming for the past decade. For although £30 million is a mere 3.5 per cent of the budget as a whole, it will be the first time in recent memory that the universities collectively have needed to operate at less than full capacity. After three decades in which student numbers have steadily increased, universities individually are unaccustomed to turning away students for whom there is space. Worse still, the university system is not equipped to decide within itself how the consequences of even a modest reduction of business should be shared. Must all universities decline by more or less the same proportion? Or is the misery to be concentrated in a few places and, if so, which?

Inevitably, confusion abounds. The Secretary of State for Education and Science, Mr Mark Carlisle, said on 6 January that he saw no reason why the latest budget cut should prevent universities from keeping up student numbers. The University Grants Committee, on the other hand, has issued a dark warning to universities that if they seek to compensate for reduced income from central funds by recruiting more students from the United Kingdom, they may in later years be penalized (*Nature* 22 January). The sources of these contradictory views are easily identified. The marginal cost of extra students is small and many even be zero in some universities and for some courses, so that outside observers may jump to the conclusion that less does not

0028-0836/81/050337-02$01.00

mean fewer. But several universities and colleges are already so hard-pressed that they are being forced to economies that harm their teaching. Laboratory classes are especially at risk. Although the present ratio of staff to students in British universities should not be taken as a magic number, Mr Carlisle's optimism is unjustifiable. And while his statement appears to imply a promise that his own department would be willing to maintain its support for students' maintenance grants at more or less the present level, the capacity of local authorities to keep on paying tuition fees must increasingly be doubted.

The response of the University Grants Committee has been characteristically more cautious. The committee seems more keenly aware of the government's capacity (or incapacity) to pay for the maintenance and tuition of students than is the Secretary of State. Its warning that individual universities should not seek to earn their way out of trouble by recruiting more home students appears to stem from a keener sense of the British government's financial difficulties than from a judicious appraisal of the needs of the university system as a whole. In its circular to universities at the end of last year, the committee said as clearly as is its habit that it will be taking steps, when it makes its financial allocations in the early summer, to control total student numbers and their distribution within universities. One consequence will no doubt be that unseemly competition for students between individual universities will be less open than it might otherwise have been. (But already many universities have partly compensated for the loss of overseas students, driven away by higher fees which were increased by a further 25 per cent last week, by taking more people from around the corner.) If the committee gets its way, there will also be no ostensible change in the present balance between the several universities in the system. No change for the time being seems to be the slogan.

There are two fallacies in this approach. First, it will not work. The competitive universities will see to that. Second, it should not be allowed to work. Further to postpone long overdue changes in the university system will merely make for greater calamity when change is eventually unavoidable. The problem is that the University Grants Committee is constitutionally unable to behave differently. Over the years, the committee has been much admired as a buffer for channelling public funds to autonomous universities in such a way that academic policy is kept out of politics. If a Member of Parliament should raise some question about the purpose of some new sociology course in some smallish university, the appropriate government spokesman will repeat the familiar declaration that academic policy is for universities, that the government habitually accepts the recommendations of the University Grants Committee on how funds should be allocated and that the inquisitive parliamentarian had better write to the vice-chancellor of the university concerned. Even though the committée is not a strictly independent public corporation — it has no bank account of its own, for example — the system worked well in the days of expansion. But the committee, which includes academics representing universities of all kinds, cannot grapple with questions of inequality — should some universities, and if so which, be treated more generously than others? Should some even be denied further support from public funds? Such questions as these are now, however, unavoidable. Who will dare to ask them?

The underlying difficulty, which should command widespread sympathy, is that there is an underlying conflict between the automony of the universities within the British system and the fact that they are supported largely by taxpayers' funds. Both horns of this dilemma are firmly part of British public policy. The independence of the universities is respected and, if threatened, would be fiercely fought for. Public funding, on the other hand, stems from the recognition that there is no other way in which a substantial proportion — for too long too low — of the British population should go on to higher education. The result, however, is that even — or especially — the smallest universities calculate that survival will in the long run be assured only if they ape the biggest and the best. Many of them are ill-placed to follow the successful civic universities, endowed with strong regional loyalties if not with cash, in the development of novel kinds of courses or even local sources of funds.

The most urgent need is that the university system should work out for itself a different pattern at which to aim. All universities are equally free, but that does not imply that they are equal or that they should be dealt with as if they are. Paradoxically, the egalitarian habits of the past few decades have, if anything, served to strengthen the dominance (outside Scotland) of the universities of Oxford and Cambridge. Some other institutions (the London School of Economics and Imperial College, both parts of the University of London, among them) have kept and even strengthened their claims on British intellectual life. Some but not all of the civic universities founded roughly a century ago have branched out in distinctive ways. Some of these occasionally give Oxbridge a run for its money, both in scholarship and the competition for students. Similarly, the group of newer universities includes some with promise, perhaps because of the strength of some department or even because their location helps in the competition for students. The plain truth, however, is that many British universities, for lack of an incentive to behave differently, are undistinguished institutions with unworkable research programmes and with curricula, modelled on Oxbridge, ill-suited to the needs of their students.

The autonomy of the universities notwithstanding, the University Grants Committee is not as powerless to influence this pattern as it seems. Even as things are, a university choosing, for example, to found a medical school would quickly be told that it would have to raise the funds itself, and might even hazard support for its other expenses if it went ahead. Less expensive developments than medical schools are prudently notified to the committee in advance. (Even in these hard times, the committee seems from last month's circular creditably to be planning to earmark some of its budget for new ventures.) There is thus a *de facto* veto on major innovation. The committee is much less able to reshape the pattern of teaching if this entails that some universities should cease doing what they have always done — the committee's attempt to rationalize the teaching of agriculture in the early 1960s, only partly successful, seems to have sapped its courage. Yet present circumstances require that several universities should be asked to stop doing several familiar things.

The simplest change to engineer would be to give up the pretence that all universities are equally able to run graduate schools. This does not, of course, imply that academics need cease to be scholars — as the example of the liberal arts colleges in the United States shows vividly. What it would imply is that small departments of this or that would no longer be given tiny quotas of research studentships by the research councils, would no longer look to the University Grants Committee for the provision of a "research base" — and would no longer face the impossible task of providing a decent graduate education to handfuls of students. The same universities might be compensated by a general understanding, by the committee and others, that they should be places where four-year courses are considered normal, not exceptional. In equity, for the sake of not denying graduates from such universities a chance to make their way in research, the present delegation of the responsibility for choosing graduate students to university departments would have to be stopped. For what it is worth, the committee and the research councils between them have all the power they need to reshape the pattern of British universities in such a way.

How is the committee to summon up the courage for such a task? And how, if at all, is it to choose between the several options in the field? Its own base in the academic world is too narrow, and there is not time for a formal semi-judicial inquiry into the working of the system which it superintends. The first need is that it should decide that a radical change of pattern is needed. Then, given the autonomy of the universities, the committee needs to organize a formal and open (*i.e.* public) consultation among them. The paradox in present circumstances is that, while many academics appreciate the need for change, none of them has an interest that his or her university should make the first sacrifical move in that direction. The committee is the only agency in sight that could free this log-jam.

Johns Hopkins wins new space institute

Princeton loses space telescope ground base

Washington

After racing neck-and-neck to the finishing line, Johns Hopkins University of Baltimore has beaten Princeton University to be the site for a new research institute responsible for the operation of the space telescope to be launched early in 1985. The Space Telescope Science Institute will be managed by the Association of Universities for Research in Astronomy (AURA), a 14-university consortium. The award of the contract to AURA was announced last week by Dr Robert Frosch shortly before he left his position as administrator of the National Aeronautics and Space Administration (NASA).

AURA already operates the group of telescopes on Kitt Peak in Arizona for the federal government. It selected Johns Hopkins as the proposed site last year — even though the university itself is not a member of the consortium and does not at present have a major astronomy department. There were four other bids to operate the institute. Three of these would have put the institute at Princeton and the fourth, from the group which operates the Fermilab near Chicago, would have placed it near the particle accelerator.

The final choice was between AURA and the Princeton proposal from Associated Universities Inc., which already operates the National Radioastronomy Center and the Brookhaven National Laboratory. Dr Frosch accepted the recommendation of an evaluation team that the contract be awarded to AURA. It is thought that a deciding factor was the scope of the management scheme proposed by AURA, based largely on its Kitt Peak experience.

The new institute will be responsible for all aspects of the operation and use of the 2.4-metre optical telescope when it is launched into orbit 350 miles above the Earth from the space shuttle. Johns Hopkins University will provide a site and a new building on the edge of its Homewood campus, at a cost of about $6 million. The AURA plan envisages an eventual staff of 150 people, including 40 full-time astronomers selected from around the world.

In addition, the institute is expected to take in up to 200 visiting scientists each year. They will be able to use the telescope 24 hours a day because, unlike surface-based optical telescopes, the sky will be permanently dark. Annual running costs are expected to be about $10 million. Competition for the management contract has been fierce after bidding was officially opened by NASA at the beginning of last year. There seems, however, to have been little of the political squabbling that has surrounded decisions about major scientific facilities in the past, in particular the controversies over the siting of new particle accelerators.

AURA has made much of the local facilities offered by Baltimore, which has recently been going through something of an urban renaissance. It also stressed the proximity of the city to the Goddard Space Flight Center, from which the manoeuvring of the telescope will be controlled and at which a small team from the institute will be based.

In the end, however, location is thought to have played a relatively minor part in the decision. Princeton is not much further from Goddard, and both cities have access to major international airports — one of the preconditions stipulated by NASA.

More important seems to have been a quantitative assessment made by the evaluation team of the facilities and management support being offered in each case. Johns Hopkins was not able to match the strong astronomy department offered by Princeton. Several of its physicists, however, including some members of the Applied Physics Laboratory (APL), have been closely involved in the design of the space telescope and its instrumentation.

Following NASA's decision, AURA announced that the acting director of the institute will be Professor Arthur Code, at present professor of astronomy at the University of Wisconsin in Madison. The acting deputy director will be Dr Robert Rich of APL. Dr Arthur Davidson, professor of physics at Johns Hopkins, will be acting chief of the research support branch, and Dr William Fastie will be responsible for scientific instruments.

One factor which had concerned the AURA team while the proposals were being evaluated was the threat of federal action against Computer Sciences Corporation (CSC). The consortium had chosen the company to provide computer services, but CSC is under indictment for overcharging the federal government on time-sharing facilities.

Shortly before the management contract was awarded, however, NASA — having checked with the General Services Agency, on whose behalf the indictment has been filed — announced that although CSC has been suspended from bidding for future time-sharing contracts, it was still free to bid for technical support contracts, since these services were provided by another part of the company.

Johns Hopkins officials have welcomed the news about the institute. University president Steven Muller suggested that, given the dominant role that the space telescope is likely to play in optical observation until the end of the century, "there is true excitement at the prospect that Baltimore will now become the world capital of astronomy".

At Princeton, there was comparable disappointment. "To have hosted the institute would have been the next important step for the Princeton scientific community", one faculty member said last week. "Now we must go back and do some reassessing."

David Dickson

Dutch partners for La Palma observatory

The British Science Research Council may have found another collaborator for its optical astronomy observatory at La Palma in the Canary Islands. The Netherlands will probably join Spain, Sweden and Denmark in the collaboration to build and run the site. Last week, the council of the Netherlands Organization for the Advancement of Pure Research (ZWO) approved the deal "subject to contract", as the lawyers say. Professor Graham Smith, director of the Royal Greenwich Observatory which is coordinating the project, welcomes Dutch accession and thinks that the Netherlands may help especially with the supply of skilled manpower for management of the project.

The La Palma observatory, originally called the Northern Hemisphere Observatory, will eventually include our major British telescopes — a 1-m diameter Schmidt telescope, the 2.5-m Isaac Newton telescope (which is being transferred from Britain), a new 4.2-m telescope and a new 15-m radio telescope. Four smaller instruments are being provided by Sweden and Denmark. Preparations for the observatory started in earnest eighteen months ago, after the protracted negotiations with Spain had been completed. Construction is well ahead, according to Professor Smith. The 1-m and the Isaac Newton telescopes are almost ready for removal to the Canary Islands and the observatory is on the verge of placing a contract for the mirrors for the 4.2-m telescope. A call has gone out to astronomers in several countries for the design of ancillary instruments for the 4.2-m telescope.

Successful bidders will be rewarded in part with observing time. The remaining contracts for the 4.2-m telescope are likely to be placed later this year, and the telescope could be working by the spring of 1985, but that date could slip by a year if the cash flow of the Science Research Council does not improve.

Much of the negotiation between the Netherlands and Britain has already been completed. In return for 20 per cent of the cost, ZWO will be allowed to allocate 20 per cent of the observing time to Dutch astronomers. It has not yet been decided precisely how the Netherlands will help to solve the manpower shortage. When the observatory is fully operational, Professor Smith estimates that about 30 technical staff will be needed in La Palma at any one time. The difficulty is in persuading sufficient British scientists to uproot themselves for three years at a time.

ZWO has decided to pay its share out of its existing budget of about £40 million a year. Most of the money will come from the £6 million a year now spent on astronomy, implying a major shift in astronomy funding. Although most Dutch astronomers are expected to welcome the agreement, radioastronomers may feel hard done by.

The next step is for Professor van Lieshout, director of ZWO, to obtain the approval of the Dutch minister for science, who is reported to be enthusiastic. But the imminent Dutch election could mean that the issue will have to be decided by a new minister. All being well, however, Professor van Lieshout hopes that an agreement could be signed and sealed within the next four months.

Toxic waste

Dutch dumps

Amsterdam

The cost to the Netherlands of dealing with chemical waste from years of heavy industrialization is mounting. So far about 3,000 dumps containing chemical waste have been found, 500 of them a recognized danger to public health. The Minister for Public Health and Environmental Protection estimated a few months ago that it would cost about £200 million to clear the 500 dangerous dumps, and this estimate is now £400 million.

In the village of Lekkerkerk, not far from the heavily concentrated chemical industries of Rotterdam, many buildings were found to have been built on a chemical waste dump. About 1,700 drums were recovered from the site, containing materials such as toluene and xylene from the dye industry and metals such as cadmium, zinc and lead. Some 300 houses were evacuated and 150,000 tons of polluted soil have had to be removed, while medical examinations may yet be carried out on the population. Several more chemical waste dumps have since been found in the same area.

After cases of cattle infertility and the discovery of dead birds, an investigation by the municipal environmental laboratory of Amsterdam has revealed that the Volgermeerpolder, a marshy area 5 miles from the centre of Amsterdam, contains about 10,000 drums of chemical waste from a 2,4,5-T factory previously owned by Philips-Duphar. The factory ceased production in 1969 and was completely dismantled and dumped in the Atlantic, but its waste remained.

According to Dr H. Heida, director of the Amsterdam environmental laboratory, the drums contain a wide range of chemicals, including chlorobenzene and chlorophenol. However, some of the drums are known to contain 2,4,5-T and possibly the dioxin 2,3,7,8-tetrachloro-cyclodibenzo-*p*-dioxin (2,3,7,8-TCDD), and it is this latter compound which it is feared may form the real danger.

Analysis of soil, water and livestock and of produce from gardens in the area has revealed the presence of chemicals from the dump in concentrations of tenths to hundredths of milligrammes per kilogramme weight.

However, the future of the dump rests on the problem of clearly identifying 2,3,7,8-TCDD. Samples from the drums have been analysed by Professor O. Hutzinger's team at Amsterdam University and have also been sent to Milan for analysis by the laboratory involved in investigating the Séveso incident. A definite solution to the problem is not expected before the summer.

The clearing of Lekkerkerk

These pollution scandals prompted a national inventory of chemical waste in the Netherlands due to be completed by the end of 1980. So far, however, only two of the eleven Dutch provinces have reported their findings.

The problems of the Netherlands have also attracted international interest. Dr David Costle, administrator of the US Environmental Protection Agency, visited the Lekkerkerk dump while he was in the Netherlands to sign a memorandum on cooperation between the two countries. Dr Tolba of the United Nations Environmental Programme, a regular visitor to the country, is particularly interested in the chemical pollution problems.

The latest revelation was in December of last year, when small amounts of the toxic substance methyl bromide were found in drinking water in the horticultural area between The Hague and Rotterdam. This chemical is used by market gardeners to disinfect the soil, and an estimated 2,000 tons a year are used in this area — 30 per cent of the total consumption in the European Community. The poison had apparently seeped through the PVC tubes used for private water distribution. As a result, the Minister for Public Health has made public water supply companies responsible also for private supply pipes. However, it now turns out that PVC tubes are widely used in the Netherlands for transporting water which has been tested for pollutants such as methyl bromide.

Casper Schuuring

Genetic engineering

Planning bugs

Washington

Echoes of the fierce public debates of four years ago are being heard once again in and around Cambridge, Massachusetts, as local city councils discuss the conditions they will place on the genetic engineering companies springing up in their midst.

The tones of the debate are more muted than before. And in each of the four communities — Cambridge, Waltham, Somerville and Newton — the talk this time is of negotiation rather than confrontation. Nevertheless, there is sufficient concern among the companies for the head of at least one to suggest the need for a "more coherent policy" towards local regulation, possible at the state level.

The most significantly affected so far seems to have been Genetics Institute. This is the company which has been set up by Dr Mark Ptashne, professor of molecular biology at Harvard University, and a local management consultant, Mr Tom Hexner, on privately-raised venture capital, after the Harvard faculty voted against university participation (see *Nature* 27 November 1980). Its backers include Venrock, a venture capital firm owned by the Rockefeller family, and Mr William Paley of Columbia Broadcasting.

Now the company faces a new hurdle — gaining acceptance in the local community. Last November, it applied to build a laboratory in Somerville, just inside the city's border with Cambridge and a few blocks from the university biology laboratories. The application has kindled a fierce public debate. At one point, for example, local citizens had suggested that research should be limited to P1 and P2 physical containment facilities, even stricter than restrictions in Cambridge, which allow work up to the P3 level.

City council members who were originally in favour of granting permission for the new laboratories with few strings attached have backed off in the face of the public controversy; many are preoccupied with severe budget cuts that have resulted from a recent reduction in property taxes.

At a public meeting last Thursday, the

0028-0836/81/050340-02$01.00

council agreed to draw up a local ordinance setting out the conditions under which recombinant DNA research can be carried out in the city. Given the uncertainty, Genetics Institute has now withdrawn its application to build the laboratory.

Mr Hexner said last week that there would now inevitably be a delay in the company's plans. "It really depends on how long the deliberations go on and what the tenor of them is; if the tenor is favourable, then we would probably resubmit", he said. An alternative would be to look for a site in Cambridge itself. In sharp contrast with the debates of four years ago, when the then mayor Alfred Velucchi tried to ban all genetic engineering from the city, an ordinance passed in 1977 is being revised in relatively amicable circumstances.

The revisions have been precipitated by the decision of the Geneva-based Biogen Inc. to construct a new laboratory in Cambridge. Biogen's co-founder, Dr Walter Gilbert, is also a professor of molecular biology at Harvard and was a strong critic of the university's proposed involvement in Genetics Institute.

Biogen is now discussing with the local council the terms under which it will be allowed to operate its laboratory. And the Cambridge Biohazards Committee and the Cambridge Experimental Review Board are discussing a revision to the 1977 ordinance which would require, among other things, that any company or laboratory involved in recombinant DNA research should implement a medical surveillance scheme and a registry of its workers.

Such provisions have already been proposed by the Department of Labor's National Institute of Occupational Safety and Health, on the grounds that any long-term, relatively low-level effects could be traced only if adequate exposure records are kept of laboratory workers and the substances they handle. Biogen has said that it would have little difficulty in meeting such a requirement. More controversial could be the suggestion of a public debate on the acceptability of the site proposed for the laboratory.

Some members of the review board are also hoping to persuade the council to demand independent approval of the safety measures adopted by the company. This might be done by employing a consultant who would report to the city council but whose services would be partly paid for by the company.

A local ordinance including several of the proposed requirements has already been passed by the city council of Waltham, Massachusetts, home of the company Collaborative Genetics. As in Cambridge, the ordinance — which also covers research at Brandeis University — is primarily designed to ensure that all local recombinant DNA research is carried out under the safety guidelines developed by the National Institutes of Health.

In some respects, however, the ordinance is stricter than the guidelines. For example, it requires a formal medical surveillance procedure and the maintenance of work records and also prohibits the use of recombinant DNA products for trials on human patients.

With this model before them, other cities — including Newton, home of New England Nuclear — which are considering their own ordinances may find it difficult to adopt stricter rules. Mr Hexler, for example, says that Genetics Institute would be pleased to live with the Waltham ordinance and that if Somerville is too restrictive, "Waltham is there and waiting".

Lamont director quits

Washington

Columbia University in New York has forced the resignation of the director of the university's Lamont-Doherty Geological Observatory, Dr Mark Talwani, after complaints from senior faculty members about a lack of effective leadership.

Dr Talwani was asked by the university to resign shortly before Christmas. The university's decision was based partly on a report on the situation at the observatory, one of the world's leading centres of oceanic and seismic research, prepared by an outside committee under the chairmanship of Dr Karl K. Turekian of Yale University.

According to the university, the report praised a number of accomplishments of the observatory, but notes the existence of "serious problems" with Dr Talwani's leadership.

The committee itself did not recommend that Dr Talwani be replaced. But after further review and consultation with senior faculty members, including a meeting in October at which "almost all the senior faculty" is said by the university to have supported the search for an alternative director, Dr Talwani was asked to resign within two weeks.

Talwani himself vigorously protested at the university's decision, claiming that it had been the product of a "conspiratorial approach", and complaining to the university trustees that because no specific charges had been levelled against him, "I have had no opportunity to defend myself".

He eventually submitted his resignation as director two weeks ago, although he will remain on the university faculty as a member of its department of geological sciences. A search committee has been established to recommend a successor, and is expected to make its recommendation within a few days. Meanwhile Dr Paul G. Richards, associate director of the observatory, has been temporarily appointed its chief executive officer. **David Dickson**

Soviet fishing

Whither whaling?

The Soviet Far Eastern Fishing Fleet has ceased whaling operations in the Pacific, it was announced in Vladivostok last week. The three factory ships serving the fleet are now being converted into fish-processing plants.

This is the first stage in the implementation of a pledge given at the International Whaling Commission (IWC) meeting in California in December 1978. On that occasion, the Soviet delegate, Vyacheslav Zemskii, pledged his country to phase out all whaling within five years, starting with the North Pacific operation.

The announcement that three factory ships are being converted is, however, somewhat surprising. According to a Moscow radio broadcast shortly before the July 1980 IWC meeting, the Soviet Union had only two factory ships left, the Sovetskaya Rossiya and the Sovetskaya Ukrayina, both sailing from Vladivostok. Both of these ships, the commentator stressed, carried the necessary international observers as well as Soviet marine ecologists.

A partial phasing out of the North Pacific operation began some years ago. In 1979, when the Soviet Union accepted the IWC's partial moratorium, in which fishing from factory ships would be confined to Minke whales, it had already closed down its on-shore whaling stations, and had to negotiate an exchange with the Japanese, ceding its North Pacific quota of 230 Bryde whales in return for 300 of the less valuable Minke whales from the Antarctic.

The closedown of the North Pacific operation does not, however, necessarily mean that the Soviet Union will support the idea of a total moratorium. Soviet commentators have always taken the line that such a policy is not in accordance with the ecological facts, being based on a emotionalism encouraged by some quarters for political reasons. Greenpeace observers have described the Soviet whaling flotillas as near derelict hulks which would cost many millions of rubles to refit. This suggests that the planners have realized for some time that pro-moratorium pressure might well force the Soviet whaling flotillas to disband, and that it was not therefore cost effective to keep the ships in trim.

With the recent drive for self-sufficiency in raw materials, stressed at the October 1980 Central Committee Plenum and in the Guidelines for the new Five Year Plan, what will the Soviet Union use to replace whale-oil?. One possibility is the jojoba, which would probably thrive in the semi-arid steppes of Soviet Asia. Unfortunately, the jojoba plant is dioecious, and, in the natural state, male plants predominate. Jojoba culture is therefore highly labour-intensive, involving the vegetative propagation of large numbers of female

0028-0836/81/050341-02$01.00

plants which then have to be bedded out with a sufficient number of males (the plant is wind pollinated.) With the problem of falling manpower, and the desire to make all agriculture more productive per man-hour, widescale introduction of the jojoba could pose considerable problems of organization.

Vera Rich

Pneumoconiosis unit

Dusty answers

Members of the staff at the British Medical Research Council's Pneumoconiosis Unit in Cardiff are alarmed about the unit's future. So too are the National Union of Mineworkers, the Agricultural Workers' Union and the Association of Scientific, Technical and Managerial Staffs, who say that they value highly the unit's work on industrial diseases. Their fears have been roused by a routine review of the unit's work, conducted by a subcommittee of the council's Physiological Systems and Disorders Board, which has apparently suggested changes at the unit. Last week, council employees and union representatives lobbied a meeting of the council at which the recommendations were to be discussed.

According to the lobbyists, the review has recommended that the unit should continue with most of its present work until a further review in 1987, but that its value should be measured increasingly by the number of contracts for research that it manages to win from industry. They also say that the review has recommended that targets be set for reductions in staff levels, that some work on allergic responses and lung function be relocated and that the unit should not receive a new high-voltage electron microscope, a replacement radiographer nor a replacement respiratory physiologist.

The subcommittee's review is a routine 3-year assessment, to which the work of all council units is subjected. Such reviews frequently lead to decisions to close some units and open others. What seems to have worried the Cardiff staff is that running down some of the work now may pave the way for closing the unit after 1987, when the present director and several other senior staff are due to retire.

Representatives of those lobbying the council's headquarters last week presented their case to the industrial liaison officer who distributed their statements among council members. Their arguments are that relocating some of the unit's work will undermine the multidisciplinary approach needed for many problems and that, by whittling away at the unit's structure now, the council may cause it to become unworkable before formal consultations on steps towards closure can be taken.

The Medical Research Council refused last week to discuss the report of the review committee or the future of the unit. It has still to inform the unit of the decision of the council meeting.

Judy Redfearn

Bulgar birthday

Two for one

"Bulgaria-1300", the unmanned space probe planned as a highlight of the country's 1300th anniversary of statehood, will now consist of two satellites. The first, Bulgaria-1300/1, will be equipped entirely with Bulgarian apparatus, and will carry out ionosphere and magnetosphere investigations. The second, Bulgaria-1300/2, will carry both Bulgarian and Soviet apparatus including several remote sensing experiments, using infrared and VHF wavelengths, and also a special Bulgarian-made multichannel camera. The experiments on Bulgaria-1300/2 will be combined with observations from a high-altitude aircraft and collated with terrestrial measurements.

No details of the experiments have yet been announced. However, according to Dr Kiril Serafimov, chairman of the Bulgarian National Committee for Space Research and Utilization, Bulgaria's "historical circumstances" are such that Bulgarian teams can take part in all five areas of space physics covered by the Comecon joint "Interkosmos" programme — space physics, meteorology, communications, biology and medicine, and remote sensing. New Bulgarian ideas, developed within Interkosmos, stated Dr Serafimov, have included Langmuir probes, ion traps and electrophotometric telescopes. During the past few years, his teams have paid particular attention to noctiluscent clouds and have reported "very interesting data" concerning discharges of auroral type over the magnetic equator. A particular Bulgarian success has been the Spektr-15 multichannel camera, whose 15 channels compare favourably with Landsat's four channels and the East German MKF-6, which has six. (In addition Spektr-15 weighs only 15.2 kg as against the MKF-6 which weighs 158 kg.) The Spektr-15 will be a major feature of Bulgaria-1300/2.

So far, however, there have been no indications of any medical or biological experiments. This seems unfortunate, as the Bulgarian space medicine experiments scheduled for the visit of their Cosmonaut Georgi Ivanov to the Salyut-6 space station were abandoned when his Soyuz transport craft failed to link up with the station. (The other "Bulgarian" parts of the programme, such as the casting of aluminium "foam" using hydrogen as dispersant, were carriked out by cosmonauts Lyaknov and Ryumin, who were already on board Salyut.) Nor are there are any hints that Soviet birthday presents to Bulgaria will respond to the broad hints that the Bulgarian space planners have been dropping ever since Ivanov's mission was aborted — another, and this time more successful, flight of a Bulgarian cosmonaut. Other states have done better, but are not as old.

Vera Rich

Reef aggregation

A new society and a new journal concerned with research on coral reefs have sprung from the frustrations of a group of interested scientists at the difficulties of funding this interdisciplinary work. The new society, called the International Society of Reef Studies, was formed after a meeting held at Churchill College, Cambridge last month.

The first president of the society is Dr D.R. Stoddart from the Department of Geography at the University of Cambridge, who was the leader of the Royal Society's expedition to the Indian Ocean island of Aldabra in the 1960s. The council of the society includes members from mainland Europe, North America, Australasia and the Far East.

One of the objectives of the society — to provide a forum of coral reef research — has been met by the proposed publication by Springer-Verlag of a quarterly journal, *Coral Reefs*, due to appear next year. The new journal will be more concerned with the structure and dynamics of coral reefs than with the flora and fauna, and will thus be complementary to the *Atoll Research Bulletin*, published by the Smithsonian Institution.

The society also plans to take over the management of the international symposia on the subject, of which the fourth is due to be held in Manila in May. Its formation illustrates the difficulties of recruiting funds for the support of research in fields that do not fall squarely within the terms of reference of established grant-making agencies, which have been acutely felt in Britain in recent years. Feeling has run high that governments are interested in coral reefs only in crises.

Brazilian ecology

Polluting by decree

São Paulo

Economic pressures have caused the Brazilian government to postpone legislation banning the use of non-biodegradable detergents which was due to come into force in January 1981.

A decree signed by President Figueiredo last month puts back the starting date for the new law by two years. Industrial pollution is now a serious problem in Brazil. In the state of São Paulo all the rivers are biologically dead and the appearance of foam on rivers is now considered normal, according to the head of the Environmental Technology Agency. Several waste-treatment plants due to open in 1981 in São Paulo will have to be abandoned if the foaming persists.

Although the intended ban on non-biodegradable detergents was drafted four years ago, nothing was done to make it

0028-0836/81/050342-02$01.00

possible to comply with the deadline. Manufacture of the non-biodegradable component of detergents, alquilbenzene sulphonate (ABS), is a monopoly of the Atlantic Richfield subsidiary Empresa Carioca de Detergentes (EMCA). Its production at 45,000 tons a year covers all Brazil's needs. SPUMA, the only company importing biodegradable linear alquilbenzene (LAB) was forced to close down more than a year ago because of prohibitive transport costs from its factory in Manaus in the Amazon region to the main consumption centres of São Paulo and Rio 4,000 miles away. The government chose not to help SPUMA by reducing import taxes and the company's machinery was bought up by a multinational company and left idle.

The Association of Cleaning Products Industries has been accused of lobbying against the entry of biodegradable detergents on to the Brazilian market. The association pleaded for a four-year delay in passing the new law on the grounds that the cost of importing the annual requirement of 35,000 tons of LAB would amount to $35 million in hard currency, increasing the $3,000 million deficit in the Brazilian balance of payments.

What this ignores, however, is the fact that the Brazilian owned company DETEN in now building a plant for the manufacture of LAB in the huge petrochemical complex under construction in Salvador, Bahia. Production is to start in April, reaching 25,000 tons by the end of 1981 and satisfying the expected Brazilian requirement of 70,000 tons per year by 1983. By then the multinational-linked EMCA will also be producing LAB in Brazil at the rate of 25,000 tons per year.

The economic argument for keeping the Brazilian market open to non-biodegradable detergents is further undermined by the statement from the Health Commission of the Brazilian Congress that EMCA had received a firm offer from CONOCO, a Shell subsidiary, to buy up all of EMCA's yearly production of ABS for $36 million for export to other even less ecologically minded countries.

When recommending the President to postpone the ban, the Minister of Industry and Commerce ignored the ecological arguments and cited only the views of the Association of Cleaning Products Industries. The Health Minister in his turn agreed to the postponement on the grounds that health issues were not involved.

The new decree leaves it up to the Ministry of Health to set "indices of biodegradability" over the next two years compatible with the proportions of LAB and ABS on the market. But the Minister of Industry has stated that the responsibility for all future regulations concerning the production, import and distribution of biodegradable products will remain with the executive branch and not with the legislature.

Maurice Bazin

Security conference

Back to Madrid

The Madrid review conference of the Helsinki Final Act reconvened on Tuesday this week for a further two months. Attention now turns from the presentation of reports on progress by the signatory states to the potentially even more acrimonious question of future prospects.

Since the previous review conference in Belgrade in 1977, East–West relations have cooled. One consequence at Madrid was the long procedural wrangle before the conference could begin, partly over whether Afghanistan should be on the agenda.

Later meetings (which were closed to the public) saw much plain speaking, notably from Dr Philip Handler, president of the US National Academy of Sciences. He pointed out that the Hamburg "scientific forum" last February had been devoid of meaning because of Western scientists' concern about "serious infringements of the human rights and freedoms of too many of their colleagues in the East". He concluded with a quotation from Sakharov: "Intellectual freedom is essential to human society — freedom to obtain and distribute information, freedom for open-minded and fearless debate, and freedom from pressure by officialdom and prejudice".

Intellectual freedom concerns only the third of the three "baskets" into which the Helsinki process is conventionally divided. The term "basket" is a relic of the Helsinki Conference in 1973 during which it was decided that there should be three large filing baskets into which delegates could drop their suggestions on, respectively, military matters, trade/technology exchange and human rights.

Western signatories have always maintained, however, that this purely practical procedure did not change the essentially indivisible nature of the process of détente. The socialist bloc, however, would prefer to deal with the three "baskets" in isolation, which, in practice, means concentrating on the military aspects. Indeed, it has often suggested that the Western emphasis on human rights is itself a breach of the Final Act, being an interference in the internal affairs of signatory states.

The discussion of human rights at Madrid has been further complicated by semantics. The United Nations has made a working distinction between "legal" rights and "programme" rights, such as the right to an adequate living standard and the highest attainable standards of physical and mental health. Western signatories insist on the narrower meaning, Soviet spokesmen on the broader.

Proposals tabled for discussion in the next two months are of two kinds, concrete and declaratory. The French, for example, will urge that military "confidence building measures" should be extended to cover the whole of Europe as far as the Urals. At present, notification is required only within a frontier zone of 250 km.

The Soviets, for their part, have called for a European disarmament conference. Poland has proposed Warsaw as a suitable venue, and October 1981 as a possible date. A recent proposal by President Urho Kekkonen of Finland, which is likely to be raised again at Madrid, is known to have strong Soviet backing: the establishment of a nuclear-free zone in Northern Europe. (They are incensed, however, at Danish suggestions that "some regions of the USSR" should be included in the zone.)

Basket Two proposals (trade and technology transfer) will have to be discussed against the background of official trade sanctions imposed on the Soviet Union following its intervention in Afghanistan, and of "personal boycott" pledges by individual scientists and the United States academy's moratorium on exchanges. Major advances are unlikely.

Basket Three will carry a whole range of proposals, from the easing of visa restrictions and the "reunification of families" (the clause of the Final Act most frequently invoked by Soviet Jews wishing to emigrate) to the rights of private citizens to monitor the implementation of the Helsinki accords.

Indians home from home

Lucknow

In an attempt to recoup some of the talent lost through its relentless "brain-drain", the Indian government has reached an agreement with the United Nations Development Programme (UNDP) to implement a project known as TOKTEN, or the "Transfer of Know-how Through Expatriate Nationals".

Under the project, which it is hoped will further India's National Development Plan, Indian expatriates who are specialists in various technical and sociological fields will be invited to return to India for periods ranging from one week to three months. During their stay contributors would be expected to pass on their skills, act as consultants in their specialist field and make suggestions on issues of policy. They would help put their ideas into practice while in India and continue to give advice afterwards.

Responsibility for running the project will lie with a committee specially formed by the government's Council of Scientific and Industrial Research. Its members include representatives from ministries, government departments, public and private sector organizations, the University Grants Committee and the Indian branch of UNDP. Meanwhile UNDP has allocated an initial $100,000 for travel and living expenses.

So far about 300 Indians — including doctors, engineers, scientists and social scientists — have agreed to take part in the TOKTEN project.

CORRESPONDENCE

Galileo's trial

Sir — Your recent leading article "Why bother to rehabilitate Galileo?" (*Nature* 30 October 1980; **287**, 767–768) begins with a pertinent review of Galileo's trial. The last part of the article unfortunately becomes an arbitrary critique of the twentieth century Catholic Church which does not belong in a scientific journal like *Nature.*

More important though, some errors are present. For instance, it is stated that directed evolution plays a "big part in the Church's view of biology", that the Big Bang is "leaped at" by the Church and that the scientific failure of these two theories would place the Church in an indefensible position. These three statements are invalid.

The official Church never taught "directed evolution". Teilhard de Chardin never was a "doctor of the Church" and the official theology of the Catholic Church is still founded on the works of men such as St Thomas Aquinas, who admitted the possibility that the world apparently acts as moved by the laws of fate and necessity (see also St Augustine).

The Big Bang was once kindly considered (but never affirmed) by Pope Pius XII. And some modern astronomers actually claim that the Big Bang is a proof of God (which is either stupid or blasphemous, and perhaps both). The finiteness or infiniteness of space, time and the number of intelligent beings in the Universe are not fundamental problems and have no bearing on the primary question "Why existence?". Science and God, for the Catholic Church, do leave the individual free to answer such questions for himself, and it seems useful that you should be aware of the affirmation of Pius XII, Paul VI and John-Paul II that science and faith each have their own field.

The article "Why bother to rehabilitate Galileo?" ends with categorical criticism of the Church's moral (sexual) recommendations. What is the point of this? The Church proposes a way of life (responsible paternity) to people who believe in the Church and in the eternal destiny of men. Ethics is not a consequence of science.

Then you continue to say peremptorily that "The Church's views on birth control . . . . are a means of making millions of small-time martyrs, pathetic contemporary analogues of Galileo" — what can be said of abortion, which involves an act similar to that of the men who condemned Galileo?

Secretary of State Alexander Haig was inexcusably confused with Earl (Douglas) Haig (1861–1928) — Ed.*Nature*

Evolutionary thought

Sir—At a time when irrationalism is gaining ground against science in popular culture I feel that I must echo some of Dr Halstead's misgivings about the use of cladistics to explain the process of evolution[1]. However, his castigation of Engels as the *eminence grise* behind cladistics is unfounded and is based upon a misunderstanding of how dialectical materialism explains discontinuous development in both nature and society.

Halstead (with Popper) sees Marxism as "working to spark off the revolution"[2]. This is the sort of ultra-leftism espoused by the early German Communist Party and later by Stalin in his "Third Period". Lenin in "Left-wing Communism — an infantile disorder" answered the former and Trotsky the latter in "Revolution Betrayed". In the biological sciences, organic change may be either gradual or discontinuous. Darwin by over-reacting to "leaps" in development, which he saw as the "new creations" of his religious opponents, ended up by formulating a theory of inheritance based on the blending of acquired characters — pangenesis. This ultra-gradualism was overthrown by genetics which reinstated the view of saltatory leaps, now based on mutations. Dialectical materialism properly understood proposes neither an opening for deism nor mutational leaps. It does propose the transformation of quantitative developments (genetic mutations and changes in ecology) into a qualitative leap in development (not in structure but in selection pressure). A genetic mutation *per se* is a leap, but not a dialectical leap.

The clearest examples of dialectical change in evolution are in the area of so-called macroevolution, where quantitative genetic changes taking place to fit an organism for one habitat pre-adapt the organism to "leap" into another ecological niche where the selection pressure is qualitatively different. Darwin describes this type of development in the speciation of the Galápagos finches, although not referring to it as a leap. The early diversification of the mammals has been described by Olson[3] as due to "Co-ordination and integration of such modifications (as) brought some members of a particular radiation to the threshold of a new radiation". Similarly, many workers explain the initiation of major periods of diversification or the invasion of new environments by such a "quantitative to qualitative and back to quantitative" hypothesis.

Even G. G. Simpson, to whom the mechanistic view of cladism may or may not have been anathema, was by no means averse to the idea of leaps. I quote: "Even within the staid horse family, which seems as a whole to be progressing rather steadily through the Tertiary, close examination shows the rates varying considerably. More broadly, evolution commonly seems to proceed in spurts and pauses in an apparently erratic way"[4].

Engels on Darwin

Sir — How right Dr Halstead is to remind us of the lengths to which Marxists have gone, and will no doubt continue to go, in their efforts to place their materialist theory of history on a scientific par with Darwin's evolutionary theory. Engels, no less, argued, in his oration at Marx's funeral, that ". . . just as Darwin discovered the law of development of organic nature, so Marx discovered the law of development of human history. . . "

Incidentally, it is worth recalling that the only Englishman at the graveside to hear this, was Marx's erstwhile young friend Ray Lankester FRS. Lankester was later knighted and served as the Director of the Natural History Departments of the British Museum (1898–1907), and is still remembered for his reclassification of the Talpidae collection. The plot thickens!

Motorbike safety

Sir — A recent letter to *Nature*[1] concerns the observation that an object appears to maintain constant size as its distance from the observer changes. It is simply "seen" as a full-sized object at varying distance. This size constancy fails quite suddenly when the object subtends an angle at the observer of less than half a degree; it is then seen as a small object, presumably of less immediate importance.

This phenomenon could be a contributory factor in a fairly common type of road traffic accident, that caused when a driver pulls out unexpectedly in front of motorcyclist who is then unable to stop.

An approaching motorcyclist presents an irregular silhouette subtending an average angle of less than half a degree at any distance greater than about 200 feet. If size constancy fails below half a degree, the motorcyclist would only be seen as small, and would therefore be less likely to register subconsciously as a real full-sized danger, until within about 200 feet.

The shortest possible stopping distances for a moving vehicle under good conditions are reported in the highway code as follows

Vehicle speed (m.p.h.)	30	40	50	60	70
Stopping distance (ft)	75	120	175	240	315

Interpolation suggests that when a motorcycle is approaching at over 54 m.p.h., so that its stopping distance is greater than the critical 200 feet, an accident might be inevitable, particularly if either driver was not concentrating on "seeing" the other vehicle at the crucial time. Many similar calculations are possible. A convex rear view mirror reduces the image size and so can make it possible for larger vehicles to approach within their stopping distances before they, too, subtend the critical angle of half a degree.

Much work has been done on the effect of factors such as brightness, contrast, colour, shape, size (and styling features disguising shape and size) on the visibility of an object. The results of this work might valuably be applied to problems of the type outlined above

The Nobel awards for medicine or physiology

from Sir Peter Medawar CH, FRS

THE joint award of the 1980 Nobel prize for medicine or physiology to Jean Dausset, George Snell and Baruj Benacerraf has been well received by immunologists and medical biologists generally. The general public and the scientific press also found the award easy to understand: Jean Dausset was prime mover in the discovery in human beings of an important system — 'HLA' — of tissue groups that affect the outcome of organ transplantation in a way analogous to that in which the principal blood groups — ABO — affect the outcome of blood transfusions.

Its relevance to tissue transplantation is not, however, by any means the most important aspect of the discovery of the so-called 'major histocompatibility complex' (MHC) of human beings and of the analogous — perhaps homologous — MHC of mice, known as H–2.

The great and abiding importance of the HLA system is twofold. First, it defines a system of polymorphism — of stable genetic differentiation — in human beings which has uncovered, as no other procedure could have done, the genetic basis of differences in susceptibility to multiple sclerosis, ankylosing spondylitis and the juvenile (insulin-dependent) form of diabetes. Even more important, it has become increasingly apparent that the MHC of man as of the mouse defines a whole system of cell-surface markers which are of the utmost importance for the organism's power to discrimate between self and non-self; indeed, an organism's power to react to a number of immunogens as antigens seems to depend on their being signalled by the gene products of the MHC.

Although Jean Dausset was prime mover in the recognition and definition of the HLA complex, this discovery — as with all others of comparable stature — was the work of a number of medical scientists standing shoulder to shoulder: the names that come instantly to mind are those of Bernard Amos, Richard Batchelor, Walter Bodmer, Ruggero Cepellini, Rose Payne, Jan van Rood and Paul Terasaki — a splendid example of international co-operation promoted by the Transplantation Society's generosity and good sense in organizing histocompatibility workshops at which all the principals met to exchange ideas, knowhow and reagents.

To explain George Snell's award we must go back to the early days of tumour transplantation. In the first decade of this century it was widely believed that a study of the factors promoting or retarding the growth of transplanted tumours held promise of a prevention or cure of malignant growth; but by the end of the decade, thanks mainly to the criticism of Peyton Rous, it came to be recognized that the study of tumour transplantation was a study of transplantation rather than of tumours, for in the days before homozygous strains of mice became available, tumour transplants were all of the kind known as 'allografts' and as such aroused immunological rejection reactions.

A very great deal of the work was done with what might be called 'any old mice'; it made no kind of sense and — what is worse — still cannot be interpreted today. This judgement applies with especial force to work on 'immunization' against transplanted tumours by the previous inoculation into their intended recipients of tumour cells of the same kind or of a variety of normal tissues.

Matters were in a desperate state until they were taken in hand by Little, Strong, Bittner, Johnson, Bagg and George Snell of the Roscoe B. Jackson Memorial Laboratory — the men who originated the inbred strains used throughout the world today. Using genetically uniform mice it became possible to formulate the elementary genetic ground rules of transplantation of normal tissues or of tumours. George Snell went further and worked out in great detail how the outcome of transplantations is governed by the genes that comprise the MHC of mice (H–2), first serologically recognized by Peter Gorer of Guy's Hospital, London, who if he had lived, would certainly have shared the Nobel prize. The study of H–2 provided the technology and the conceptual background that made possible the recognition of the MHC of man.

This has been the international year of the MHC, for the award to Baruj Benacerraf also relates to the MHC — in particular with that sub-region of it that has to do with '*Ir*' (short for immune response) genes. When Benacerraf and H.O. McDevitt first recognized this sub-region it was widely thought that they had discovered the gene that coded for the antigen-specific T-cell receptor, but it now seems more likely that the *Ir* region is involved with the presentation of antigen to T-helper cells.

The work of this year's recipients of the Nobel award for medicine or physiology has a twofold lesson to teach. The first is of the immense fruitfulness of collaboration between mice and men in the solution of medical biological problems. The second, not quite so obvious, is that the discovery of HLA provides an exemplary case history in rebuttal of the notion that scientific discovery can be premeditated. What advice, for example, should one give to a young man intent on finding out the genetic basis of differences in susceptibility to multiple sclerosis, ankylosing spondylitis or insulin-dependent diabetes? It would be the *reductio ad absurdum* of the notion that scientific discovery can be premeditated to recommend that the young research worker should embark on a study of tumour transplantation, specifying the use of heterozygous mice, until its contradictions and vicissitudes drove him nearly mad whereupon he should proceed at once to work out its genetic and serological basis, from which the results could be translated to human beings and the rest would follow.

In days when businessmen and others who ought to know better are advocating a diminution or even abandonment of 'pure' research in favour of its practical applications it cannot be too strongly emphasized that discoveries such as HLA — as of diagnostic X-ray radiography — were made by the ordinary processes of scientific discovery, slow, messy and uneconomic though they undoubtedly are. It is in fact only unworldly impractical daydreamers who think that scientific discoveries can be premeditated or can be arrived at by the working of some calculus, some organon of discovery. It was the tough practically minded, no-nonsense men of affairs — particularly of great affairs — the world's Rockefellers, Sloans, Nuffields and Wolfsons who proved to understand most clearly the need and to provide most generously the means for what is so mistakenly called 'pure' research. □

Meteorite breakup

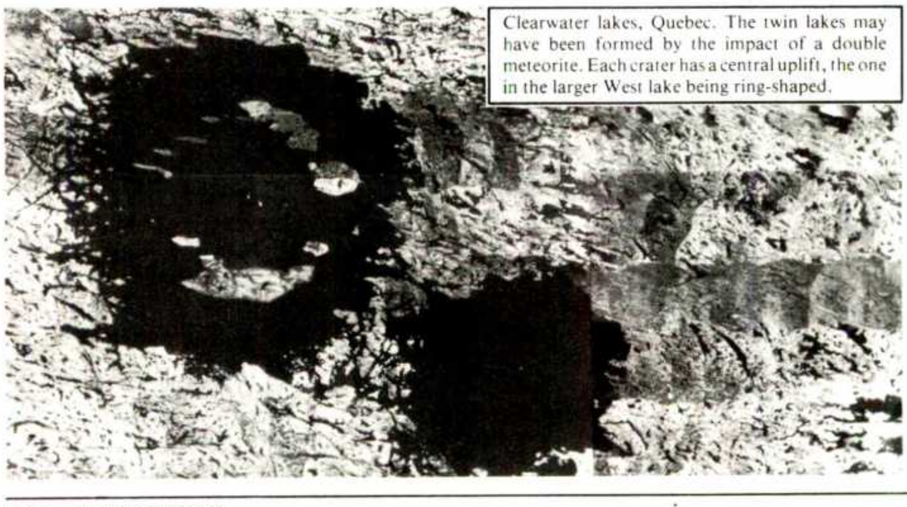
from Michael R. Dence

INTEREST has revived in crater groupings on the solid planets since the report that some asteroids may be double (Tedesco *Science* **203**, 905; 1979). Earlier debates between those who considered that groups resulted from two or more simultaneous impacts and those who considered them to be chance clusters of unconnected events have run in favour of chance (see Woronow *Icarus* **34**, 324; 1978). Yet some crater associations, most notably on Earth, seem to require coeval impact events. Can all such groups be accounted for by breakup of single bodies before impact or are they evidence for meteoroid pairs in space? To answer this question statistical studies have now been augmented by attempts to derive a quantitative understanding of meteorite disruption by an atmosphere or by tidal rupture.

The breakup of meteoroids or of re-entering satellites has been described by many eyewitnesses. Disintegration of meteorites has also been photographed and led in the case of the Innisfree Alberta fall of February 1977 to the recovery of nine fragments of the aerolite (Halliday, Blackwell & Griffin *J. R. astr. Soc. Can.* **72**, 15; 1978). Much larger meteorite showers may contain many hundreds of fragments. In such falls the meteorite fragments, or the craters they produce if they land with sufficient velocity, are usually distributed over an area elongated in the direction of flight of the bolide. The strewn field or scatter ellipse is commonly only a few square kilometres in area, but, as in the case of the great 8 March 1976 fall at Kirin, North China, may cover several hundred square kilometres. Although, on average, the scatter ellipse is one-third as wide as it is long, some are almost circular while others show a down-range dispersion more than eight times the cross-range scatter. Commonly, but by no means invariably, the largest fragments or craters are found at the down-range end of the ellipse.

What causes this scatter? The general principles have been understood for some time and a few falls have been analysed in considerable detail. The veteran Russian meteoriticist E. L. Krinov concluded that the massive Sikhote-Alin fall of 12 February 1947 came from an iron meteorite weighing more than 70 tonnes which broke up in three stages. From the pattern of secondary scatter ellipses superimposed on the main ellipse, Krinov deduced that there was an initial high-altitude breakup followed by two additional disruptions, the last at an altitude of 6 km or less (*Meteoritics* **9**, 255; 1974).

This and other large falls, mostly of iron meteorites, have now been modelled quantitatively by Passey and Melosh (*Icarus* **42**, 211; 1980) with some unexpected results. They trace the history of individual meteoroids of varying size and crushing strength after they enter the atmosphere at an altitude of 70 km. Velocity and entry angle are also varied in the calculations. Initial fragmentation is taken to be largely the result of aerodynamic pressures on pre-existing defects or planes of weakness, though they recognize that thermomechanical stresses may also be effective. The mechanics of breakup are not fully understood and the estimation of appropriate properties such as crushing strengths is one of the main uncertainties of the analysis. Following breakup, dispersion down-range is considered to result mainly from atmospheric drag. Since the small fragments are decelerated more effectively than the large, they tend to fall short of the main mass. Lift may counter the effect of drag, but Passey and Melosh argue that it is only effective for fragments lighter than 10^2 kg. For larger masses they conclude that lift is a small fraction ($\sim 10^{-3}$) of drag, otherwise many more would lie down-range of the main mass, or crater, than is generally observed. Parenthetically it may be noted that Sikhote-Alin is one instance where many sizeable craters are down-range from the largest.



Clearwater lakes, Quebec. The twin lakes may have been formed by the impact of a double meteorite. Each crater has a central uplift, the one in the larger West lake being ring-shaped.

A feature of their analysis is the attention Passey and Melosh give to cross-range dispersion. This they attribute to a combination of the effects of bow shock interaction, spin of the meteoroids acquired before entry, and spreading induced by crushing as the meteoroid decelerates. All of these effects they judge to be quantitatively similar and capable of explaining most of the observed scatter transverse to the direction of flight. They calculate that maximum separation is achieved when breakup occurs at an altitude of about 15 km.

More of a problem is their conclusion that, for meteoroid masses of 10^4 to 10^9 kg, multiple crater fields result when the angle of entry of a bolide is less than 30°. Indeed, in analysing specific terrestrial crater fields, formed for the most part by iron meteorites, they generally favour entry angles of less than 20°. However, the examples they draw on include 70 per cent of the terrestrial inventory of craters 20 to 200 m across with associated meteorite fragments. As the probability of the entry angle being 30° is only one in four and is even less for lower angles, it is evident that the result implies a marked deficiency of craters from high-angle impacts. As there are no other grounds for believing this to be the case, their analysis requires further examination. One method of expanding the set of conditions for producing crater fields is to lower the strength assumed for the meteoroids. Passey and Melosh adopt yield strengths between 10^7 and 5×10^8 Nm^{-2} in their representative calculations. This range may be appropriate for the low-altitude, final breakup of the Sikhote-Alin meteoroid, but its initial, high-altitude disruption implies considerably lower strength for the main mass. We are brought again to the need for an improved theory of meteorite fragmentation.

Further problems arise when bodies of mass greater than 10^9 kg are considered. Basically, much larger bodies on entering the atmosphere may rupture but no combination of atmospheric deceleration, lift, bow shock interactions or gravity will allow sufficient separation for the formation of more than one crater. For typical velocities of 15 to 20 km s^{-1}, separations of the order of 20 times the radius of the impacting bodies are required to achieve clear separation of the resulting craters. Nonetheless, pairs of large craters, formed by bodies of the order of 10^{12} kg, are found on Earth. The best known are the 32 km and 24 km diameter pair at Lac à l'Eau Claire (Clearwater Lakes, see figure), northern Quebec, Canada and the 24 km Rieskessel and 3.5 km Steinheim Basin combination in southern Germany. The former have a centre-to-centre separation of 31 km, the latter of 45 km. Radiometric

Michael R. Dence is Acting Director of the Gravity and Geodynamics Division of Energy, Mines and Resources, Ottawa.

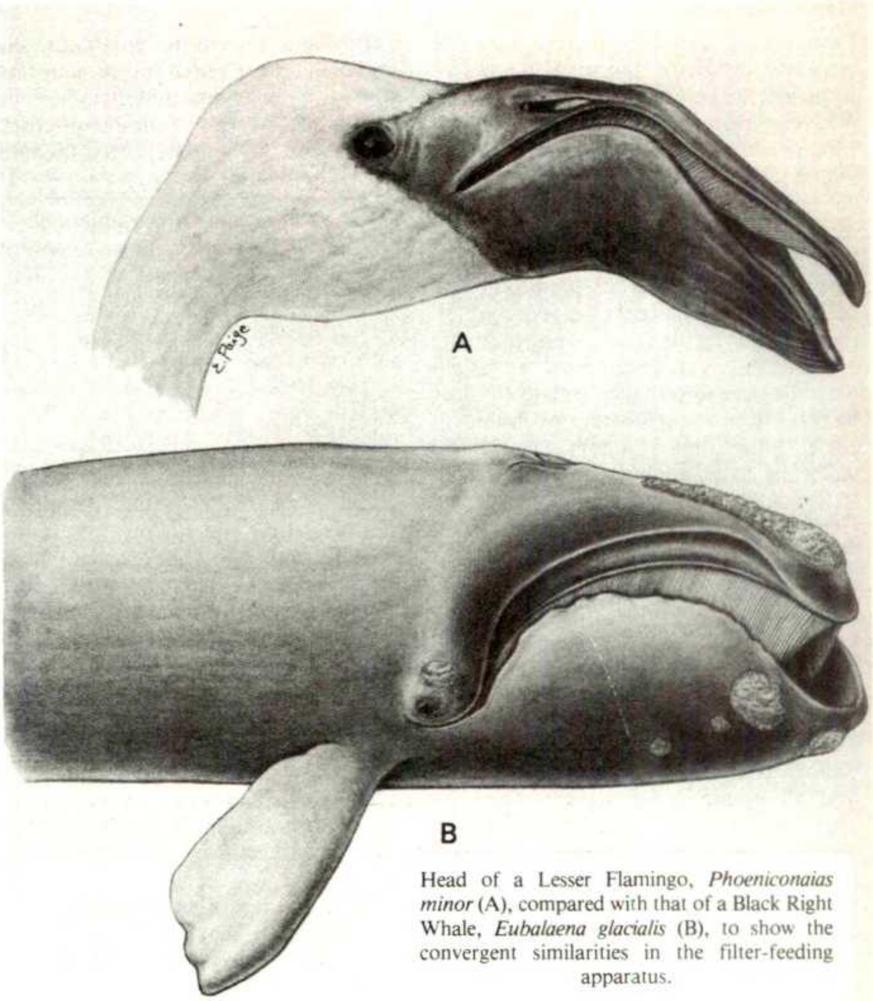
Flamingos, stilts and whales

from Andrew Milner

THE phylogenetic position of the flamingos (family Phoenicopteridae) has long been the subject of controversy among avian systematists with some workers supporting relationship with the Anseriformes (ducks and geese) whilst others favour association with the Ciconiiformes (storks, herons and ibis).

The evidence has been reviewed recently by Olson and Feduccia (*Relationships and Evolution of Flamingos (Aves: Phoenicopteridae)* Smithsonian Contributions to Zoology **316**, Smithsonian Institution Press; 1980) who have developed an earlier proposal by Feduccia that the flamingos fall within the Charadriiformes (waders, gulls and auks). Characteristics of the musculature, the skeleton, the natal down and the endoparasitic cestodes all lead to the conclusion that the closest living relatives of the flamingos are the Recurvirostridae (stilts and avocets) and, more specifically, the Australian Banded Stilt (*Cladorhynchus*). This remarkable bird lives in colonies frequenting temporary salt lakes in southern Australia and its behaviour, pattern of breeding and life history all bear specific similarities to those of flamingos. The earliest certain fossil flamingo from the Eocene of Wyoming is described by Olson and Feduccia and supports their hypothesis by being morphologically intermediate between recurvirostrids and flamingos. One phylogenetic anomaly, the presence of anseriform-type feather lice in flamingos but not in *Cladorhynchus*, is attributed to the presumed common lifestyle and physical proximity of early flamingos and the early colonial Anseriformes such as *Presbyornis*.



Head of a Lesser Flamingo, *Phoeniconaias minor* (A), compared with that of a Black Right Whale, *Eubalaena glacialis* (B), to show the convergent similarities in the filter-feeding apparatus.

The filter-feeding mechanism of flamingos is structurally and mechanically different from that of ducks but is remarkably convergent with that of the baleen whales, particularly the Right Whale! Despite the differences in scale and orientation during feeding, the two filter feeders share structures such as a large fleshy tongue accommodated in a deep-sided lower jaw and a recurved rostrum permitting the presence of a row of elongate filtering devices suspended from each upper jaw. The similarity in structure and function of the feeding apparatus of whale and wader suggests to the authors that the 'crooked beak' of the flamingo may have been a fundamental adaptation to filter-feeding which preceded the 'inverted-head' feeding posture rather than following it as has generally been assumed.

Andrew R. Milner is in the Department of Zoology, Birkbeck College, University of London.

---

and geological dating leaves little doubt that each pair was formed simultaneously. In addition, in neither is there a structural basis for assuming a highly oblique impact angle. It seems that both pairs may indeed be the product of the impact of double meteorites.

The idea is in fact not new having been examined by R. W. Tanner in 1963 (*J. R. astr. Soc. Can.* **57**, 109). Recently it has been considered in greater detail by P. D. Noerdlinger (*Icarus* in the press) who, after an exhaustive study of tidal disruption mechanics, confirms that Tanner's analysis is essentially correct. In the general case of tidal rupture at a distance of several Earth radii the separation that fragments achieve approximates only the initial radius of the parent body. Overlapping or nested craters will result. It is conceivable that the separation found at the terrestrial crater pairs might be achieved by tidal or atmospheric rupture of a body of low strength which, entering at an oblique angle, became a satellite for several orbits. Clearly such an event has an extremely low probability, but the Ries-Steinheim and Clearwater pairs are two occurrences in a total population of approximately two dozen large ($\sim$ 20 km) craters (Grieve & Robertson *Icarus* **38**, 212; 1979). Once again the existing crater statistics argue that multiple cratering events, even in this size range, are not of great rarity.

On the other hand Noerdlinger contends that the population of meteoroid doubles is also probably small. Rupturing an asteroid so that the pieces remain in close association requires a delicate balance between the energy of fragmentation, gravity and angular momentum. The association may also be difficult to maintain for any appreciable time. The entire life cycle of double meteoroids and asteroids is in need of a careful, quantitative evaluation of the circumstance under which they can form and their subsequent stability before final capture, separation or disintegration. Such a study would be relevant to another important issue — the formation and lifetime of ring systems as now revealed in spectacular detail by the Voyager images of Jupiter and Saturn.

Cement — a respectable material?

from D.D. Double

FAMILIARITY breeds contempt. We see cement everywhere, mixed with sand to form mortar between bricks, mixed with pebble aggregate to make concrete. World-wide production of cement approaches a billion (10^9) tonnes per annum and of this 95 per cent is Portland cement, the remainder being more specialized products such as high alumina cement. This figure very substantially exceeds the production of steel, traditionally its nearest counterpart in large-scale engineering construction. Yet, in spite of its obvious technological importance, relatively little has been done to explore the possibilities of cement other than as a convenient gluing agent in a cheap bulk filler material. Relegated to this rather unsophisticated role, outside the established industry, cement has not received the attention that it deserves.

But this situation may be changing. In general, there is increasing interest in inorganic materials that can be produced cheaply and which might compete with or even replace other common materials which are more costly in economic or ecological terms[1,2]. In this context, silicate- and aluminate-based systems seem an attractive proposition and one of the obvious sources for development is cement (principally Portland but also other hydraulic cements). Materials scientists, who have hitherto mostly ignored cement as a not-quite-respectable material, are now taking a different view.

Portland cement is remarkably cheap and materials required for its manufacture (limestone or chalk, and clay) are widely abundant. In terms of the energy costs for production it compares very favourably with other materials.

Energy cost for production
(per unit volume, relative to cost of cement)

Portland cement	1
Glass	1.3
Aluminium	35
Steel	20
Polystyrene	5

Whereas other materials, such as glasses, ceramics and metals, usually require high-temperature, and therefore expensive, shape-forming processes, cement develops its strength by reaction with water at ambient temperatures. Before setting, it is easily castable and made into complex shapes. With a density around 2.4, compared for example with that of aluminium 2.7, a hardened cement paste is relatively light. It has low thermal and electrical conductivity, is inherently non-combustible and, as far as one can tell, is generally non-toxic. Young's modulus has quite a respectable value around 20 GN m^{-2}.

With all these potential advantages, one might wonder why cement has not been used more widely in more diverse ways. The reason is quite simple — as normally made, it is very weak and brittle. Although a hardened cement can sustain quite appreciable compressive loads, its tensile strength and fracture toughness — two parameters that often determine the practical use of a material — are disappointingly low, respectively 5–10 MN m^{-2} and about 20 J m^{-2}. The situation in relation to other common materials is illustrated in figure 1. Engineers are well aware of the mechanical deficiencies of cement as a binder. Wide safety margins are usually used when dealing with structural concrete sections and methods are devised (reinforcing, prestressing, cantilevering) to avoid putting concrete under any substantial tensile stress.

It is obvious that if cement is to be exploited in new and unconventional ways then improvements have to be made in the mechanical properties. Cement will never be as strong as steel but, referring to figure 1, one can see that only relatively modest improvements are required to bring it on a par with a range of other materials. Cement could become a serious contender at a tensile strength of 100 MN m^{-2} and 10^3–10^4 J m^{-2} in a work of fracture. The question is whether such improvements are possible.

How does nature deal with the problem of forming strong inorganic solids in an aqueous medium at normal temperatures? The classic example is the calcium carbonate found in shells of marine organisms. Measurements of mother-of-pearl shell (nacre) show that it has a modulus around 100 MN m^{-2}, a tensile strength between 70 and 100 MN m^{-2} and a fracture energy greater than 1,500 J m^{-2} (ref. 3). It is clearly a much more impressive material than $CaCO_3$ in the form of chalk, limestone or even the best quality marble. It achieves these properties by developing an intricate structure of low porosity consisting of plates of crystalline $CaCO_3$ (aragonite) held together by very thin layers of a protein polymer 'glue' (figure 2). Limpet shells have a more complex cross-laminated structure and certain crab shells show an interesting, and presumably purposeful alternation between calcitic and aragonitic crystal forms of $CaCO_3$. These examples demonstrate that, through appropriate reorganization of the micro-structure, a rather unpromising substance can be transformed into a mechanically sound material. The same principle should apply in the case of cement.

In general, hydraulic cements harden by reaction with water through precipitation of near-insoluble hydration products which progressively fill the spaces between the residual cement grains, forming a cohesive matrix that binds the composite mass together. In Portland cement, the main binding agent is a colloidal calcium silicate hydrate gel of rather indefinite

Fig. 1 Tabulation of tensile strength versus work of fracture for a range of common materials.

composition and structure. In fractured samples this gel is often seen as irregular interlocking fibres growing from the surfaces of the cement grains and interspersed with plates of crystalline calcium hydroxide, a by-product of the hydration reaction (figure 3). The mechanism by which hydration occurs and the factors responsible for the development of strength are still not fully understood (see for example ref. 4). It is recognized, however, that the main source of weakness is the residual porosity within the hydrated cement microstructure. As normally made, a hardened cement paste has a total porosity of about 20 per cent and contains pores with sizes ranging from the order of 1 mm to less than 100Å.

The importance of the article in this issue of *Nature* (p.388) by Birchall, Howard and Kendall is the convincing demonstration that, by deliberate manipulation of the porosity, very substantial improvements can be made in the strength of cement. The flexural strength values quoted, between 60 and 70 MN m^{-2}, are about an order of magnitude greater than those for 'normal' cements, and even exceed previous estimates of the maximum intrinsic strength.

This has been done by application of classical theory relating to the fracture of brittle solids (Griffith's theory) and by recognition of the fact that it is porosity distribution that determines the fracture strength and not total porosity, as has hitherto been supposed. Although the total porosity of their samples remains fairly high, the increases in strength have been achieved by refinement of the porosity distribution to eliminate the large pore range — the macrosopic flaws that provide sources for easy propagation of cracks through the microstructure. Thus, the article shows that cement is not intrinsically as weak as has been supposed and also illustrates that the improvements are attainable by fairly simple methods without the need to apply elaborate and costly treatments such as hot pressing, autoclaving and resin impregnation — methods that have been investigated by previous workers.

This may be only the beginning of the story. After physical processing to reduce the porosity to dimensions comparable with the size of the cement grains and the hydrate particles, researchers should perhaps be looking to methods of chemically modifying the hydration reaction in such a way as to promote greater cohesion within the cement paste. Previous attempts to do this have not been successful probably because of the overriding effect of macro-porosity. Chemical cross-linking by the incorporation of reactive organic molecules is one possibility; an enhancement of the natural polymerizing ability of the colloidal silicate in Portland cement is another. The chemistry is extremely complex but, nevertheless, there would seem to be considerable scope in this area. Fibre reinforcement is a well proved method of augmenting the mechanical properties of a material, particularly the fracture toughness. It has been applied with some success in the case of cement using asbestos, glass, steel and polymer fibres, but in many cases the mechanical deficiences of the cement matrix have imposed limitations. An enhancement of the inherent strength of cement could provide considerable impetus to the development of such composite materials.

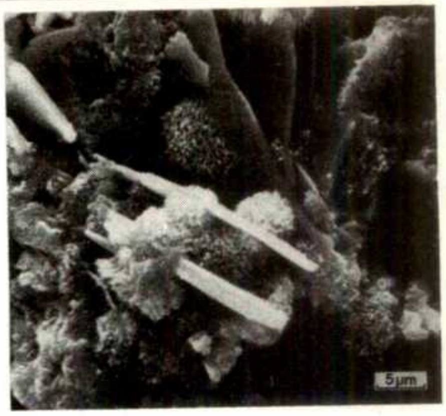

Fig. 3 Fracture surface of hardened Portland cement paste, showing fibrillar growth of calcium silicate hydrate gel from surfaces of cement grains and interspersed crystals of calcium hydroxide. Scanning electron micrograph.

There is still a long way to go but if the necessary improvements are possible, it is difficult to predict where cement-based materials might eventually be used. One can visualize a variety of new domestic uses and even in the area of transport. Boats have been made out of reinforced cement (ferrocement) for many years. Cement, or something rather like it, may yet fly — not as a turbine blade in a jet engine certainly, but perhaps as an important structural part of the airframe. If that day comes, then cement will have become a very respectable material indeed. □

Understanding interatomic forces

from Gillian Peach

THE ANALYSIS of spectra often provides the only diagnostic tool with which to study the physical conditions of a plasma or gas in the laboratory or in space. The interactions between the atoms that are emitting (or absorbing) radiation and neighbouring atoms can, however, produce a marked effect upon the observed spectrum. In 1907 R.W. Wood (*Astrophys. J.* **26**, 41) wrote "I have found what appears to be indisputable evidence that the appearance, and even the apparent position, of an absorption band can be profoundly modified by the presence in the absorbing vapour of a chemically inert gas" and it is now generally understood that the presence of a background gas can produce a broadening and shift of the individual spectral lines, and also an asymmetry in the line shape which becomes more marked as the pressure of the background gas increases. Over the last eighty years there has been an enormous number of studies of this phenomenon (see Fuhr *et al. NBS spec. Publ.* **366**; 1972 and Suppl. 1974, 1975, 1978). In many cases, the emitter-perturber interaction is well known, and a study of line shapes is used to determine the density of perturbing particles in the emitting region; a typical example is that of hydrogen lines perturbed by protons and electrons. However, when atomic spectra are perturbed by neutral atoms or molecules, the line shapes are analysed to

0028-0836/81/050349-02$01.00

provide information on the basic emitter–perturber interaction. This type of analysis can be extremely valuable, since it can give information on interatomic forces where one of the atoms involved is in an excited state. Studies of atom–atom scattering predominantly yield information on interactions between two atoms that are both in their ground states (see Massey *Electronic and Ionic Impact Phenomena* 2nd edn, Vol.3, Oxford University Press; 1971).

The problem of analysing these line shapes is a fascinating and difficult one. In general, the shape of the line profile is determined by the simultaneous interaction of the emitter with many perturbers; but under certain circumstances, however, the problem can be reduced to the interaction of just one perturber with the emitting atom. If the frequency separation, $\Delta\nu$, from the line centre is sufficiently large, the mean interaction energy required, $V = h\Delta\nu$, is predominantly produced by a single perturber making a close collision with the emitter. The contribution from more distant perturbers is negligible by comparison. Thus the analysis of the shape of the line wings can give detailed information on the inner region of the atom–atom potential. This approach has been used for many years (see Kuhn *Proc. R. Soc.* **A158**, 212; 230; 1937), and an excellent modern example of such an analysis is given by York *et al.* (*J. chem. Phys.* **63**, 1052; 1975). They are able to obtain the potential energy curves for the $X^2\Sigma$ and $A^2\Pi$ states of the systems Na–Ar, Na–Kr and Na–Xe. *Ab initio* calculations of the adiabatic potentials for such systems are difficult and costly, although a good deal of progress has been made in the last few years by adopting semi-empirical model or pseudo-potential methods (see Peach *J. Phys.* B **11**, 2107; 1978; Philippe *et al. J. Phys.* B **12**, 2493; 1979).

When the frequency separation from the line centre is small the mean interaction energy V is also small, and is produced by many perturbers making weak collisions with the emitter; the probability of a close collision is very low. This picture provides the basis of the impact approximation, a simple description of which is given by Peach (*Contemp. Phys.* **16**, 17; 1975). The impact approximation predicts a lorentzian profile for the line given by

$$I(\Delta\nu) = \frac{1}{\pi}\,\frac{w(\Delta\nu)}{(\Delta\nu - d)^2 + w^2}$$

where in this case, the half width at half maximum is $w(\Delta\nu) \equiv w$, and is independent of frequency. The shift in the position of the line is given by d. Szudy and Baylis (*J. quant. Spectrosc. Radiat. Transfer* **15**, 641; 1975; **17**, 269, 681; 1977) have developed a scalar theory of line broadening which is less restrictive than the impact approximation. The scalar nature of the theory means that it is assumed that the frequency shifts produced by the individual perturbers are additive, but allows for the fact that the perturbing collisions are of finite duration. Their theory predicts a first-order correction to the pure lorentzian profile in the core of the line, which is given by $w(\Delta\nu) = w + a\Delta\nu$, where a is a constant. The parameter a depends only on the average time of duration of the collision, the nature of the interactions between the emitter in both its initial and final levels and a perturber, and the temperature of the gas. Thus the line contains a dispersive component which leads to an asymmetry in the line core. Asymmetries in the far wings of lines occur for different reasons; in this case completely different regions of the emitter–perturber potentials are being sampled. Very recently the first quantitative measurements of asymmetries in line cores have been reported (Walkup *et al. Phys. Rev. Lett.* **45**, 986; 1980). They have studied the shape of the resonance lines of sodium perturbed by helium, neon, argon, krypton and xenon. They show conclusively that the lines contain a dispersive component as predicted by the theory, and obtain accurate values for the contant a. About the same time Kielkopf (*J. Phys.* **B13**, 3813; 1980) also published width, shift and asymmetry parameters for the sodium resonance lines perturbed by the same systems. His measurements are also for similar pressures and temperature, $P = 10$–600 torr and $T = 450$K. However, his quoted errors are somewhat larger than those given by Walkup *et al.* If a pure van der Waal's potential is used for the emitter–perturber interaction, good agreement is obtained between theory and experiment for the systems Na–Ar, Na–Kr and Na–Xe. In fact this agreement is better than actually stated in the paper of Walkup *et al.* as can be shown when the full profile given by the scalar theory is used. For the systems Na–He and Na–Ne the agreement is not good; this is readily understandable since the heavier rare gases have larger dipole polarizabilities and hence the long-range part of the potential becomes relatively more important. These measurements present an exciting new challenge to the theorists. It is clear that calculations are required which use realistic interatomic potentials; on the basis of a pure van der Waal's potential, it is not possible to obtain the different values of the asymmetry parameter that are observed for the two lines. This difference gives us direct information about the difference between the $A^2\Pi$ and $A^2\Pi$ potential curves for the sodium-rare gas systems. It seems certain that more such measurements will be made, and will be used to probe regions of interatomic potentials that are not accessible in studies of the far wings of spectral lines, or in other types of atom–atom scattering experiments. □

Current issues in conservation

from Jared M. Diamond

WHEN nature reserves are looked at with the understanding gained from studies of island biogeography then the problems of avoiding major losses of the world biota seem even more difficult than at first thought. Nature reserves can be thought of as islands in a sea of man-transformed habitats. Not only will a reserve which saves only a small part of a particular habitat start out with fewer species than a larger one, it will ultimately lose a greater fraction of its species and it will lose them faster (Terborgh *Bioscience* **24**, 715; 1974). This is best illustrated by the well documented losses of species in Panama's Barro Colorado Island Reserve within this century (Willis *Ecol. Monographs* **44**, 153; 1974). Biogeographic arguments for large reserves are reinforced by genetic ones: a population with an effective size of less than 500 gradually loses the genetic variation that underlies ability to adapt, and an effective population size of less than 500 leads to inbreeding depression (Soulé and Wilcox *Conservation Biology* Sinauer; 1980). As discussion at two recent conservation meetings* in South Africa showed, even in Kruger National Park (South Africa's largest reserve) numerous key species such as lions, ground hornbills, wild dogs, and saddle-billed storks have populations whose long-term prospect of survival is only marginal from this perspective. Biologists have long felt intuitively the importance of large reserves, but lacked the detailed arguments that have been emerging in the past decade. To many participants in the South African meetings, the detailed arguments were chilling.

The meetings revealed that biologists, park managers, and government planners have important differences in vocabulary, values, and areas of concern, and that it takes effort to bridge these communication barriers. It is clear that biologists who wish to be effective have to learn the vocabulary in which public planners express themselves, to broaden their perspective so as to be aware of social and economic constraints that concern planners, and to be specific. Part of the reason for the limited success of biologists in persuading

*A symposium on the conservation of threatened natura habitats was held in Cape Town on September 11-12 and workshop on the same topic at Tsitsikama National Park on September 14-18, 1980.

0028-0836/81/050350-02$01.00

governments to establish large reserves may be the failure to offer specific arguments in terms of fraction of species expected to be lost, expected rates of losses, and likely identities of lost species in a reserve of a given size. More generally, planning and management should be part of one continuous process, with progressively more specific stages such as: formulation of a national plan of conservation priorities; selecting areas, sites, and shapes of reserves; zoning the reserve for different uses; and developing an integrated programme of research, monitoring, and management.

The last word, management, is initially anathema to many biologists. Yet a recurring theme at these meetings was that nature reserves cannot be left alone; they have to be managed. Many biologists assume, not even consciously, that a reserve need only be set aside; nature will 'manage itself' and preserve the ecosystem, and human intervention is precisely what one wants to avoid. The fatal flaw in this reasoning is: each reserve was formerly part of a much larger biogeographic unit, and it was this larger unit which 'managed itself', that is, species and habitats rarely disappeared in the whole unit; they might disappear locally but persisted or expanded elsewhere within the unit. When a reserve becomes isolated, it is doomed to change because of the loss of processes outside its boundaries that were necessary for its maintenance. The smaller the reserve, the further and faster it will change. The reasons for these inevitable changes are multiple: reserve boundaries often intersect paths of regular seasonal movements (for example, the game fence around Kruger intersecting the former west–east seasonal migrations of game); populations isolated in a reserve may be too small to be self-sustaining, though they were able to sustain themselves in the larger system; the landscape is a shifting mosaic of habitats, and a small reserve that temporarily loses a habitat essential for certain species loses those species permanently; and extinctions of a few species lead to extinctions of other species dependent on them, via effects called trophic cascades.

A spectacular example of the need for managing even large reserves is the disaster that resulted from a hands-off approach to Tsavo National Park, where reserve status led to an increase in the number of elephants producing a complete transformation of the habitat, and ultimately a crash of the elephant population. Biologists have to resign themselves: measures such as culling, reintroductions, transfers of animals, maintaining a habitat mosaic by controlled fires, and provision of water in arid areas must be standard tools of a reserve manager. The smaller the reserve, the more effort is required, but even Kruger requires constant human intervention to avoid losses of key species and transformations of habitats. We face a cruel dilemma: without management, we will lose species and habitats; yet, only for a few species have we the biological knowledge necessary to manage well. This is not the leisurely world of academia, where one completes one's marshalling of evidence before publishing. Here, as elsewhere in the field of conservation, one must act on very limited information, often mere guesses.

Finally, the South African picture. Measured against standards of other countries, especially less wealthy countries, South Africa has done much for conservation. It has dozens of well-run reserves, including two large ones (Kruger and Kalahari Gemsbok) that are famous throughout the world. Measured against standards of what South Africa actually needs to protect its own biological heritage, there are glaring gaps (Huntley in *Biogeography and Ecology of South Africa*, 1333 (ed. M.J.A. Werger), Junk, 1978). For two habitats that covered a large fraction of South Africa, the Highveld Grassland and the Karoo, there is currently *no* large reserve at all. The Cape lowland fynbos, one of the world's richest and most distinctive temperate-zone plant communities, is represented in only a few small reserves. Unless much larger areas can be protected soon, the scale of plant extinctions in the fynbos is likely to constitute one of the most serious biological losses on Earth in the next few decades. Finally, the Pafuri area of Kruger National Park is being considered for coking coal mining. On the one hand, Pafuri is ecologically the richest area of Kruger and contains many tropical species not found elsewhere in South Africa. On the other hand, the Pafuri coking coal reserves are sufficient for only about 10 or 15 years of exploitation, and South Africa already has coal reserves adequate for its own use for centuries and exports coal to other countries. The basic concept of a national park is an irrevocable assignment of land for protection of its resources in perpetuity. It would be ironic if South Africa, which played a leading role internationally in developing this concept, were now to take the lead in dismantling it at Pafuri.

Chlorinated dioxins and the environment

from Alastair Hay

WERE it not for the bacteria and fungi to be found in the soil, the chemical industry would be having a hard time of it. Most of the organic chemicals produced by manufacturers as herbicides and pesticides are degraded by soil microorganisms. But this is not true for all chemicals. When it comes to the degradation of the polychlorinated dibenzodioxins (PCDDs) it seems that bacteria cannot cope.

The best known of the PCDDs is the tetrachlorinated isomer 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). An unwanted by-product produced in the manufacture of 2,4,5-trichlorophenols TCDD is a stable compound. A temperature in excess of 800°C is required for its thermal degradation — but, more conveniently, TCDD can be subjected to photolytic degradation provided a hydrogen donor in the form of a suitable solvent is present.

But it is not just the stability of TCDD which causes problems; the chemical is also extremely toxic with an LD_{50} as low as $0.6\mu g\ kg^{-1}$ in the guinea pig. TCDD has also been shown to be a tetratogen and carcinogen in various animal species.

It is hardly surprising, therefore, that the discharge of 250–500g of TCDD over a populated area at the Italian town of Seveso in July 1976 should be a subject of concern. The chemical was vented directly into the atmosphere when a 2,4,5-trichlorophenol reactor overheated.

Studies performed by the US Air Force had suggested that soil bacteria are capable of degrading TCDD and that the half life of the chemical — depending on the bacteria present — was between 230 and 320 days (Young *et al.* USAFA-TR-76-18; 1976).

At Seveso however, the half life is much longer and considerably in excess of 10 years according to results presented at a recent workshop* by A. di Domenico (Istituto Superiore de Sanita (ISS), Rome). It seems that photolytic degradation of TCDD did occur at Seveso in the weeks following the discharge of the chemical from the reactor. This breakdown took place when the chemical was on surfaces exposed to sunlight. Within a couple of months, however, the TCDD had been washed from plant surfaces and percolated into the first few centimetres of topsoil, where it has remained ever since. Di Domenico claims that the soil concentrations of TCDD in the most heavily contaminated region of Seveso have changed little in the 4 years since the accident.

Further evidence of the poor biodegrad-

---

*A Workshop on the Impact of Chlorinated Dioxins and related compounds on the Environment; held at the Istituto Superiore di Sanita in Rome from 22 to 24 October, 1980. The proceedings of the workshop will be published as a book by Pergamon Press.

0028-0836/81/050351-02$01.00

ability of TCDD by microorganisms was provided by R. Hütter (Swiss Federal Institute of Technology, Zurich) and I. Camani (ISS, Rome). Both reported that they had not observed any microbial degradation of TCDD under laboratory conditions. A previous report by Matsumura and Benezet (*Environ. Health Perspect.* **5**, 253; 1973) had suggested that there were some microbial strains which would detoxify TCDD, albeit with a low efficiency.

The fact that TCDD is so resistant to breakdown by soil microorganisms could mean that other PCDD isomers are equally difficult to degrade. Unfortunately there has been practically no investigation of the persistence of these other isomers in the environment. That they occur as environmental pollutants, however, is beyond dispute. Several laboratories in Europe have reported the presence of PCDD isomers in the fly ash from municipal and industrial incinerators. Scientists at the Dow Chemical Company claim that they can also be detected in ash from household chimneys, cigarettes and even charcoal-broiled steaks (see *Nature* **281**, 619; 1979).

It is not entirely clear which compounds act as precursors of PCDDs in incinerators. According to O. Hutzinger (University of Amsterdam) the principal precursors are chlorinated phenols and polyvinyl chloride (PVC). Lignin too is a likely source, says Hutzinger, and it is conceivable that inorganic chlorine might be available in incinerators for the chlorination of dibenzodioxins. Dow scientists were the first to claim that chlorine from both inorganic and organic sources could be used in the formation of PCDDs.

Whilst there is a measure of agreement on the environmental sources of PCDD, there is a marked disagreement about the type of isomer obtained in fly ash. W. Crumment (Dow Chemicals, USA) claims that fly ash contains an equal distribution of PCDD isomers containing 4,5,6,7 and 8 chlorine atoms. The tetrachlorinated isomer 2,3,7,8-TCDD is the most toxic PCDD isomer and Dow is claiming that it is present in the ash in significant amounts. Others disagree. H.R. Buser (Swiss Federal Research Station, Wadenswiss) and R.L. Harless (Environmental Protection Agency, USA) both claim that TCDD only accounts for 1% of the PCDD content of fly ash from municipal incinerators. A. Liberti (Consiglio Nazionale delle Ricerche, Rome) reported that he had not observed an equal distribution of PCDD isomers in fly ash from municipal incinerators. According to Liberti, octachlorinated dibenzodioxin — many times less toxic than TCDD — was always present in the greatest concentrations, followed closely by heptachlorinated and hexachlorinated PCDD isomers.

Can anything be done to reduce the amount of PCDs produced in large incinerators? Apparently it can. There are two alternatives; either to reduce the amount of organic chlorinated compounds burned in incinerators, or to increase the efficiency of incineration. K. Olie (University of Amsterdam) pointed out that the PCDD content of fly ash from incinerators in Holland was 20 times higher than the content of fly ash obtained from Bratislava (Czechoslovakia) where far less PVC is incinerated. As for improvements in combustion efficiency, W. Crummett pointed out that by using extra fuel in an incinerator at the Dow Chemical Company the octachlorodibenzodioxin concentration in fly ash was reduced from 180–810 p.p.b. to 0.01–0.1 p.p.b.

High temperatures are a well recognized way of degrading PCDDs. Much less is known, however, about the biological degradation of these chemicals in mammals. TCDD is the only isomer whch has been studied in any detail and Poiger and Schlatter (*Nature* **281**, 706; 1979) have reported that the chemical is hydroxylated in the rat. Metabolism of TCDD also occurs in the dog and H. Poiger (University of Zurich) now believes that this metabolism is a means of detoxifying the chemical as the acute toxicity of the metabolite is at least 100 times lower than that of TCDD itself.

One of TCDD's more worrying properties is its ability to cause malformations in animals. H. Nau (Freie Universitat, Berlin) reported that when TCDD was administered to pregnant mice only very low concentrations of the chemical were found in the embryo and fetus between gestational days 11 and 18. TCDD concentrations in the fetus were between 0.04 and 0.14% of the maternal dose, two orders of magnitude lower than the concentration in maternal liver — the organ in which TCDD accumulation was greatest. Repeated doses of $5\,\mu g\ kg^{-1}$ on days 7–11 of pregnancy produced cleft palate in 65% of fetuses whereas $25\,\mu g\ kg^{-1}$ given as a single dose on day 7 caused cleft palate in only 16% of foetuses. There were two important conclusions to be drawn from these results said Nau. Firstly, the incidence of malformations clearly depends on the frequency of dosing, and secondly, only small amounts of TCDD are required to produce fetal abnormalities.

Detecting small amounts of TCDD in humans has always been a problem. With TCDD being lipid soluble a fat biopsy was the obvious method of choice. But biopsies have their limitations, particularly because they are uncomfortable for the donor. According to C. Rappe (University of Umea) this discomfort is no longer necessary for he has developed an assay for PCDDs using only 10 ml of blood plasma.

Workers employed in tanneries constantly handle hides whch have been treated with pentachlorophenol preservatives. Rappe examined workers recently exposed to pentachlorophenol or who had been exposed 6 months previously. The results showed that pentachlorophenol is cleared from plasma when the individual is no longer exposed to the chemical. But the picture is quite different for the PCDDs which contaminate pentachlorophenol. These are far more persistent and are only cleared from plasma at a very slow rate.

Rappe's new assay will have considerable repercussions for those concerned about the health of individuals exposed to PCDDs. It will now be possible to measure the PCDD levels of workers exposed to the chemical in industry and to set more rigorous health standards. Blood measurements will be essential for interpreting clinical symptoms following individual exposure to PCDDs. In the longer term they may even assist in assessing the risk to humans of TCDD causing malformations or cancer. □

REVIEW ARTICLE

The origin of human cancers

John Cairns*

Imperial Cancer Research Fund, Burtonhole Lane, London NW7 1AD, UK

The limited evidence available suggests that most human cancers are not caused by conventional mutagens but are more likely to be the result of genetic transpositions. Although the molecular biology of transposition is starting to be understood, the external factors that influence its frequency have not yet been studied in any detail.

DIFFERENT human populations tend to suffer from different kinds of cancer: the inhabitants of third world countries have an excess of liver cancer, those of western nations have an excess of cancer of the breast and colon, the Japanese have an excess of stomach cancer, and so on. Most of this variation must be due to varied diets, customs and environment rather than to differences in genetic constitution, because nations have been observed to undergo changes in cancer incidence from one generation to the next and migrant populations tend to take on the pattern of cancer that is characteristic of their new homes. Cancer is therefore thought to be a preventable disease.

In the western world the two commonest cancers are cancer of the skin and the lung, and each of these happens to be so strongly dependent on a single factor (that is, sunlight and smoking) that their cause could be identified without the need for any understanding of the underlying mechanism of carcinogenesis. The preventable causes of the other common cancers are less clear-cut and it may be difficult to identify them until much more is known about mechanism. Eventually the techniques of nucleic acid chemistry should allow us to itemize all the differences in nucleotide sequence and gene expression that distinguish a cancer cell from its normal counterpart, and perhaps at that point the steps involved in carcinogenesis will cease to be in doubt. But until then we have to be content with circumstantial evidence. This review discusses the evidence and makes certain deductions about the molecular biology of human cancer.

Experimental carcinogenesis

Much of cancer research is based on the reasonable premise that we should be able to learn about human cancer by studying carcinogenesis in animals. During the 65 years since coal tar was shown to be carcinogenic for the skin of rabbits, many ways have been found for producing cancer in experimental animals. The problem is to decide which of these very diverse forms of carcinogenesis is likely to be the best model for most human cancers.

The easiest and most widely studied method is to expose the chosen target in the animal to physical or chemical agents that damage DNA. Because the carcinogenic potency of such agents is fairly well correlated with their ability to cause point mutations[1-3], these forms of cancer are commonly assumed to arise as the result of local changes in DNA sequence (in the rest of this article, the words 'mutation' and 'mutagen' are used specifically for such local changes). However, the process cannot be quite as simple as that. In most cases, repeated doses of the mutagen have to be administered over an appreciable fraction of the animal's lifespan, and in those few situations where a single dose of mutagen is carcinogenic the resulting cancer usually does not appear for a long time[4]. Thus the creation of a cancer cell is thought to involve a sequence of events of which perhaps only the early steps bear any direct relation to the interaction between mutagen and DNA. This is borne out by the observation that the later events can be caused by other agents ('promoters') that are not themselves mutagenic. The conventional explanation is that 'initiation' represents the production of mutants and that the subsequent steps of promotion are required because the relevant mutations either happen to be recessive (and so will only be detectable following deletion or somatic recombination) or usually involve repressor genes (and so are not expressed until the existing stock of repressor molecules has been depleted by further cell multiplication). But this type of interpretation is not without difficulties. The first step in the sequence seems to be too efficient[5-7]; in certain situations, even quite low doses of mutagen are capable of initiating the process in almost every exposed cell. Conversely, the later steps seem to be too sluggish[8,9]; in several instances, more than 10 cell divisions may be needed following initiation to achieve expression of the new phenotype in any of the descendent cells.

Cancers can arise following infection with certain viruses. Here the explanation seems at first sight more straightforward, for it is easy to see how novel phenotypes could result from an interaction between the genes of a virus and those of the host. However, the interval between initial infection by the virus and final appearance of the cancer can be a large fraction of the animal's lifespan[10], and so even here the exact biology of the carcinogenic process may sometimes be quite as obscure as in most chemical carcinogenesis.

Cancers can also be produced in animals by transplanting certain tissues, such as ovary[11] or embryo[12], into special sites where the cells can multiply without restraint; similarly, cancers may arise in the tissues next to implanted sheets of plastic, apparently because the cells have lost the restraining influence provided by contact with each other[13]. It seems unlikely that any conventional form of mutation can play a part in these types of carcinogenesis, particularly as the cancer cells produced by transplantation can sometimes be restored to a normal, regulated pattern of growth by transplantation back to more demanding sites[14-16].

Lastly, a number of cancers have been observed to arise spontaneously in animals that are given unlimited food, but not

in animals whose intake of calories has been slightly restricted[17]. The mechanism of carcinogenesis by these few extra calories is completely obscure.

Those seem to be the main ways of causing cancer in animals. It is not obvious what, if anything, they have in common, and in the absence of any additional source of information we could therefore have no way of knowing which of these experimental cancers are the best models of the common human cancers; and if we do not know that, we cannot guess what class of environmental agent is likely to be the most important factor in causing human cancer.

The genetics of susceptibility to cancer

When the precise chemistry of any biological process is in doubt, it has usually been helpful to determine what kinds of mutation affect the process. This stratagem has been applied successfully in working out various metabolic pathways and in identifying many of the components involved in the synthesis of macromolecules, and it would seem to be the surest way of finding out what classes of biochemical event tend to be rate-limiting for human carcinogenesis. The method is, however, subject to certain logical restraints.

(1) When the main effect of a mutation of a multicellular animal is to alter the phenotype of one particular class of cells, the fact that it also raises the incidence of cancer in these cells may not be relevant when we come to consider the cause of other cancers. For example, some forms of inherited immunodeficiency are associated with an increased incidence of certain rare cancers arising in cells of the immune system[18]; obviously, this tells us little or nothing about the origin of the common cancers in other tissues.

(2) In general, mutations that increase the incidence of any cancer should be interpreted with some caution. Going back to the previous example, it is conceivable that the leukaemias and lymphomas of immunodeficient children arise by some special pathway, so that they may not even be a good model for the leukaemias and lymphomas that occur in normal subjects.

(3) The most informative mutations are usually those that stop things from happening. For example, mutations that block the induction of aryl hydrocarbon hydroxylase make mice more sensitive to the short-term toxicity and less sensitive to the long-term carcinogenicity of certain polycyclic aromatic hydrocarbons[19,20]. If we could show that similar mutations in humans lowered the incidence of any of the common cancers, this would suggest that these compounds are important in human carcinogenesis. So far, however, such studies in human populations have been inconclusive[21,22].

(4) In practice, much of our information may have to come from negative evidence. For instance, if a mutation that completely blocked the metabolism of certain potential carcinogens had no effect on the incidence of cancer, this would constitute very strong evidence that these chemicals and their metabolic products were probably not important. In fact, the first case we shall consider is an example of negative evidence.

If the conventional dogma is correct and cancer is usually initiated by localized somatic mutations produced by the chemical mutagens in our environment, we would expect inherited defects in DNA repair to have a marked effect on the incidence of the common cancers. Yet this turns out not to be true. The test case is the disease called xeroderma pigmentosum (XP). This arises when both copies of any one of the genes involved in the main pathway for excision repair contain an inherited defect[23,24]. The result seems to be equivalent to the effect of the *uvr* mutations of *Escherichia coli* and *Salmonella typhimurium*, which make these bacteria into exquisitely sensitive tester strains for most chemical carcinogens. Like such bacteria, the cells of XP patients have a defect in DNA excision that makes them up to 10 times more sensitive to the lethal[25-32] and mutagenic[33-38] effects of most mutagens (the main exceptions being X rays and certain simple alkylating agents). As a result of this defect, XP patients are extremely sensitive to UV light. They suffer an age-specific incidence of skin cancer that is several thousand times higher than normal and they frequently die from malignant melanoma; as these skin cancers arise on the exposed parts of the body, they are presumably the result of mutations induced by UV light in the basal cells of the skin, perhaps coupled with some radiation damage to the local immune system of the skin[39]. Yet, even though the repair defect of XP patients extends to all the tissues that have been tested and apparently affects the response to all bulky lesions and major distortions of the double helix[24], it does not result in any obvious increase in the common fatal cancers (such as cancer of the lung, alimentary canal and breast). This is a striking anomaly, but it seems to have been pointed out only once before[40]. For example, not one death from internal cancer was recorded in any of the published clinical reports on series of XP patients[41-50] summarized in Table 1; and a survey of the entire literature on XP for the past 40 years[51] (which included a search through 6 years of US death certificates[52] and therefore must comprise many hundreds of cases) has revealed only seven internal neoplasms and only two or three deaths from cancers that could not have been caused by sunlight. Now, it is possible at this point to indulge in some special pleading—by arguing, for example, that XP patients do not live long enough to experience the common internal cancers which, for some as yet unknown reason, cannot be brought forward in time as readily as skin cancers. But the most reasonable conclusion is that the commonly fatal cancers are not caused by the kind of lesions of DNA that XP patients (and bacterial *uvr* mutants) are specifically unable to repair.

That conclusion is strengthened when we consider Bloom's syndrome; an inherited disease that apparently does increase the incidence of the common cancers. Its molecular biology is not understood, but the disease is associated with a high frequency of chromosomal aberrations and exchanges[53,54]. (Interestingly, the patients' cells do not show any very marked increase in sensitivity to various mutagens[24].) From a registry of cases it has been possible to calculate very crude estimates of 'life-tables' and of relative risk for carcinomas and for leukaemias and lymphomas (Fig. 1, Table 1). We see that the death rate from cancer is raised about 100-fold in each age group (Table 1). This demonstrates that it is possible to observe such increases in risk even when the number of subjects is small and their lifespan very limited; for XP, where the numbers are greater and lifespan is somewhat longer, it should have been even easier; in this sense, therefore, Bloom's syndrome serves as a control. (Two other inherited diseases, Fanconi's anaemia and ataxia telangiectasia, are associated with chromosomal instability, and they too show a high incidence of leukaemia; however, the published reports are not sufficiently detailed for the calculation of life tables.)

Comparison of the clinical records for XP and Bloom's syndrome therefore leads to the following conclusions. (1) For most people the main source of mutagenic lesions in DNA is UV light. (2) Chemical mutagens (of the kind detected in the usual tests for mutagenicity) seem unlikely to be the rate-limiting components in most human carcinogenesis. (3) Large-scale changes in the genome (such as rearrangements and deletions) seem to be more hazardous than the local changes produced by conventional mutagens.

The karyotype of human cancers

If genetic rearrangement or deletion is a critical step in the formation of most human cancers, the change might often be large enough to produce a visible alteration in chromosomal anatomy. Unfortunately, it is not easy to obtain good metaphase spreads for the cancer cells in solid tumours, and so most studies of karyotype have been confined to the leukaemias[55] and to a few solid tumours, such as meningiomas[56] and gliomas[57], which contain neoplastic cells that grow readily *in vitro*. In these diseases, visible chromosomal rearrangements have proved to be more the rule than the exception, and for many cancers the karyotype has actually been observed to become progressively abnormal with time. It is therefore clear that at least the later stages in development of cancers are usually associated with large-scale changes in the genome.

For obvious reasons, much less is known about the earlier stages of carcinogenesis. About 90% of chronic myeloid leukaemias show a translocation from chromosome 22 to 9, which creates the characteristically shortened 22 known as the Philadelphia chromosome[58]; in several instances[59-61] the translocation has been observed to be present quite early in the sequence of events leading to the leukaemia, suggesting that it was primarily this alteration that allowed the precancerous stem cell to multiply without restraint and gradually colonize most of the bone marrow. (The exceptional cases of chronic myeloid leukaemia that do not have the translocation run a distinctly less favourable clinical course[62], and so they can probably be classified as a different kind of cancer, brought on by a different sequence of events.) Similarly, patients with ataxia telangiectasia are often found to be harbouring an expanding clone of lymphocytes with a translocation affecting chromosome 14 (refs 63, 64) and the lymphatic leukaemia which commonly occurs in these patients apparently develops within these clones. (Interestingly, myelomas and one class of lymphomas may also show translocations to chromosome 14 (ref. 65).) Those are the clearest examples where a particular change in karyotype appears to be an essential, early step in carcinogenesis. Of course, it is possible that still earlier in each of those sequences some crucial step occurred that made inevitable the subsequent emergence of cells bearing these particular rearrangements. For example, benign meningiomas have often been observed to be diploid in their early stages[66], and it is only later that they tend to be dominated by a characteristic cell that has lost one chromosome 22 (ref. 56); and there are certain kinds of cancer, such as acute myeloid leukaemia, that sometimes maintain an apparently normal karyotype throughout the whole course of the disease[66].

These studies of karyotype can therefore be interpreted in one of two ways. The obvious conclusion is that large chromosomal rearrangements are usually the crucial steps in carcinogenesis, but that there are exceptions and in certain classes of cell the critical changes either are not rearrangements or are on too small a scale to be detected by chromosomal banding techniques. It is, however, possible to argue that the cellular environment within any growing cancer is very abnormal and applies strong selection pressure for very unusual phenotypes, and these are most easily generated by large-scale rearrangements of the genome; the observed changes in karyotype could therefore be trivial secondary events that occur after all the rate-limiting steps of carcinogenesis have been completed.

The evolutionary analogy is worth pursuing a little further. The normal architecture and programmes of cell renewal in multicellular animals seem to be so arranged that the various multiplying stem cells do not, as a rule, compete with each other for territory[67]. For example, it is clear from studies of X-chromosome mosaicism that adult human tissues are made up of a large number of very small families of cells which therefore cannot be undergoing clonal selection[68,69]; similarly, the haematopoietic stem cells that circulate in the blood of mice are capable of establishing themselves in the marrow and forming clones of descendants, but they will only do so if the resident stem cells occupying the available sites in the marrow have been killed[70]. So one of the crucial steps in the development of a cancer must be the change that allows a stem cell to compete favourably with its neighbours and form an expanding clone within which further natural selection can then take place. We should therefore consider the possibility that the formation of a cancer proceeds by the same mechanism as the evolution of a new species. In other words, we might expect normal non-cancerous cells to be like species that are not evolving quickly: they will accumulate local alterations in base sequence and amino acid sequence due to forced or unforced errors in DNA replication, but these will tend to be neutral and have little effect on phenotype[71]. In contrast, a family of cancer cells should be like a species that is undergoing a rapid evolution in morphology. Such evolution is now thought to be due mainly to pleiotropic changes in the regulation of gene expression that are the result of large-scale alterations in gene arrangement and chromosome constitution[72,73]. In short, the analogy with evolution would predict that cancer should usually be due to gene rearrangements rather than to the local changes in sequence produced by conventional mutagens. Before considering what is known about the molecular biology of such rearrangements, it is worth examining the other half of the proposition, namely that carcinogenesis by conventional mutagenesis is not making a major contribution to the national incidence of cancer.

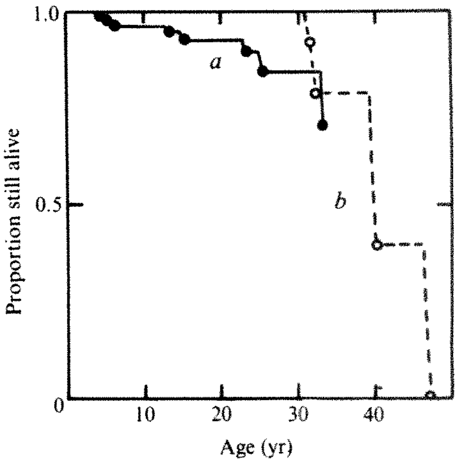

Fig. 1 Life tables for patients with Bloom's syndrome. The calculations have been based on a collection of 89 cases (J. German, unpublished), 12 of whom have died of cancer. *a*, Proportion who have not yet died of leukaemia or lymphoma; *b*, proportion who have not yet died of carcinoma.

Mutagenesis and cancer

It seems clearly established that localized lesions in DNA can be carcinogenic: for example, pyrimidine dimers must be the cause of the skin cancers produced when animals are irradiated with UV light, because the cancers can be prevented by photoreversal with visible light (a reaction that seems to be specific for dimers)[74]; similarly, the formation of O^6-alkylguanine in DNA is apparently the basis for carcinogenesis by certain alkylating agents because the cancers tend to be confined to the tissues that are unable to repair that particular lesion[75,76]. So the issue is not simply whether conventional mutagens are capable of causing cancer, but whether they reach our cells in sufficient quantity to make a major contribution to our present national incidence of cancer. In short, it is a question of the balance between dose of mutagens and the efficiency of our various pathways for DNA repair.

Although skin cancer due to UV light is the commonest cancer in western nations, it is seldom fatal and accounts for only 1% of all cancer deaths. But when there is a defect in the relevant DNA repair pathway (as in XP) the age-specific incidence of skin cancer can be raised several thousandfold and life-expectancy drop to about 20; this shows the extent to which an efficient system of repair is protecting us against one of the major hazards of our environment. Similarly, the repair pathway that handles the lesions produced by X-ray irradiation seems to be equally effective, because only about 1% of all cancer deaths are believed to be attributable to the natural sources of ionizing radiation[77]. Presumably there has always been strong selection pressure for adequate methods of DNA repair, and so it is hardly surprising to find such low levels of risk from agents like UV light and X rays, which have not changed in intensity for millions of years.

There are reasons for thinking that our exposure to the chemical mutagens in our environment is now actually somewhat less than it used to be. The argument runs as follows[78]. Experimental animals tend to show a rather limited range of responses when mutagens are added to their diet; a few, very reactive chemicals produce cancer of the oesophagus and stomach, but most mutagens produce cancer of the liver. In humans, however, liver cancer accounts for only 1% of the cancer deaths in countries like the United States and Europe; oesophageal cancer is not very common outside certain parts of Africa, Iran and China; and stomach cancer is on the decline in all industrialized nations. So it seems likely that when affluence brings us the opportunity to choose what we eat, we tend to avoid foods heavily contaminated with mutagens and are therefore able to stay well within the capabilities of our DNA repair pathways. Actually, even in undeveloped countries the level of exposure to chemical carcinogens seems to be within most people's capacity for repair; in Africa, for example, the liver cancer caused by aflatoxin is largely confined to people chronically infected with hepatitis B virus[79], which indicates that although aflatoxin is known to be one of the most potent carcinogens for certain experimental animals it is not present in a high enough concentration even in Africa to produce many cancers in normal people.

So much for the 'natural' mutagens in our environment. Fortunately, the novel unnatural mutagens that we have met in the first half of this century as a result of our industrialization seem to be no more powerful than the natural ones[80]. Occupational cancers probably account for less than 5% of all cancer deaths[81]; and the number attributable to mutagenesis is actually less than this because a large proportion of today's occupational cancers are due to asbestos, which is negligibly mutagenic[82] although it is known to produce chromosomal abnormalities[83]. These numbers are, of course, trivial compared with the effect of tobacco. This has proved to be the outstanding carcinogen of the twentieth century and is now responsible for about a third of all cancer deaths. But it is not at all clear that these cancers can be classified as due to mutagenesis. Although cigarette smoke condensate contains mutagens[84], it is much more powerful as a promoter than an initiator in experimental carcinogenesis[85,86]. Furthermore, if tobacco were mainly acting as a mutagen, there should have been some reports of lung cancer in XP patients; after all, strong sunlight (which in normal people is about as carcinogenic as heavy smoking) can produce skin cancer in these patients by the time they are 7 years old, and so smoking should have given some of them lung cancer by the time they are 30.

Table 1 Deaths from internal cancers

	Bloom's syndrome*			Xeroderma pigmentosum‡	
		obs./exp.†			obs./exp.
Age	Patient years	Leukaemias and lymphomas	Carcinomas	Patient years	All cancers (excl. skin)
0–4	340	1/0.013	0/0.017	640	0/0.059
5–14	640	3/0.020	0/0.019	886	0/0.055
15–24	327	2/0.011	0/0.016	450	0/0.036
25–34	108	2/0.005	2/0.013	213	0/0.035
35–44	16		1/0.008	109	0/0.038
45–54	3		1/0.005	54	0/0.107
Totals		12/0.127			0/0.330

The observed values were obtained from various clinical reports. For Bloom's syndrome the estimates are probably fairly reliable, because the condition is very rare and so the fate of each case is usually followed rather closely; of these 89 cases, 17 are known to have died (12 from cancer). Because XP is much less rare, cases tend to be reported but not followed up, and so the existing literature may be used to give some idea of their incidence of cancer but will give an underestimate of their death rate. During the limited period when these 140 cases were observed, 71 had had skin cancer (which was fatal in 8 cases), 1 had had a brain tumour and 1 had chronic myeloid leukaemia.

*89 cases (J. German, unpublished).

†Expected values were calculated from the current age-specific cancer death rates in England and Wales.

‡140 cases reported in refs 41–50.

All these arguments are indirect, but they do suggest rather strongly that local changes in DNA sequence, produced by conventional mutagens, are probably making only a minor contribution to our national death rates.

Genetic transposition as a cause of cancer

In the last decade, the routes leading to genetic diversity have become much better understood[87,88]. Diffusion of heritable information is now known to occur not only by 'legitimate' recombination between homologous regions of different genomes, but also by 'illegitimate' recombination between largely nonhomologous regions (which can be in different parts of the genome or even in different individuals). The second of these processes is equivalent to a chromosomal rearrangement and allows the shuffling of certain modules of information ('transposons') so that new combinations of genes can be tested for survival advantage. The process depends on the presence of certain short sequences in the DNA that are the substrates for various recombinational enzymes ('transposases'), and it represents a much more drastic form of genetic variation than localized changes in base sequence because it can alter the expression of whole regions of the genome.

Transpositions can be site specific (for example, the changes in surface antigens of *Salmonella* and certain trypanosomes) or nonspecific (such as the spread of antibiotic resistance between different bacteria); they are usually solitary, but they can occur in clusters; and their frequency can vary from 1 per cell division down to 10^{-10}. A transposon can be the substrate for a transposase encoded elsewhere in the genome or it can make its own specific transposase. As the result of moving to a new site, a transposon can start or stop being transcribed; but the main effect can be not on itself so much as on neighbouring genes, which can be turned on or off or made unstable by its presence.

Transposition is therefore a very special form of genetic regulation because it can be programmed to occur at any predetermined rate, can be concerned with any desired number of alternative states, and can be made virtually irreversible. For example, the switch in the mating type of yeasts is the result of a transposition which occurs at a rate that is itself under separate genetic control[89]; but the change has all the characteristics of a step in differentiation because it concerns the function of a large number of genes but normally is confined to one particular branch of the cell lineage (the mother cells, rather than the buds)[90]. It is not yet clear whether transposition is important in vertebrate development. As the result of certain experiments on nuclear transplantation, there has been a tendency in recent years to regard the nuclei of the somatic cells of vertebrates as totipotential and therefore not fundamentally different from the germ line[91]. However, the fact remains that although it is easy to produce a normal animal using the nucleus taken from a fertilized egg or an early blastula cell, no one has ever succeeded in producing a normal animal using the nucleus taken from a somatic cell of an adult. It is therefore quite conceivable that changes in gene arrangement do occur during vertebrate development, especially as it is now known that antibody diversity is generated by specific transpositions that occur during the differentiation of B lymphocytes[92,93].

As pointed out in the earlier sections of this review, there are good reasons for believing that the steps leading to human cancer are more likely to be transpositions than localized changes in sequence. It is therefore important to find out what classes of external agents or features of cellular behaviour raise the frequency of such transpositions. Interestingly, conventional mutagens often appear to have no effect. Indeed, it was the inability of any mutagen to raise the spontaneous reversion rate of certain forward mutations in *E. coli* that initially marked out these mutations as being unusual[94] and eventually led to the discovery that they were due to the movement of insertion sequences; similarly, the movement of certain transposable elements in yeast has been found to occur 'spontaneously' but does not appear to be strongly catalysed by any of the common mutagens[95]. However, rates of transposition can be influenced by external factors. For example, transpositions are only a minor cause of mutation in rapidly multiplying bacteria[96], but they are a major source of forward mutations in stationary cultures[97]; the growth of *Drosophila* cells *in vitro* leads to the proliferation of certain repetitive sequences[98]; the frequency of the transpositions that produce variegation in *Drosophila* and in *Antirrhinum* petals is inversely related to temperature[99,100]; and the integration of a tumour virus can be associated with transpositions in the neighbouring host DNA[101]. Lastly, many mutagens are known to cause sister chromatid exchanges and other chromosomal interactions in mammalian cells, although it is not always clear to what extent these gross changes are functionally equivalent to genetic transpositions.

The assay of mutagens using bacterial tester strains has been one of the most fruitful practical results of molecular genetics. Its success stems from the fact that the chemistry of DNA is the same for all forms of life and so the chemistry of mutagenesis (and of repair) also tends to be the same. The molecular biology of transposition promises to be more idiosyncratic. The transposable genetic elements were discovered by McClintock[102] in 1950 and their possible role in carcinogenesis was first discussed by Temin[103] in 1970, but it is still too early for there to have been much systematic molecular biological investigation of the factors that trigger transpositions, either in prokaryotes or in eukaryotes. The rate of movement of most transposons will have been subject to evolutionary pressures and many transposons will therefore have acquired their own individual controls. Thus it may not be a simple matter to devise a general assay for the factors that drive the carcinogenic transpositions.

I thank Errol Friedberg, Richard Peto, Jeffrey Miller, Julian Gross and Bryn Bridges for useful advice and discussion, James German and Kenneth Kraemer for unpublished information about patients with Bloom's syndrome and XP, and David Roberts for a literature search for clinical reports on XP.

Thermodynamic stability and kinetics of perovskite dissolution

H. Wayne Nesbitt, G. Michael Bancroft, William S. Fyfe, Suresh N. Karkhanis & Akio Nishijima

Perovskite, a SYNROC host mineral for nuclear wastes, is thermodynamically unstable in natural waters and in association with common minerals. Leach experiments demonstrate that $CaTiO_3$ (perovskite), $SrTiO_3$ and $BaTiO_3$ are as reactive as some silicate glasses below 100 °C, but leach much more slowly than glasses above 100 °C.

THE use of titanates and zirconates as hosts for nuclear waste in the SYNROC process has recently been proposed[1,2]. Three minerals are used as hosts—perovskite ($CaTiO_3$), Ba-hollandite ($BaAl_2Ti_6O_{16}$) and zirconolite ($CaZrTi_2O_7$). SYNROC relies heavily on geological and geochemical observations in selecting stable host minerals. Although the SYNROC minerals are not thermodynamically compatible with some siliceous rocks, the minerals are considered likely to be thermodynamically stable in the presence of water. Moreover, it has been reported that these minerals are kinetically stable in extreme hydrothermal conditions (up to 900 °C and 5,000 bar), and are thus vastly more stable to leaching than borosilicate glasses[1,2].

We report here thermodynamic calculations and leaching kinetics from 25 °C to 300 °C on the simplest of the three SYNROC minerals, perovskite, and its Sr and Ba analogues. Perovskite is suitable for such a thermodynamic and kinetic study because its dissolution reactions are simple, and the thermodynamic data for perovskite and its reaction products are known for a wide range of temperatures. By comparison with glasses, the leach rate of perovskite and its analogues is very insensitive to temperature, due to an interesting combination of the thermodynamics and kinetics of $MTiO_3$ (M = Ca, Sr, Ba) dissolution.

Thermodynamic stability

We first consider the thermodynamic stability of perovskite in the presence of the most common silicates, and then consider the three most likely reactions of perovskite in natural waters.

The plagioclase and alkali feldspars are the most abundant minerals in the Earth's crust followed by quartz (and polymorphs) and orthopyroxenes. These three mineral groups contain 50 mol % SiO_2 or more and constitute between 80 and 90% of all minerals present in the crust[3]. Perovskite stability in the presence of these siliceous minerals must be considered for they may react directly or indirectly (via a fluid) with the titanate.

Consider the reactions:

$$\underset{\text{perovskite}}{CaTiO_3} + \underset{\text{quartz}}{SiO_2(c)} \rightleftharpoons \underset{\text{sphene}}{CaTiSiO_5} \qquad (1)$$

$$\underset{\text{perovskite}}{2\,CaTiO_3} + \underset{\text{plagioclase}}{NaAlSi_3O_8} \rightleftharpoons \underset{\text{sphene}}{2\,CaTiSiO_5} + \underset{\text{nepheline}}{NaAlSiO_4} \qquad (2)$$

$$\underset{\text{perovskite}}{CaTiO_3} + \underset{\text{alkali feldspar}}{KAlSi_3O_8} \rightleftharpoons \underset{\text{sphene}}{CaTiSiO_5} + \underset{\text{leucite}}{KAlSi_2O_6} \qquad (3)$$

$$\underset{\text{perovskite}}{CaTiO_3} + \underset{\text{orthopyroxene}}{2\,MgSiO_3} \rightleftharpoons \underset{\text{sphene}}{CaTiSiO_5} + \underset{\text{olivine}}{Mg_2SiO_4} \qquad (4)$$

The thermochemical data for these phases[4] have been used to calculate the free energies for each of the reactions (ΔG^0_R) at various temperatures. The free energies of all reaction are negative at 25 °C indicating that sphene is stable relative to perovskite in the presence of quartz, feldspars and orthopyroxenes. The ΔG^0_R values become progressively more positive at higher temperatures but all values remain more negative than −10 kJ even at 900 °C. The incompatibility of perovskite and quartz, orthopyroxene and particularly feldspar severely restricts the repository or vault type if this potential for perovskite alteration is to be minimized. Virtually all plutonic and most volcanic rocks would have to be discarded for they generally contain feldspars and/or orthopyroxene. The only igneous rocks suitable would be low Si, high Ca rocks such as those given by Carmichael *et al.*[5]. Alternatively, non-siliceous rocks such as evaporite deposits and carbonates would minimize this source of potential alteration.

Kaolinite [$Al_2Si_2O_5(OH)_4$] is one of the most common clay minerals produced by weathering of aluminous silicates (such as feldspars) near the Earth's surface[6]; hence it is an important constituent of many muds, mudstones, shales and argillaceous rocks. Perovskite stability in its presence can be determined from:

$$\underset{\text{perovskite}}{CaTiO_3} + \underset{\text{kaolinite}}{\tfrac{1}{2}Al_2Si_2O_5(OH)_4} + \underset{\text{water}}{\tfrac{1}{2}H_2O} \rightleftharpoons \underset{\text{sphene}}{CaTiSiO_5} + \underset{\text{gibbsite}}{Al(OH)_3} \qquad (5)$$

The free energy of the reaction is negative at low temperature indicating that clay minerals can supply sufficient SiO_2 to destabilize perovskite. The result demonstrates that even shales and argillaceous rocks would be inadequate vaults in that they provide the potential for perovskite alteration. Ringwood *et al.*[1,2] recognized the incompatibility of quartz and perovskite and they emphasized that thermodynamically compatible geological materials should be used for vaults. The above calculations emphasize that the choice of suitable host rocks is much more restricted than they suggested—if thermodynamic stability dictates the choice.

Experimental evidence shows that perovskite does react with common minerals at measurable rates. Schuiling and Vink[7] studied the hydrothermal stability of perovskite in the presence of siliceous minerals. The results agree with the above calculations. Furthermore, they converted at least 5% of the perovskite to sphene in only 3 weeks (700 °C, 1,000 bar pressure), as this amount is required for positive detection by X-ray diffraction. Their studies demonstrate that perovskite is unstable in the presence of quartz, feldspars and orthopyroxene.

0028–0836/81/050358—05$01.00

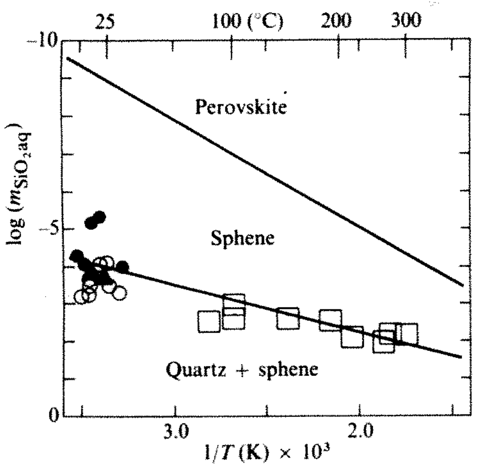

Fig. 1 log $m_{SiO_2(aq)}$ plotted against $1/T$ for reaction (6). The m_{SiO_2}. T values are plotted for groundwaters emanating for dunites and peridotites (●), serpentinites (○), limestones (△) and hydrothermal waters (□). These all plot very close to the lower solid line representing solutions saturated with quartz.

Aqueous solutions are almost ubiquitous in the crust, even to great depths[8] and of all interactions involving perovskite, reaction with subsurface waters are most likely; consequently the stability of perovskite in natural groundwaters must be investigated. Two reactions limit the stability of perovskite. One is

$$\underset{\text{perovskite}}{CaTiO_3} + \underset{\substack{\text{aqueous}\\\text{silica}}}{SiO_2(aq)} \rightleftharpoons \underset{\text{sphene}}{CaTiSiO_5} \qquad (6)$$

where

$$\log K_6 = -\log[SiO_2(aq)] \qquad (7)$$

Square brackets denote activities. The $\Delta G^0_{R(6)}$ and $\log K_6$ values were calculated and the equilibrium aqueous silica concentrations plotted against the inverse of temperature (Fig. 1). Groundwaters emanating from dunites, peridotites[9,10], serpentinites and limestones as well as hydrothermal waters have been plotted and all fall within the sphene stability field. Perovskite is unstable in these waters. Quartz solubility is given by

$$\underset{\text{quartz}}{SiO_2(c)} \rightleftharpoons \underset{\text{aqueous silica}}{SiO_2(aq)} \qquad (8)$$

where

$$\log K_8 = \log[SiO_2(aq)] \qquad (9)$$

The lower solid line (Fig. 1) represents solutions saturated with respect to quartz.

Carbon dioxide is dissolved in most natural groundwater[11] and is one of the most abundant gases dissolved in hydrothermal waters[9]. Carbon dioxide in natural waters (carbonic acid) may enhance the thermodynamic and kinetic instability of perovskite as shown below

$$\underset{\text{perovskite}}{CaTiO_3} + CO_2(g) \rightleftharpoons \underset{\text{rutile}}{TiO_2} + \underset{\text{calcite}}{CaCO_3} \qquad (10)$$

For this equilibrium relation

$$\Delta G^{\circ}_{R(10)} = -RT \ln K_{(10)} = +RT \ln P_{CO_2} \qquad (11)$$

Both the $\Delta G^{\circ}_{R(10)}$ and the equilibrium carbon dioxide pressure (P_{CO_2}) have been evaluated. The logarithm of the equilibrium partial pressure has been plotted against the reciprocal of temperature (Fig. 2). Some near-surface groundwaters from limestones[11] and from some ultramafic rocks[12] plot well within the rutile + calcite field. White *et al.*[11] compiled typical groundwaters emanating from a large variety of igneous, metamorphic and sedimentary rocks and all have P_{CO_2} values sufficiently high to alter perovskite to the much more stable (and common) assemblage, calcite + rutile. The calculations demonstrate that perovskites are generally unstable in CO_2-bearing groundwater and hydrothermal waters. Limestones and dolomites would, therefore, be unsatisfactory repository materials at least in environments where the temperatures are < 200 °C.

Table 1 Weight loss and Ca^{2+} leached into solution* for perovskite single crystal

	Conditions	Weight loss (μg)	Total Ca^{2+} (μg)	Leach rate† ($kg\ m^{-2}\ s^{-1}$)
I	300 °C, 1 week	500	430	8.9×10^{-9}
II	300 °C, 2 weeks	100	54	5.6×10^{-10}
III	100 °C, 1 week	220	94	2.2×10^{-9}

* This single crystal from Magnet Cove, Arkansas, weighed ~120 mg and had a ~0.8 cm^2 geometric surface area. The electron probe analysis of this sample showed it to be homogeneous and gave the analyses: 38.9% CaO, 42.3% TiO_2, 7.8% Nb_2O_5, 5.9% FeO, 1.2% Al_2O_3 and 0.8% SiO_2 (total 96.9%). The high Fe and Nb analyses are common for perovskites in carbonatites from Magnet Cove[13]. The remainder of the analysis is most likely rare earths[13]. A few extremely small inclusions of apatite were also seen, and analysed by the probe.

† Based on Ca^{2+} leached into solution. $kg\ m^{-2}\ sec^{-1} = 1.16 \times 10^{-4}\ g\ cm^{-2}\ day^{-1}$.

A third reaction also influences perovskite stability:

$$\underset{\text{perovskite}}{CaTiO_3} + H_2O(l) \rightleftharpoons Ca^{2+}_{(aq)} + \underset{\text{rutile}}{TiO_2} + 2\,OH^-_{(aq)} \qquad (12)$$

and when recast using hydrogen ions is

$$\underset{\text{perovskite}}{CaTiO_3} + 2\,H^+ \rightleftharpoons Ca^{2+}_{(aq)} + \underset{\text{rutile}}{TiO_2} + H_2O(l) \qquad (13)$$

Both the $\Delta G^{\circ}_{R(13)}$ and the equilibrium constant (K_{13}) have been calculated where

$$\log K_{13} = \log [Ca^{2+}]/[H^+]^2$$

Square brackets denote activities; activities of the solids and $H_2O(l)$ are taken as unity and the thermodynamic data is from Robie *et al.*[4] and Helgeson[10].

Equilibrium diagrams which include the relations of equations (6) and (13) have been constructed for 25 °C. Figure 3 delineates the stability of the three Ti-rich solids (plus amorphous silica) in the presence of aqueous solutions. Perovskite is stable only in groundwaters of very high $[Ca^{2+}]/[H^+]^2$ values ($> 10^{18.3}$) and very low aqueous silica values ($< 10^{-9}$). Solution compositions typical of near-surface ground waters in igneous rocks (ref. 12, Tables 1, 2 and 3) have been plotted (Fig. 3). Waters derived from limestones, dolostones and evaporites (data from ref. 12, Tables 6, 7 and 8) plot in the same region. As Fig. 3 shows, natural waters are too rich in $SiO_2(aq)$ and have

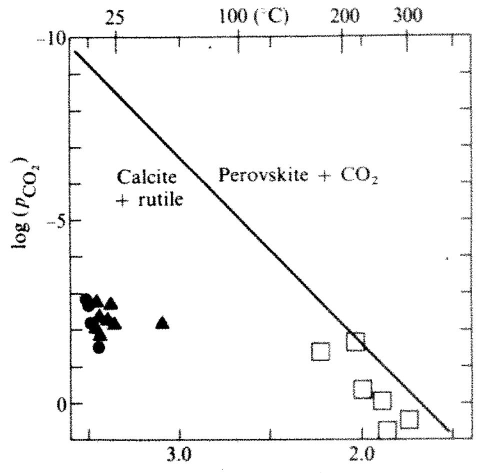

Fig. 2 log P_{CO_2} plotted against $1/T$ for reaction (10). P_{CO_2}, T values are plotted for near-surface groundwaters from limestones (△), ultramafic rocks (●) and hydrothermal solutions (□).

$[Ca^{2+}]/[H^+]^2$ values too low to be equilibrated with perovskite. Furthermore these variables are not greatly influenced by the nature of the rock from which they were collected. This is not surprising because the composition of a groundwater is the net result of reactions with all minerals and rocks it has contacted, not just the last materials encountered. For example, groundwaters which have flowed through an igneous rock may have picked up appreciable SiO_2 (aq) by dissolution of feldspar. The SiO_2(aq) will not necessarily be precipitated if the groundwater contacts limestones or evaporites. We conclude that there is probably no 'inert' vault material for perovskite because the most likely reaction is between perovskite and groundwaters, the groundwaters having contacted and reacted with various rock types.

Experimental

Four different types of samples were studied: a perovskite single crystal from Magnet Cove, Arkansas[13,14], perovskite grains from Wolgedee Hill, Western Australia, and synthetic $SrTiO_3$ and $BaTiO_3$. All samples showed excellent X-ray powder diffraction patterns characteristic of the titanate (see footnotes to the tables for other details).

Leaching experiments were performed using stainless steel autoclaves and distilled water. Because we expected very low leaching rates at low temperatures, we began our leaching experiments at 300 °C. The Magnet Cove sample was polished with 0.5 μm alumina on a micropolishing cloth before leaching for one week at 300 °C in 60 ml water, repolished, and then leached for two weeks in identical conditions. After repolishing, the sample was leached for one week at 100 °C.

The other three samples were placed in 10 ml of water in smaller stainless steel autoclaves—usually for one week. Several leach runs were made on the Australian perovskite at 100 °C, before using the same samples for leaching at 300 °C, and then 100 °C again. The samples were then ground to expose fresh surface before leaching for several weeks at 25 °C. The Ba and Sr titanates were leached at 25 °C, 100 °C, 200 °C and 300 °C often for two or three weeks (one week at a time). They were not polished or scraped between runs.

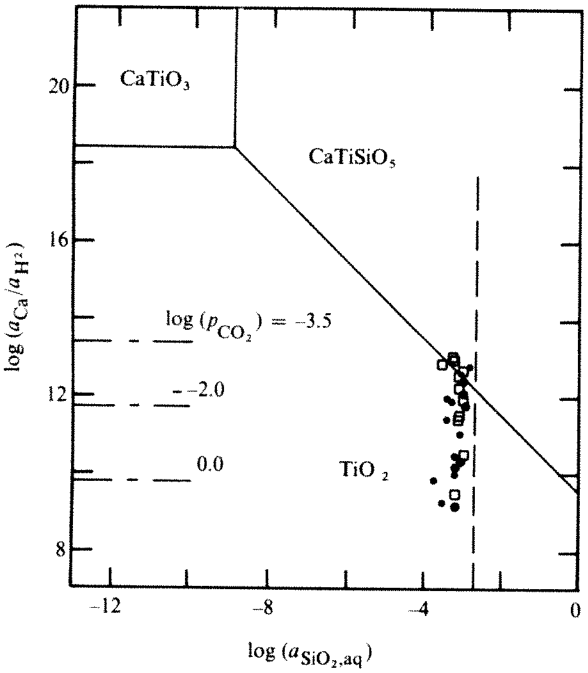

Fig. 3 $\log[a_{Ca^{2+}}/a_{H^+}{}^2]$ plotted against $\log a_{SiO_2(aq)}$ combining equations (6) and (13) at 25 °C. Solution compositions are plotted for basalts and gabbros (□), rhyolites and granites (●). The equilibrium line delineating the stability fields of sphene and rutile is obtained by subtracting the log k values of reaction (6) and (13). The dash-dot lines represent calcite solubility at the stipulated partial pressures of CO_2.

After leaching, the samples were examined by a Philips 501 SEM and an ESCA 36 spectrometer, and the solution was analysed for Ca, Sr, Ba and sometimes Ti by atomic absorption spectroscopy.

Results and discussion

In the first set of experiments with the Magnet Cove single crystal, we were able to obtain both an accurate weight loss and total amount of leached Ca^{2+} (Table 1). Although we did not deliberately exclude CO_2, the weight loss and Ca^{2+} in solution are consistent qualitatively with reaction (13) taking place. According to this equation the total weight of leached Ca^{2+} should be ~72% of the weight loss. Note that the leach rate in experiment II (5.6×10^{-10} kg m^{-2} s^{-1} or 4.8×10^{-6} g cm^{-2} day^{-1}) is much lower than that in I (8.9×10^{-9} kg m^{-2} s^{-1}) while the leach rate at 100 °C if anything is higher than the latter 300 °C leach rate. Scanning electron micrographs on the leached crystal indicated new crystals on the surface, but these were not large enough to identify.

Four separate ~0.5-g samples of the Western Australia perovskite grains were then leached for seven days in 10 ml of distilled water at 100 °C. The average amount of Ca^{2+} ion leached into solution was 78 ± 20 μg. An approximate surface area of 10 ± 2 cm^2 was obtained by microscopic examination, and the leach rate becomes 1×10^{-10} kg m^{-2} s^{-1}, substantially lower than that obtained on the single crystal. Two of the perovskite grain samples were then leached at 300 °C and then 100 °C for one week, yielding leach rates of 1×10^{-11} kg m^{-2} s^{-1} and 6×10^{-11} kg m^{-2} s^{-1} respectively. After crushing the samples to expose fresh surface, the samples were leached at 25 °C for twenty consecutive weeks, yielding 10 ± 2 μg Ca per week, and a leach rate of $<1\times10^{-11}$ kg m^{-2} s^{-1}.

The reason for the difference in leach rates between the crystal and grains is not clear. It is not due to the tiny apatite inclusions (Table 1) in the perovskite crystal because our leach tests on apatite show similar leach rates to perovskite. We could find no evidence for extensive weathering or other impurities, such as calcite, in the crystal. We cannot, of course, absolutely rule out very minor, more soluble impurities affecting the leach rates. However, since glass leach rates decrease greatly with increasing SiO_2, it does not seem unreasonable that the low TiO_2 perovskite crystal (42.3% TiO_2) has a substantially higher leach rate than the high TiO_2 perovskite grains (58.01% TiO_2).

Table 2 summarises the leach data for the $SrTiO_3$ and $BaTiO_3$ synthetic samples. Several interesting points emerge. First, as for the above perovskite samples, the leach rate decreases markedly with leaching time. For $SrTiO_3$ at 100 °C, the leach rate (in kg m^{-2} s^{-1}) decreases from 1.5×10^{-8} for a one day leach to 1.9×10^{-9} for a two week leach (Table 2). Second, as for the two perovskite samples, the leach rates for both the Sr and Ba samples at all temperatures from 25 to 300 °C are within an order of magnitude of each other . Third, as for the perovskite grains, the leach rate at 100 °C is significantly higher than the leach rates at the lower and higher temperatures. Fourth, the leach rates on the synthetic perovskite analogues are similar to the crystalline $CaTiO_3$ results (Table 3), but considerably larger than those for the Western Australia perovskite grains.

The leach rates for perovskite and the Sr and Ba analogues are summarized in Table 3. Except for our Western Australia perovskite sample, the results were obtained on disk-like materials in static tests in similar volumes of water. Our results are at least qualitatively consistent with SYNROC leaching results[15] on powder samples[16]. The Ca leach rates reported earlier[16] (10 days leaching) are within an order of magnitude for all temperatures between 25 °C and 450 °C, and the leach rates drop markedly with time[16]. For example, as for our Sr sample at 100 °C (Table 2), the Ca leach rate from SYNROC at 100 °C drops by an order of magnitude from a 1 day to a 10 day leach. The leach rates reported[16] (8×10^{-12} to 6×10^{-11} kg m^{-2} day^{-1} from 25 °C to 450 °C) are certainly lower than our crystal and disk leach rates by as much as two orders of magnitude, but are rather close to our leach rates on perovskite grains. Powder

Table 2 Sr and Ba leach rates in perovskite analogues

Sample	Leaching T(°C)	Leaching time (days)	Surface area (cm^2)	1st week Sr or Ba (μg)	1st week Leach rate (kg m^{-2} s^{-1})	2nd week Sr or Ba (μg)	2nd week Leach rate (kg m^{-2} s^{-1})	3rd week Sr or Ba (μg)	3rd week Leach rate* (kg m^{-2} s^{-1})
$SrTiO_3$	25	7	2.1	300	2.3×10^{-9}	190	1.5×10^{-9}		
	100	1	2.1	265	1.5×10^{-8}				
	100	7	2.2	500	3.7×10^{-9}	170	1.3×10^{-9}	120	9.3×10^{-10}
	100	14	0.9	205	1.9×10^{-9}				
	200	7	2.4	100	7.0×10^{-10}	45	3.1×10^{-10}	ND†	$<6\times10^{-11}$
	300	7	2.0	60	5.0×10^{-10}	35	2.9×10^{-10}	ND	$<6\times10^{-11}$
$BaTiO_3$	25	7	2.1	140	1.0×10^{-9}				
	100	7	2.1	510	4.1×10^{-9}	450	4.1×10^{-9}	350	2.7×10^{-9}
	200	7	2.0	110	9.2×10^{-10}	110	9.2×10^{-10}	90	7.4×10^{-10}
	300	7	1.8	ND	$\leq4\times10^{-10}$	ND	$\leq4\times10^{-10}$	ND	$\leq4\times10^{-10}$

Samples were prepared by mixing the alkaline earth carbonate with TiO_2 for 3 h, calcining at 900 °C for 3 h, remixing for 3 h, calcining at 1,000 °C for 3 h, remixing, pressing and molding; before recalcining at 1,150 °C for 24 h. These samples weighed about 0.5 g, had geometric surface areas of ~2 cm^2, and had densities at least 90% of the theoretical values.

* Leach rates based on amounts of Sr or Ba in solution. Reproducibility is ±40%.

† ND, concentrations of Ba or Sr were below atomic absorption detection limits.

leach rates (using BET surface areas) can be as much as two orders of magnitude lower than disk leach rates using geometric surface areas[17,18].

Table 3 compares the leach rates for the titanates with those of rhyolite[19], and borosilicates[20]. Typical of a process controlled by kinetic factors, the glass leach rates increase dramatically with temperature. As a result, the leach rates for glasses at 200 °C or 300 °C are orders of magnitude larger than the titanates. However, at 100 °C and below the leach rates are similar: and at 25 °C it seems that, except for the Western Australia sample, the titanate leach rates are in fact larger than those for rhyolite[19] or higher melting (1,300 °C) borosilicates (K. B. Harvey, personal communication).

The unusual temperature dependence of the titanate leach rate is due to an interesting combination of the thermodynamics and kinetics. At 100 °C and 300 °C, the equilibrium Ca^{2+} concentrations for equation (13) at neutral pH are ~170 M (~7×10^6 μg per g or p.p.m.) and ~5×10^{-3} M(~200 p.p.m.) respectively. The relatively large leach rates at low temperatures are at least partially due to the large driving force provided by the extremely large equilibrium concentrations (equation (5.20) in ref. 8). The solubility of $Ca(OH)_2$, drops dramatically with increasing temperature from over 1,000 p.p.m. Ca^{2+} at 20 °C, to 370 p.p.m. at 100 °C to 20 p.p.m. (or 200 μg in 10 ml) at 250 °C (ref. 21). The solubility of the Sr and Ba hydroxides are likely to be similar. Indeed, $SrTiO_3$ and $BaTiO_3$ leached at 300 °C become coated with small crystals which we have observed by scanning electron microscopy. Preliminary X-ray diffraction, and electron spectroscopy for chemical analysis (ESCA) results provide evidence that these crystals are indeed the alkaline earth hydroxides which have reprecipitated on the surface.

Table 3 Leach rates of glasses and titanates (kg m^{-2} s^{-1})

	25 °C	100 °C	200 °C	300 °C
$CaTiO_3$ (crystal)	—	2.2×10^{-9}	—	8.9×10^{-9}
$CaTiO_3$ (grains)*	$<1\times10^{-11}$†	1×10^{-10}	—	1×10^{-11}†
$SrTiO_3$	2.3×10^{-9}	3.7×10^{-9}	7.0×10^{-10}	5.0×10^{-10}
$BaTiO_3$	1.1×10^{-9}	4.0×10^{-9}	9.2×10^{-10}	3.5×10^{-10}
Rhyolite‡	1.0×10^{-10}	4.1×10^{-9} 3.5×10^{-10}§	3.7×10^{-8}	1.5×10^{-7}
Na borosili‖ cates¶	$\geqslant6\times10^{-12}$ $10^{-9}-10^{-10}$	$\geqslant1.2\times10^{-9}$ 1.4×10^{-8}		

All results are given for the leaching of disks in the first week unless otherwise noted. The titanate leach rates are determined from Ca^{2+}, Sr^{2+} of Ba^{2+} in solution, while the glass results are determined from weight losses. The leach rates drop off drastically with time. For example, rhyolite and borosilicate leach rates can be in the 10^{-12} range after 3 month's leaching at 25 °C.

* These Western Australia grains had diameters of ~0.6 mm. The probe analysis gave: 37.66% CaO, 58.01% TiO_2 (total 95.67%) with small amounts of Na, Sr, Nb, Fe and other trace elements (see ref. 14).

† These leach rates will be comparatively low, because the sample had been leached before.

‡ Ref. 19.

§ Leach rates from Na (in solution not corrected for congruent dissolution).

‖ 30 day static leach (K. B. Harvey, personal communication). These glasses melted at ~1300 °C.

¶ Ref. 20.

Thermodynamics are clearly very important in controlling the leach rate. Moreover, it is not valid to do experiments at high temperatures and extrapolate to low temperature to obtain mineral leach rates using the kinetic model of glass leaching[1].

Perovskite geochemistry

Titanium is an accessory element of many common minerals[22] including sheet silicates (biotite), amphiboles (hornblende) and pyroxene (augite). It is an essential constituent of only a few minerals, such as sphene ($CaTiSiO_5$), ilmenite ($FeTiO_3$), rutile and its polymorphs (TiO_2) and perovskite ($CaTiO_3$). Ilmenite, sphene and rutile are not susceptible to alteration in sedimentary and hydrothermal environments and these resistate minerals may accumulate in sediments to be mined as mineral sands[23]. Despite the apparent stability of Ti-rich phases, one mineral, perovskite, may not be a resistate. Geological information supports this suggestion. Perovskite is a rare mineral formed only in rocks of unusual composition. In contrast, ilmenite, sphene, and rutile are common minerals found in rocks of extremely diverse composition, suggesting that they are stable relative to perovskite in most geological environments. Rocks containing perovskite are of plutonic and volcanic origin (ref. 22, p. 423), displaying exceptionally low SiO_2 and high CaO concentrations[5]. They have been generated in very high temperature–pressure environments, probably being produced in the mantle rather than in the Earth's crust (ref. 5, p. 526). We may therefore expect the rocks and constituent minerals to be unstable in upper crustal environments. Furthermore these rocks contain, in addition to perovskite, leucite ($KAlSi_2O_6$), kalsilite ($KAlSiO_4$) and nepheline ($NaAlSiO_4$) all of which are less stable than feldspars, in the presence of natural waters[10]. Their survival at the Earth's surface may result more from the volume of rock to be altered and from the arid climates in which they are found (Wyoming; Western Australia; southern Spain) than from their resistance to weathering and groundwater solutions. Perovskite is also observed in limestones thermally altered by granitic intrusions[22] but again the environment is unusual and very restricted. Minerals formed in such a setting may well be very unstable in other, more common, environments. From the geological evidence we conclude that perovskite will be stable only in unique geological settings. Our thermodynamic and kinetic studies strongly support this suggestion.

Conclusions

Contrary to earlier suggestions, we have found that perovskite is thermodynamically unstable in most rocks, and in natural waters. Perovskite appears to be kinetically far more stable than glasses at high temperatures ($T \gg 100$ °C). However, at the more important temperatures of $\leqslant 100$ °C, the comparison depends on the type of both glass and perovskite under consideration. For example, our best perovskite leach rate is lower than low melting borosilicates at all temperatures; but is comparable to, or greater than, the higher melting (1,300 °C) borosilicate at 25 °C. Our synthetic samples leach more rapidly at 25 °C than even some low melting borosilicates. Obviously, perovskite is not 'vastly' more stable kinetically than glass and silicates generally as has been claimed[1,2], and much more work is required to understand fully the kinetic stability and decomposition pathways of perovskite and other SYNROC minerals.

Ideally, minerals used as nuclear waste hosts should be thermodynamically stable. A mineral which is thermodynamically unstable and has a low laboratory leach rate, could well leach much faster in the field due to chemical or biological catalysts. Considerable efforts should now be made to examine the thermodynamics of mineral and glass solubilities considering the backfill and repository or vault materials.

We thank the Atomic Energy of Canada Ltd for financial support and Dr H. H. Schloessin and Dr B. Mason for perovskite samples. This paper was presented in part at the Workshop on Alternate Nuclear Waste Forms and Interaction in Geologic Media, held at Gatlinburg in May 1980.

The Norse merman as an optical phenomenon

W. H. Lehn
Department of Electrical Engineering, University of Manitoba, Winnipeg, Canada R3T 2N2
I. Schroeder
60 Thatcher Drive, Winnipeg, Canada R3T 2L3

Mediaeval Norse writings that describe the merman are considered accurate observations of a natural phenomenon. Images of common sea mammals, severely distorted by strong, non-uniform atmospheric refraction, fit the mediaeval descriptions remarkably well. Three examples are presented: computer-generated images of a killer whale and a walrus, and a photograph of a suitably distended boulder. The mediaeval correlation of a merman sighting with the advent of storms is also verified.

MEDIAEVAL manuscripts contain occasional passages, apparently deriving from invention or superstition, for which a basis can be found in observation or experience. However, some texts, such as those that describe the merman, have defied positive identification. In the seventeenth century it was first suggested that the merman was simply a dugong or manatee[1], a view that was generally accepted by the end of the nineteenth century[2]. Although this interpretation is very unsatisfactory, it has remained the most prevalent theory[3].

In general, modern scientists have avoided the study of such anomaly sightings, partially because it is regarded as a non-soluble problem, and partially because it can be so easily distorted[4].

This article considers the merman, as conceived by twelfth and thirteenth century authors. The natural source of the merman legend will be identified, and the high level of sophistication attained by the Norse in observing and correlating natural phenomena will be demonstrated. Finally, the concept of the merman will be traced through its subsequent evolution.

Mediaeval accounts

The *King's Mirror*, written in the mid-thirteenth century, is noted for its highly accurate descriptions of sea mammals and other natural phenomena[5]. The section dealing with the North Atlantic contains only three items that assume an aspect of the marvellous: the *hafgerdingar* and the merman, found in the Greenland Sea, and the *hafgufa*, or kraken, in the Iceland Sea[6]. The explanation of the *hafgerdingar* (sea fences) as a visual effect created by anomalous atmospheric refraction[7] suggests that the merman be reconsidered.

The author of the *King's Mirror* describes the merman as:

> "This monster is tall and of great size and rises straight out of the water.... It has shoulders like a man's but no hands. Its body apparently grows narrower from the shoulders down, so that the lower down it has been observed, the more slender it has seemed to be. But no one has ever seen how the lower end is shaped, ... No one has ever observed it closely enough to determine whether its body has scales like a fish or skin like a man. Whenever the monster has shown itself, men have always been sure that a storm would follow."

He proceeds to discuss its mate, the mermaid, which differs from the merman in that it possesses heavy hair, breasts, large webbed hands, and a fish's tail, but also "rarely appears except before violent storms".

An earlier account of the merman is found in the *Historia Norvegiae*, written[8] about 1170:

0028–0836/81/050362—05$01.00

"there is the whale, and there is the merman, the largest wild beast, but without head and tail, thus it is just like a treetrunk when it leaps up and down, and it does not show itself without its foretelling danger for seafarers."

These two passages, the only descriptions of the merman that have survived from mediaeval times, will be analysed here. First the merman's shape will be considered as an optically distorted image; then the correlation between such a sighting and the advent of storms will be briefly assessed.

Atmospheric optics

The atmosphere occasionally produces optical distortion strong enough to make ordinary objects unrecognizable, even at fairly close distances. Such distortions have been suggested as the source for many of the sightings, both ancient and modern, of lake and sea monsters[9]. Common sea mammals, so distorted, fit the mediaeval merman descriptions.

The underlying optical theory, here briefly summarized, is given elsewhere[10–12]. Light rays travelling nearly horizontally follow paths whose vertical curvature κ depends on the distribution of atmospheric density ρ with elevation z. The curvature is given by

$$\kappa = \frac{\beta}{1+\varepsilon\rho}\,\frac{d\rho}{dz}$$

where $1+\varepsilon\rho$ is the refractive index of air ($\varepsilon = 0.000226$). The density is related to the more easily measured absolute temperature T by[13]

$$\rho = \frac{\beta p_0}{T(z)}\exp\left[-g\beta\int_0^z \frac{dz'}{T(z')}\right]$$

where p_0 is the surface pressure, g the acceleration due to gravity, and $\beta = 3.49\times10^{-3}$, a constant of proportionality. Temperature inversions, with their associated stable atmosphere, cause a downward refraction of light rays. Irregularities in the temperature profile, especially thermoclines, create the irregularities in refraction necessary for severe image distortion.

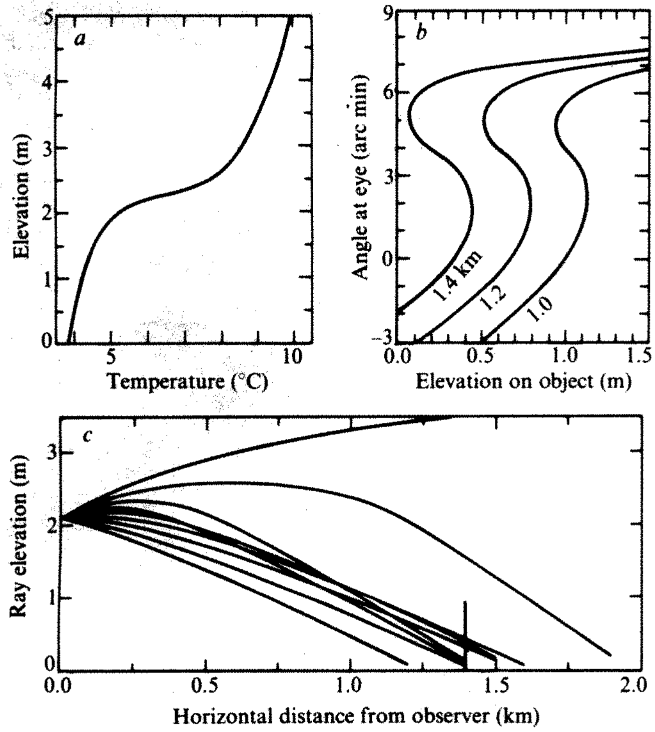

Fig. 1 *a*, Temperature profile used in *Example 1*. *b*, Transfer characteristics generated by the profile of *a*, for object distances of 1.0, 1.2 and 1.4 km. Eye elevation is 2.1 m. *c*, Paths described by light rays in temperature conditions of *a*. The uppermost ray enters the eye at an angle of +9′; the lowest with −3′. The angular increment between successive rays is 1.5′; the spacing of 0.5′ used to plot *b* is too dense to produce a meaningful plot at this scale. The ordinate measures ray elevation above the (curved) surface of the sea. The location and height of the whale's head (see Fig. 2*a*) is indicated by the vertical bar at 1.4 km.

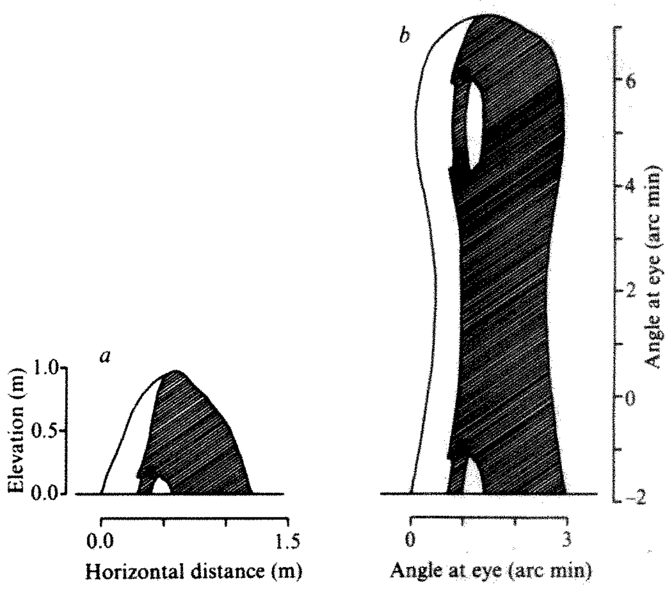

Fig. 2 *a*, A killer whale, spy-hopping. *b*, The distorted image of the whale, seen from a distance of 1.4 km in the temperature conditions of Fig. 1*a*. If the same temperature profile were to prevail for some distance beyond the whale, then the *hafgerdingar* would be present; the apparent horizon would be above the top of the image, at an elevation of +10′, about 10 km from the observer. For a normal atmosphere these values are −2.5′ and 5.7 km.

Computer programs developed for ray tracing[13,14] have been used to identify temperature profiles that create merman images. The reconstructions that follow are based on inversions with thermoclines situated a few metres above the sea.

Example 1: A killer whale projecting its head vertically out of the water is an excellent source for merman images. Such activity, called 'spy-hopping', is common among cetaceans of many sorts[15,16]. It is also specifically mentioned by Shackleton[17] as a hunting procedure used by killer whales[18].

In the image-construction process, several quantities can be manipulated: shape of temperature profile, elevation of observer's eye and distance from observer to object. After some computer experimentation with all of these elements, the following typical conditions were chosen to illustrate the effect. Figure 1*a* shows the temperature profile: a moderate inversion of total strength 7.5 °C and with a thermocline at elevation 2.2 m. The atmosphere is assumed laterally homogeneous over the short ranges involved, so that this temperature profile prevails everywhere between object and observer. If the observer's eye is now placed at an elevation of 2.1 m, the light rays entering the eye follow the paths shown in Fig. 1*c*. The elevations at which these rays intersect an object plane at some distance from the eye are plotted as a transfer characteristic in Fig. 1*b*. These curves determine the nature of the image perceived by the observer. The eye assumes each incoming ray to be straight, and projects it back on to the object plane to give an (apparent) image point. A complete set of curved rays, as in Fig. 1*b*, thus causes a redistribution of all the object points on the object plane. As the ray bending is in a purely vertical plane no lateral image distortion is present.

The original and distorted images are compared in Fig. 2*a* and *b*, respectively, for an object distance of 1.4 km. Figure 2*a* is adapted from a photograph of a killer whale[19]. The distorted image in Fig. 2*b* is unlikely to be recognized as a whale.

Space restrictions mean that the many possible variations of the image cannot be displayed. With changes in the determining parameters, the shape can appear more or less slender; the midsection can become quite a narrow 'neck' or 'waist'; and the white eye-spot may not be imaged in the 'head'.

Example 2: A similar image-constructing process was carried out for a walrus. As this is a smaller animal, a shorter range was

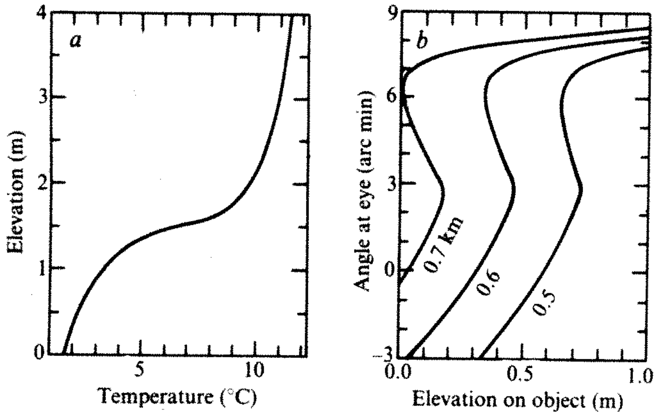

Fig. 3 *a*, Temperature profile used in *Example 2*. *b*, Corresponding transfer characteristics, for object distances of 0.5, 0.6 and 0.7 km. Eye elevation is 1.45 m.

chosen (0.7 km) to have a sufficient horizontal angle subtended at the eye. A steeper temperature profile was required to produce the necessary refraction over the reduced range. Figure 3*a* shows the temperature profile, an inversion of strength 11 °C with a thermocline at about 1.5 m elevation. The transfer characteristics corresponding to an eye elevation of 1.45 m are shown in Fig. 3*b*.

Figure 4 compares the original with the distorted image. A walrus photographed in its natural habitat[20] forms the basis for Fig. 4*a*. The distorted image for the stated conditions is in Fig. 4*b*. Again many variations are possible in this distortion: the figure can become stockier or narrower; it need not have a thin 'waist'; and the apparently fierce 'mouth' and 'teeth' at the top of the figure can become much larger.

Example 3: A photograph of a present-day merman is given in Fig. 5*b*. It appeared over Lake Winnipeg on 2 May 1980, a hot calm day, while there was still some ice on the lake. The inland temperature at the time was about 28 °C, while the lake surface was near 0 °C. The source of the apparition, subsequently identified, was an insignificant boulder (Fig. 3*a*) sited 1.10 km from the camera.

Comparison with mediaeval descriptions

The author of the *King's Mirror* describes the merman with great care, while the less well-informed author of the *Historia Norvegiae* provides only a very general description. Yet the overall impression is identical.

Both accounts describe the merman as a huge animal rising straight out of the water. The lack of detail in the *Historia Norvegiae* implies that the animal had only been seen at some distance, a fact confirmed by direct statement in the *King's Mirror*. The enormous size could, therefore, only have been estimated by comparing its appearance with that of known objects at apparently similar distances.

The man-like shape implied by its name is consistent with the visual impression of an object viewed at some distance, when vertically elongated. As the horizontal dimension remains unchanged, the resulting image acquires a large height-to-width ratio, a form identified with man.

The accounts diverge only in the detailed configuration and in the specific features. The *Historia Norvegiae* suggests a cylindrical body, while the *King's Mirror* gives it shoulders like a man's, with a tapering body. As shown in Figs 2*b*, 4*b* and 5*b*, both shapes are a natural consequence of refractive distortion. Further, the *Historia Norvegiae* claims the merman has no head at all, while the *King's Mirror* lists a pointed head, having eyes, mouth, nose, chin and neck. Again, the process of refraction permits various upper terminations, and refracted markings in approximately the right place (Figs 2*b*, 4*b*) can create the impression of a face. As small atmospheric irregularities tend to disintegrate the image, producing a whiskery or hairy effect[9], such characteristics could be attributed to its mate, the mermaid. At the distances implied in the *King's Mirror*, the human eye, whose resolving power is between 0.5 and 1 arc min, registers only the major outlines; finer details are interpolated by the perception process. Eventually, numerous sightings similar in overall impression but differing somewhat in detail would result in a generalized description and the identification of a species.

The elevation of the observer is important in all optically induced anomaly sightings. The refractive distortion generally diminishes if the image can be viewed from above the thermocline. However, such variations would go unnoticed by Norse mariners, for the working of their ships was carried out from the deck, a few metres above the sea[21]. The subsequent use of much higher decked ships and the establishment of elevated lookouts would explain the infrequent merman sightings in later centuries.

Finally, the distorted boulder of Fig. 5*b* bears a striking resemblence to the *umibohzu*, or "priest of the sea", a giant-like monster known to the Japanese[22]. An even stronger likeness occurs in a narrow-necked version of Fig. 2*b*, in which the *umibohzu*'s eyes are produced by the whale's white eye patch. Clearly the Japanese were interpreting the same visual phenomena in much the same way as did the Norse.

Correlation with the environment

The thermoclines that generate merman images are best created when a warm air mass slowly moves over significantly cooler surface air. In conditions of relative calm, the boundary between the two air masses will possess the flatness and uniformity necessary for well-defined (but distorted) images.

A typical situation is illustrated by the last stages of a warm front, when the warm–cool interface has almost descended to the surface. This has been experimentally verified by Wegener's observations of good superior mirages in the North Atlantic[11,23], which he later correlated with the arrival of warm fronts[24]. However, neither he nor subsequent polar researchers have studied the fine structure of the temperature distributions that the lowest air layers must possess to produce merman images.

Scoresby[25], an experienced Arctic whaler, recorded numerous examples of anomalous refraction which strongly resemble the marvels of the *King's Mirror*: the elevated horizon, a dense appearance of the atmosphere, and the vertically elongated hulls of ships as if in a heeling position. Though Scoresby recognized some forms of refraction phenomena and correlated them with an easterly wind, he attributed others to vapours in the atmosphere, or confused them with ice-blink. He thus associated unusual visual effects with storms but did not identify

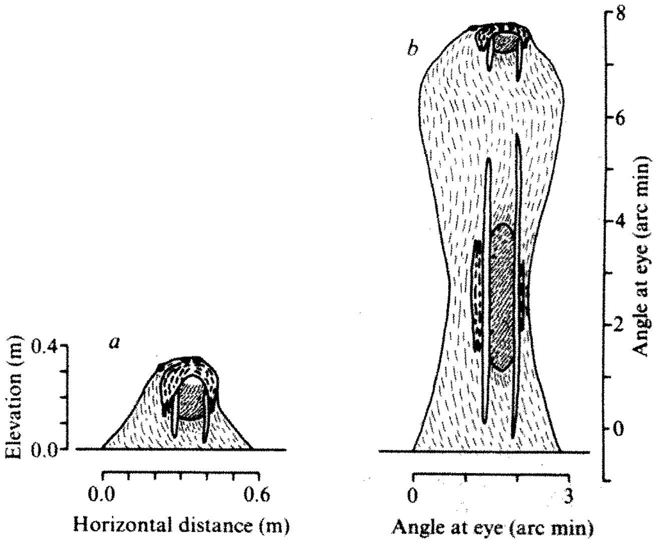

Fig. 4 *a*, Walrus. *b*, The distorted image of the walrus, seen from a distance of 0.7 km in the temperature conditions of Fig. 3*a*. Again, the *hafgerdingar* will be present if the same temperature profile exists over a sufficiently wide area. The horizon elevation would be +13′, at a distance of 15 km, compared with −2′ at 4.8 km for a normal atmosphere.

them with refraction. The dead calm followed by a sudden rise in temperature, the typical conditions noted by Scoresby just before a major storm, are ideally suited to the development of a thermocline. I have observed such an effect on a very localized scale, in the Canadian Arctic, over the Beaufort Sea: the sudden appearance of a medium-range mirage, followed within 40 min by a sudden temperature rise, rainstorms, and disappearance of the mirage. The amount of optical distortion depends directly on the temperature difference between the two air masses, which in turn determines the strength of the front and the severity of the subsequent storms.

Similar refractive distortions will have provided the Norse with sufficient opportunity to observe elongated images of the sea mammals which they used as navigational guides[26]. Because Severin's experience in the *Brendan* indicates that whales do not avoid small sailing vessels[27], the limiting factor would have been the frequency of suitable atmospheric conditions rather than the presence of a suitable subject. These observations belonged to the thirteenth century mariner's general body of knowledge, and were recorded as such in the *King's Mirror*. It is fitting that the *King's Mirror* places both phenomena, the *hafgerdingar* and the merman, together in its text. From the optical reconstruction, as well as Scoresby's observations, clearly some form of *hafgerdingar* will be observed along with the merman. Both are correctly associated with the advent of storms on the open sea, and are located in the Greenland Sea where such extreme conditions were also observed by Scoresby.

Subsequent development

The precise descriptions in the *King's Mirror* directly contrast with those of Olaus Magnus three centuries later. His monsters, composites of several species assembled from fragmented reports[19], reflect the general level to which Norse maritime knowledge had declined. As knowledge of the North Atlantic was regained by western European explorations, unrecognizable sightings reminiscent of the merman were occasionally reported[28,29]. Nevertheless, the Norse merman had become largely a legendary creature, and skepticism as to its existence hardened when scientists identified it with the newly discovered dugong and manatee, both warm water mammals. To clarify this problem, Pontoppidan collected written accounts, as well as verbal reports from reliable witnesses. His attempt to isolate the factual from the mythical established the North European merman as an existing species with some well-defined characteristics. This study formed the basis for all future work even though Pontoppidan did not have access to the *King's Mirror*, a manuscript long believed lost[1].

It is of interest to examine the evolution of the thirteenth century merman into Pontoppidan's eighteenth century composite. Not only had the natural habitat of the merman shifted from the Greenland Sea to the coastal waters of northern Europe, but the conditions in which the merman was sighted had also changed. Many of the sightings accepted by Pontoppidan were reported on very warm, calm days. These observations suggest that the characteristic vertically distended appearance of an optically distorted image was still being identified as a merman; for such weather conditions, though different from those of the advancing front, also develop strong temperature gradients and consequent refraction. Further, while the specific correlation with frontal activity on the open sea had totally disappeared, the fear of the merman had survived as a generalized bad omen. Finally, the species had become approachable; whereas the early Norse reported only distant sightings, actual catches and findings of partially decomposed remains were claimed in the seventeenth and eighteenth centuries.

A similar evolution can be traced for the *hafgufa*. As originally described, it was a featureless monster of enormous dimensions in the Iceland Sea[6]. So few sightings had ever been reported that the author of the *King's Mirror* estimated its world population at one or perhaps two, and hesitated to include it in a compendium of sea life. By the eighteenth century, this monster had multiplied remarkably to inhabit the entire North Atlantic, especially the coastal waters of Norway. Pontoppidan recorded the varied accounts of this creature but found the information so diverse and inconsistent that he did not attempt to identify it with any known species[1]. However, by the end of the nineteenth century, the kraken had assumed the characteristics of a giant squid, an idea which has become increasingly accepted[2].

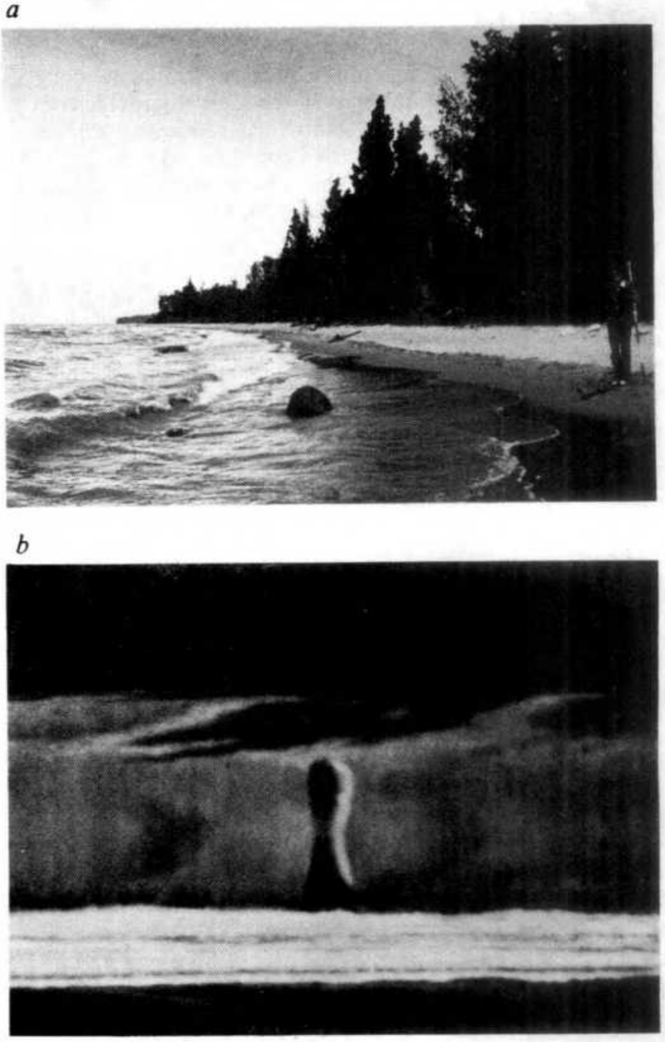

Fig. 5 *a*, Lake Winnipeg, 28 May 1980. The boulder in centre foreground was identified as the source of the image in Fig. 5*b*. It is ~68 cm wide and should show 30–35 cm above water on a calm day. *b*, The boulder distorted into a merman shape, 3:17 p.m. CDT (central daylight time), 2 May 1980. The image subtends 5.4′ vertically and 2.2′ horizontally. The photograph was made from a distance of 1.10 km using a mirror lens (focal length 1,250 mm) on Kodachrome 64 film. the exposure was 1/250 s at *f*/11, and the lens elevation was 2.5 m above the lake. A photograph taken just previously, at 3:15.5 p.m., shows the distortion as incompletely developed. The merman image of this boulder lasted for only a few minutes. Such conditions occur almost every spring on Lake Winnipeg.

The *King's Mirror* is so accurate in its description of the merman and the *hafgerdingar* that a serious effort should be made to identify a natural phenomenon closely fitting the original *hafgufa*. Its appearance suggests that it may be a consequence of submarine volcanic activity in Icelandic waters. Steenstrup[26] used this theory to explain the *hafgerdingar*. But the *hafgerdingar* are much better described as an optical phenomenon, while Steenstrup's theory is a superior match, both in appearance and location, to the thirteenth century *hafgufa*.

Following the deterioration of contact between Iceland, Greenland and Norway, the merman and the *hafgufa* had become culturally isolated. Cut off from their origins, these stories were free to develop according to local conditions. Progress in identifying these marvels was hampered by the fact that they had evolved in time, a problem similar to the one identified in a recent analysis of the Gunnbjorn Skerries[30]. When renewed interest in the North Atlantic stimulated scholars to seek out all previously known information, both the skerries and the marvels of the *King's Mirror* emerged as composite remnants from the mediaeval age.

Conclusion

The merman described in the early sources, like the *hafgerdingar*, is, in fact, an accurate description of an unusual optical phenomenon. Its appearance is exactly that predicted by computer simulations of anomalous atmospheres, and the weather conditions with which it is associated agree with modern observations in arctic regions. The correspondence of these two marvels with reality leads directly to the conclusion that the *hafgufa* account must also be considered as an observed natural phenomenon.

The extent to which Norse expertise deteriorated, once trans-Atlantic navigation ceased, is clearly demonstrated by the many unrealistic accounts found in sixteenth century sources. Clear and precise reports were superseded by confusion and the supernatural. The tendency of modern scholars has, therefore, been to dismiss as inaccurate or superstitious any observations inconsistent with their own experience. The optical interpretation of the merman and the *hafgerdingar* enables a clear differentiation between thirteenth and sixteenth century concepts and furthers an appreciation of the visual impressions which formed an integral part of Norse maritime experience.

Structure of the haemagglutinin membrane glycoprotein of influenza virus at 3 Å resolution

I. A. Wilson, J. J. Skehel* & D. C. Wiley

Gibbs Laboratory, Harvard University, 12 Oxford Street, Cambridge, Massachusetts 02138

The haemagglutinin glycoprotein of influenza virus is a trimer comprising two structurally distinct regions: a triple-stranded coiled-coil of α-helices extends 76 Å from the membrane and a globular region of antiparallel β-sheet, which contains the receptor binding site and the variable antigenic determinants, is positioned on top of this stem. Each subunit has an unusual loop-like topology, starting at the membrane, extending 135 Å distally and folding back to enter the membrane.

INFLUENZA virus acquires a lipid membrane during maturation by 'budding' through the host-cell membrane. The resulting viral membrane contains the two virally coded integral membrane glycoproteins, haemagglutinin and neuraminidase[1]. The haemagglutinin (HA) of the A/Hong Kong/1968 virus is a trimer of 224,640 molecular weight (MW). It may be solubilized from the viral membrane by bromelain digestion, which removes a 5,406 MW C-terminal hydrophobic (anchoring) peptide from each subunit[2–4]. This observation, extended by the results of subsequent primary sequencing experiments[5–14], places the haemagglutinin in a class of integral membrane proteins characterized by a three-domain structure with a large hydrophilic, carbohydrate-containing domain on the external surface of the membrane, a small, uncharged hydrophobic peptide of 24–28 amino acids spanning the membrane, and a small, hydrophilic domain (10–55 amino acids) on the internal side of the membrane (Fig. 1*a*). Other well characterized examples of this class of membrane glycoprotein include the human and murine histocompatibility antigens HLA and H-2 (refs 15, 16), erythrocyte glycophorin[17], and the animal virus membrane proteins. Such proteins show enzyme or 'recognition' activities, in contrast to proteins active in membrane transport, of which the structurally best defined example is bacterial rhodopsin[18,19].

Typical of membrane glycoproteins, the haemagglutinin chain is initially synthesized to include an N-terminal hydrophobic 'signal' peptide[11,20,21], which is subsequently removed as part of the process by which the protein is transported across and anchored into the membrane[22,23] (Fig. 1*a*). Each polypeptide chain of the trimer is glycosylated at seven sites with a total carbohydrate of 13,000 MW (19% by weight)[6,11]. We wish to understand the structural correlates of these properties. What is the nature of the membrane attachment of this protein? What is the location and biological role of the carbohydrate? As a virus membrane protein, the haemagglutinin expresses a number of surface activities whose structural bases are also sought. How

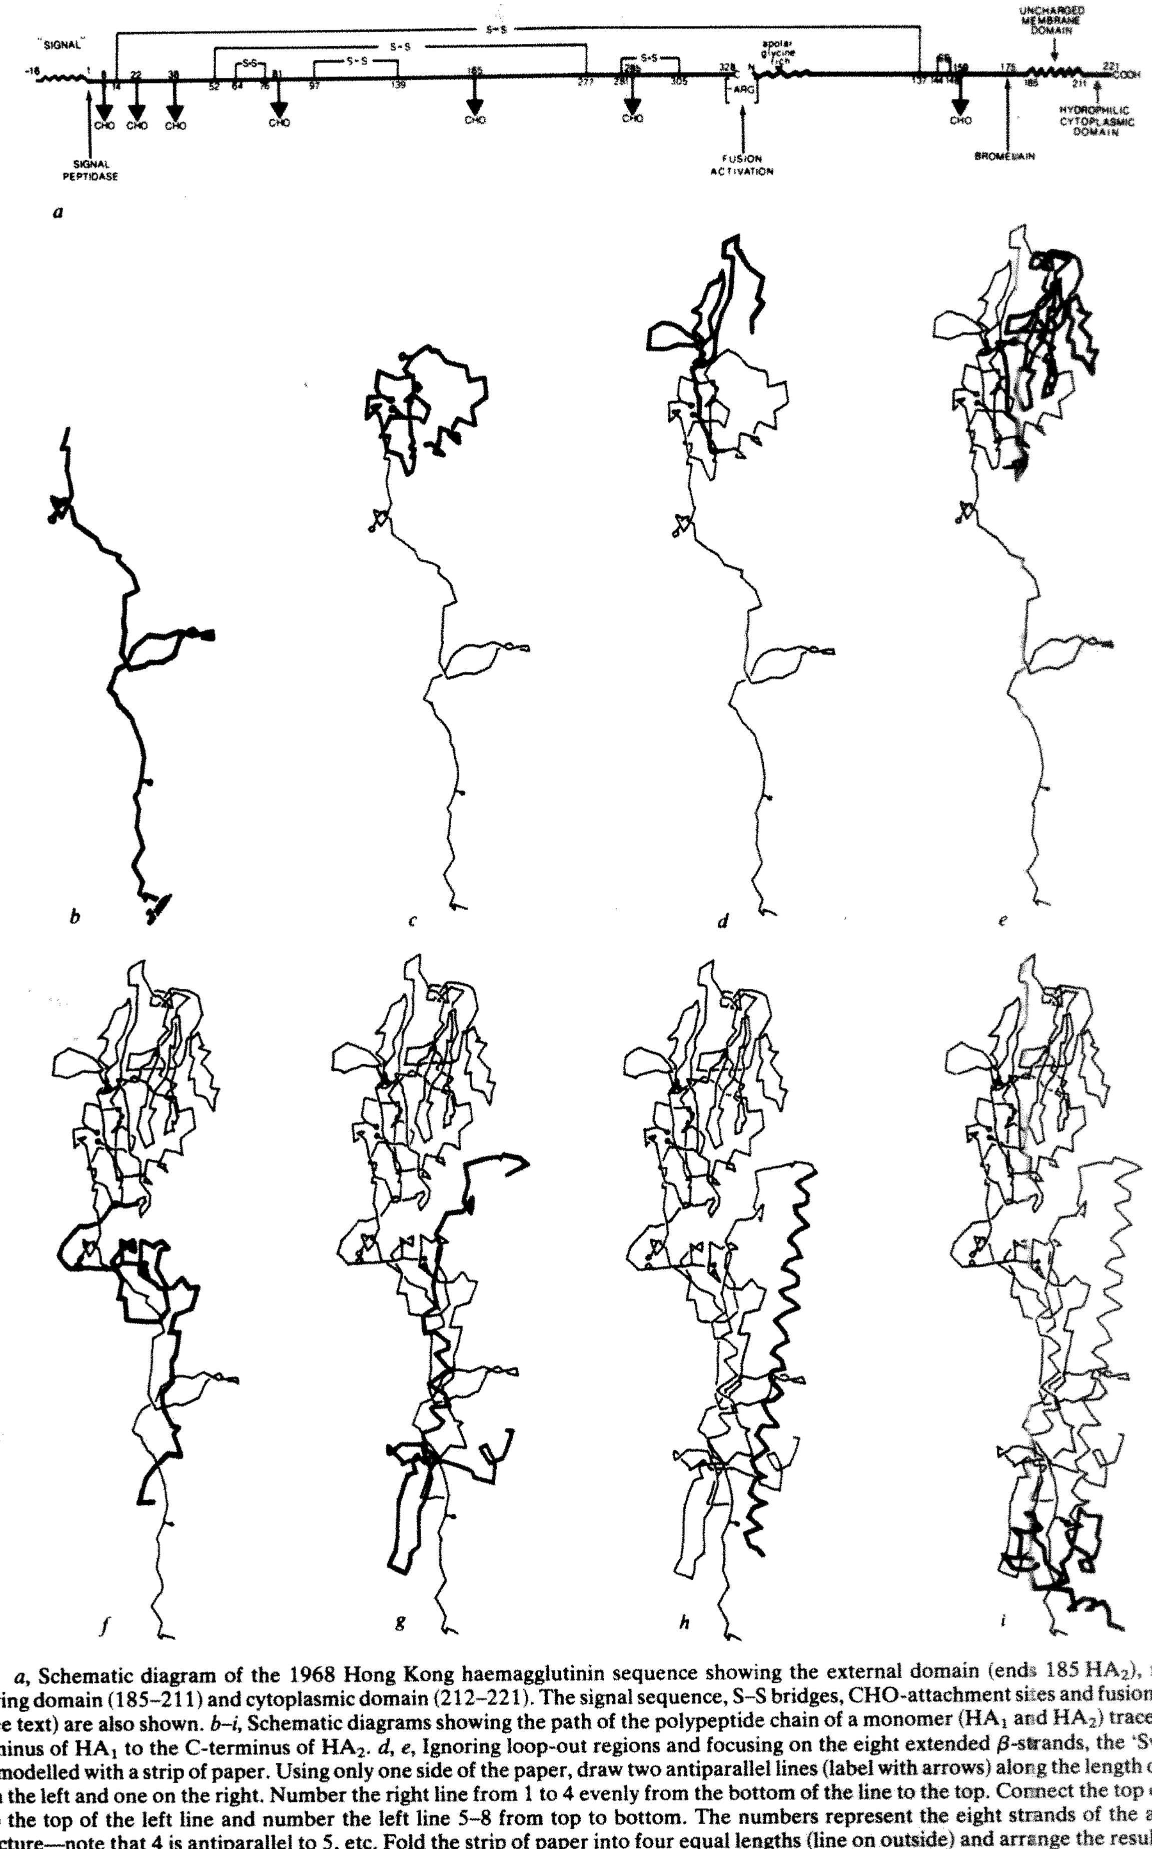

Fig. 1 *a*, Schematic diagram of the 1968 Hong Kong haemagglutinin sequence showing the external domain (ends 185 HA_2), membrane anchoring domain (185–211) and cytoplasmic domain (212–221). The signal sequence, S–S bridges, CHO-attachment sites and fusion activation site (see text) are also shown. *b–i*, Schematic diagrams showing the path of the polypeptide chain of a monomer (HA_1 and HA_2) traced from the N-terminus of HA_1 to the C-terminus of HA_2. *d, e*, Ignoring loop-out regions and focusing on the eight extended β-strands, the 'Swiss roll' is easily modelled with a strip of paper. Using only one side of the paper, draw two antiparallel lines (label with arrows) along the length of the strip, one on the left and one on the right. Number the right line from 1 to 4 evenly from the bottom of the line to the top. Connect the top of the right line to the top of the left line and number the left line 5–8 from top to bottom. The numbers represent the eight strands of the antiparallel β-structure—note that 4 is antiparallel to 5, etc. Fold the strip of paper into four equal lengths (line on outside) and arrange the resulting 'Swiss roll' so that strands 1, 8, 3 and 6 are visible in that order from one side and 2, 7, 4 and 5 are seen from the other (Fig. 2). The point between strands 4 and 5 corresponds to amino acid 208 (HA_1) in the haemagglutinin structure (Fig. 3*a*). The eight strands are approximately 1, 119–123; 8, 251–259; 3, 174–182; 6, 229–237; 2, 163–170; 7, 241–248; 4, 200–205 and 5, 210–213 (Fig. 3*a*). (This figure is intended as a description of the structure, not a folding pathway.)

does this protein recognize the sialic acid-containing host-cell receptor[24]? How does the post-translational removal of an arginine (329), dividing the chain into two disulphide-linked chains, HA_1 (328 amino acids) and HA_2 (221 amino acids)[11,14], activate infectivity and membrane fusion activity[25–27]? How does variation in the amino acid sequence of the structure alter the antigenic determinants of the molecule and lead to recurrent epidemics of respiratory disease?

We report here a first description of the results of the 3Å-structure determination of the external, glycoprotein domain of the influenza virus haemagglutinin, which provides initial answers to certain of the above questions. The host-receptor binding site and antigenic determinants are located on a globular region which lies on top of a long fibrous coiled-coil (Fig. 2). The fusion activation peptide is located near (35 Å) the virus membrane end of the molecule. The polypeptide fold is unusual, like a long loop, starting at the membrane, extending 135 Å distally, and ending at the membrane. This tertiary structure indicates that the molecule is probably extruded from the membrane as a single chain during biosynthesis and may even remain attached via the signal peptide to the membrane during folding. Most of the oligosaccharide chains are found near the membrane end of the molecule. The identification of antibody binding sites and the contribution of their variation to the recurrence of respiratory disease in man is discussed in the accompanying article[28].

Structure determination

The bromelain-released haemagglutinin (30 mg ml^{-1}) crystallizes in tetragonal space group $P4_1$, $a = 163.2$ Å, $c = 177.4$ Å from 1.28 M sodium citrate, 0.1% azide, *p*H 7.5 (ref. 29). A single isomorphous derivative, mercury phenylglyoxal[30], was used in structure determination. 1° oscillation photographs (12-h exposure) were recorded at 4 °C, using an Elliot G-X-6 rotating anode source operated with a 100 μm focus at 40 kV and 20 mA, and Franks focusing optics[31]. Up to 15° of data could be recorded from each crystal by exposing a fresh volume to X rays after 24 h exposure (Table 1).

Table 1 Data collection statistics

Data set	No. films	Total reflections measured	Unique reflections	R_{sym}	R_{whole}	R_{asym}
Native	78	408,672	83,015	0.12	0.11	0.18
Derivative	62	338,738	78,077	0.13	0.13	0.20

$R = \sum |s_i I_{hi} - \bar{I}| / \sum \bar{I}_n$ where s_i = scale factor for crystal *i*, I_{hi} = intensity of reflection *h* of crystal *i* and $\bar{I}_n$ = average intensity of reflections. R_{sym}, symmetry-related reflections on the same film; R_{whole}, fully recorded reflections from different films; R_{asym}, all reflections (≥50% recorded) on different films, final scaling.

Solution of the 3 Å difference Patterson revealed six heavy-atom locations per molecule (Table 2*a*), two sites 27 Å apart per monomer, which define a non-crystallographic, molecular 3-fold axis. (Details of the structure determination will be published elsewhere.) The asymmetric unit contains one glycoprotein trimer[32] of 208,422 MW and is 78% solvent (by weight). The standard isomorphous replacement (SIR) phases of 59,669 reflections were determined to 3 Å resolution with an overall figure of merit of 0.34 and overall phasing power of 1.38 (Table 2*b*). Eleven cycles of refinement of these and previously undetermined phases of a total of 74,194 reflections by non-crystallographic 3-fold symmetry averaging[33] dramatically improved the quality of the electron density maps and the agreement of calculated and observed amplitudes ($R = 0.47$ cycle 1, $R = 0.27$ cycle 11). The molecular envelope required redetermination three times during refinement to include protruding regions of protein and carbohydrate that had been truncated by the original estimate of the envelope but that were clearly apparent in difference Fourier maps.

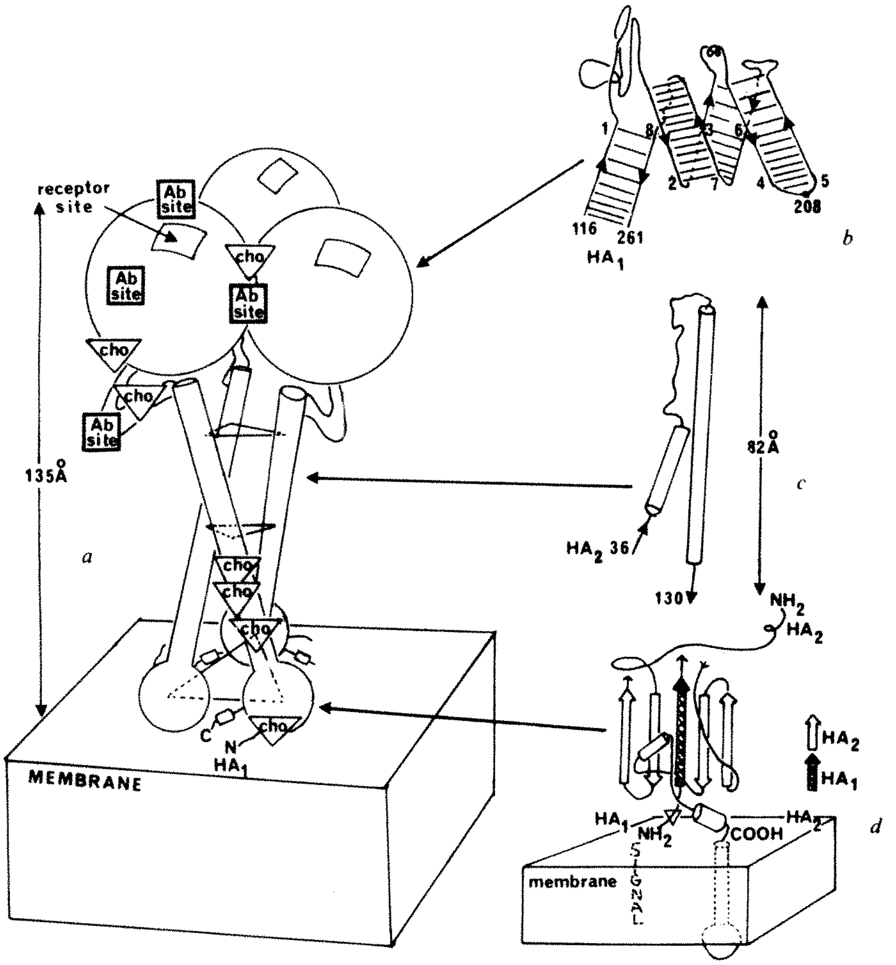

Fig. 2 *a*, Schematic diagram of the 1968 haemagglutinin trimer showing carbohydrate attachment sites (CHO), antigenic sites (Ab site) (see ref. 28), the host–receptor binding site and the arrangement relative to the membrane. *b*, The eight-stranded β-sheet structure and looped-out region in the globular domain. *c*, HA_2 residues 36–130, including two α-helices (cylinders), form part of the fibrous region. Three of the long helices, one from each monomer, pack together as a triple-stranded coiled-coil which stabilizes the trimer. *d*, The membrane end of the molecule contains a five-stranded β-sheet. The central strand is the N-terminal of HA_1 and the adjacent strands come from the C-terminal chain of HA_2. Broken lines suggest the path of the hydrophobic anchoring peptide cleaved by bromelain. The possible attachment of the N-terminus to the membrane by the signal sequence is also indicated. The site of the first oligosaccharide chain (residue 8) is shown as a triangle.

Interpretation of electron density map

A minimap (4 Å cm^{-1}) was calculated for the trimer, sectioned normal to the 3-fold axis. The subunit boundaries were clearly visible. Ambiguities in chain tracing were resolved with the aid of the amino acid sequence (provided by Fiers *et al.*[11] and Ward *et al.*[14]). α-Carbon positions of residues 4–328 of HA_1 and residues 1–175 of HA_2 have been located. The amino terminus of HA_1 and the C-terminus of HA_2 are close to the membrane end of the haemagglutinin and therefore to the bromelain cleavage site at residue 175 of HA_2 (ref. 34). The unaveraged map indicates that deviations from 3-fold symmetry may occur in the amino-terminal region of HA_1 by interaction of one of the amino-termini with an adjacent molecule in the crystal. The side-chain densities are well defined and unambiguous for 50–60% of the residues and another 20–30% fit moderately well. Only 15% of the residues have weak side-chain or main-chain density, and the chain can clearly be traced throughout the entire molecule.

Location of the six disulphides showed that only one disulphide linkage connects HA_1 and HA_2 (refs 7, 35).

Description of the structure

The haemagglutinin trimer is an elongated cylinder, 135 Å long, with a triangular cross-section varying in radius from 15 to 40 Å. The structure is divided into two distinct regions: (1) a long fibrous region, containing residues from both HA_2 and HA_1, is centred on a 76 Å triple-stranded α-helical coiled-coil extending from the membrane surface; (2) a globular region containing residues entirely from HA_1 sits on top of the fibrous stem and includes an 8-stranded β-structure.

Assembly of the trimer seems to be a requirement for stabilization of the elements of the subunit tertiary structure in the fibrous stem region.

Tertiary fold. The unusually extended tertiary structure of the haemagglutinin may be appreciated by following the schematic drawing of its chain tracing (Fig. 1). The first 63 amino acids reach from the N-terminus at the membrane end of the molecule in an almost extended conformation 96 Å along the molecular length before becoming involved in a compact fold (Fig. 1*b*, *c*). The fold (Fig. 1*c*) contains a short disulphide loop (64–76) and a three-turn helix.

β-Structure. The distal end of the molecule forms an 8-stranded antiparallel β-sheet structure from residue 116 to 261 (Fig. 1*d*, *e*; see also Fig. 3). Similar 'Swiss roll' β-structures have been described in tomato bushy stunt virus[36] and southern bean mosaic virus[37], and have been discussed by Richardson[38]. Two looped-out regions between strands in the β-structure seem to be important antigenic regions: the 125–163 loop between β-strands 1 and 2, and the 187–199 α-helix-containing loop between β-strands 3 and 4 (ref. 28). This β-structure also provides the framework for the sialic acid-receptor binding site (see below).

Switch region. The globular β-region reconnects to the fibrous stem by only two disulphide loops 52–277 and 281–305 (Fig. 1*f*). The globular region is thus an HA_1 loop connected to the fibrous stem by only two antiparallel chains, the N-terminal chain extending away from the membrane and the C-terminal chain returning towards the membrane. In the fibrous region the C-terminal chain of HA_1 extends 60 Å towards the membrane end of the molecule, remaining antiparallel to the amino-terminal HA_1 chain.

HA_1–HA_2 junction. The N-terminus of HA_2 is 21 Å from the C-terminus of HA_1, indicating a substantial rearrangement in this region when the haemagglutinin is activated by cleavage (Fig. 1*g*). The HA_2 amino-terminal glycine-rich sequence forms an uncommon series of four contiguous reverse turns before wrapping transversely around the fibrous coil region ~35 Å from the membrane end of the molecule.

Fibrous helices. Two antiparallel α-helices form the backbone of the fibrous region of each subunit. A short α-helix (29 Å) extends distally from the membrane and connects by an extended chain to a very long (53 amino acid, 14 turn) α-helix which stretches 76 Å back towards the membrane (Fig. 1*g*, *h*). In the trimer, this long helix twists around two identical helices from other subunits to form the coiled-coil core of the fibrous region. The conformation of the extended chain (HA_2, 59–76) and the first half of the long α-helix (HA_2, 77–100) seems to be stabilized predominantly by extensive contacts with the other subunits of the trimer (Fig. 3).

Terminal globular region. The membrane end of the fibrous region contains a compact globular fold which includes a 5-stranded antiparallel β-sheet. The structure of this sheet is noteworthy—the central strand (no. 3) is the amino-terminal chain of HA_1, and the extended chains of HA_2, 350 amino acids away in the sequence, form the two strands flanking it on each side (nos 1, 2 and 4, 5) (Figs 1*g*–*i* and 2). The chain terminates in a three-turn α-helix at the bromelain cleavage site, Gly 175 (ref. 34), at the extreme membrane end of the molecule (Fig. 1*i*). An uncleaved haemagglutinin would enter the membrane 10 amino acids further along. At this stage in the analysis we cannot rule out the possibility that the C-terminal helix was normal to the membrane and may have rearranged as a result of bromelain digestion.

The complete HA_1 chain contains about 36% β-sheet, 6% α-helix and 16% reverse turns. The HA_2 chain has a significantly more regular secondary structure with 14% β-sheet, 53% α-helix and 15% reverse turns.

Biosynthesis and folding. The preceding description of the tertiary structure is not intended to suggest a pathway for the folding of the protein. The acquisition of the three-dimensional fold of a molecule that has been synthesized in the cytoplasm and that has had most of its mass transported to the external side of the membrane is poorly understood.

The tertiary fold of the haemagglutinin structure suggests that the molecule was extruded from the membrane as a single chain

Table 2 Solution of 3 Å difference Patterson with SIR phase refined parameters and statistics

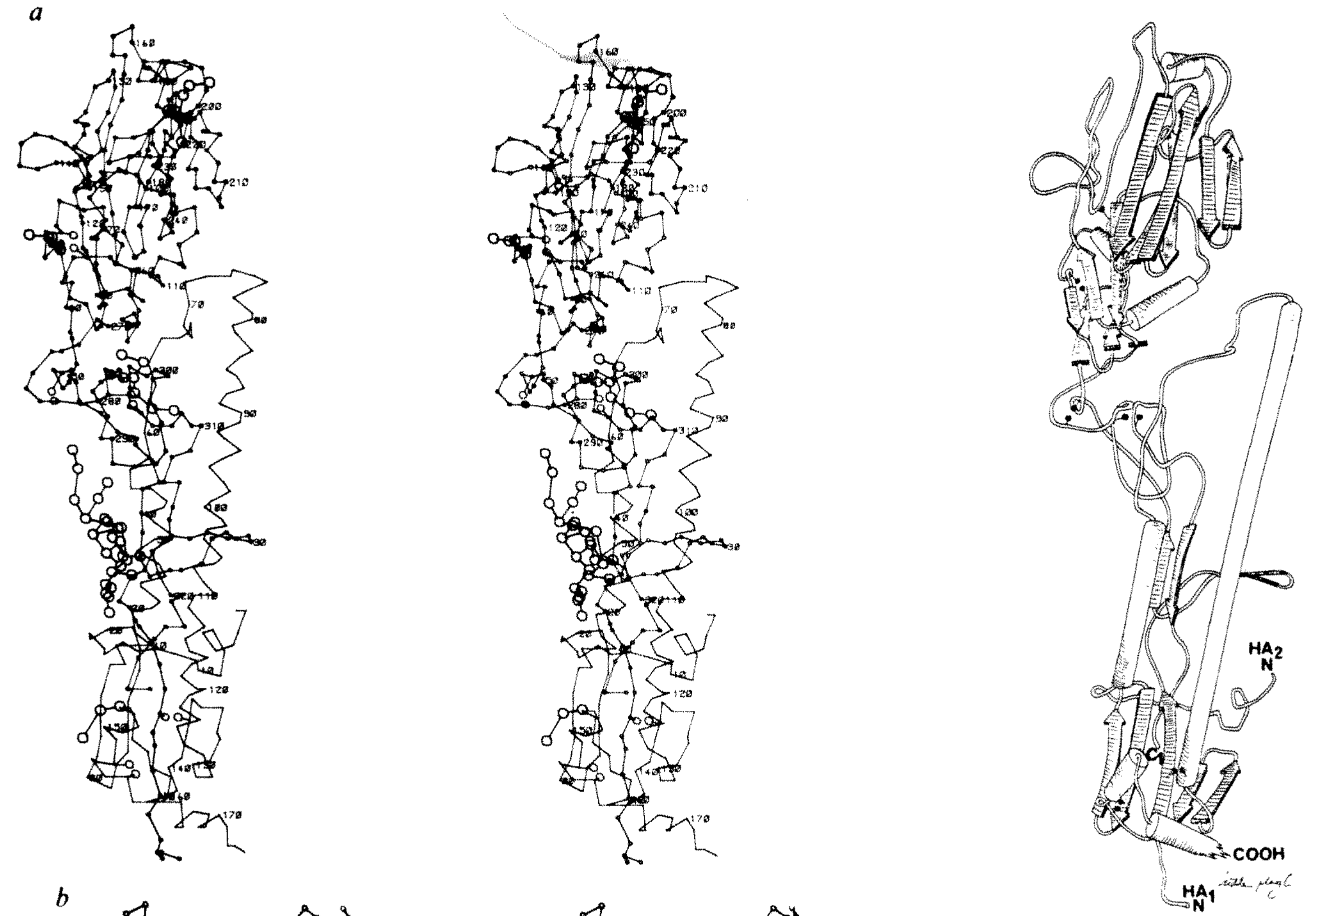

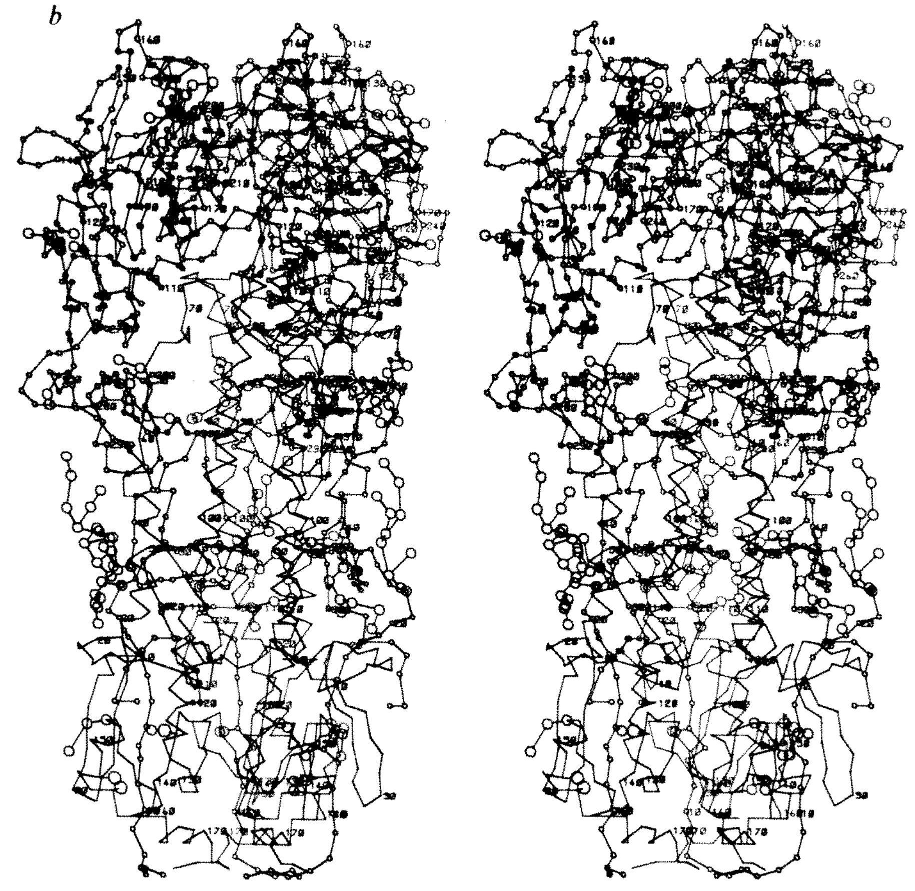

Fig. 3 *a*, Stereo drawing of the α-carbon tracing of an influenza haemagglutinin monomer: ∘, HA_1; –, HA_2; hexose, ○. We expect the present estimate of hexose ring positions to change when stereochemically precise model building and refinement is completed (see text for further explanation). The schematic diagram on the right shows flat, twisted arrows for extended β-chains, cylinders for helices, and filled circles for disulphide bonds. *b*, Stereo drawing of the haemagglutinin trimer: ∘, HA_1; –, HA_2; hexose, ○. The molecule is 135 Å long and 15–40 Å in radius.

(a globular region found at the end of a 'structureless' first 63 amino acids) as opposed to a more cooperative refolding that can be imagined if the entire molecule emerged from the membrane by a concerted conformational change[23,39].

Furthermore, the loop-like topology, with both the N- and C-termini of the chain at the extreme membrane end of the molecule, suggests that the structure may have folded, attached to the membrane not only by the carboxy-terminal anchor peptide (or extruding chain) but also by the amino-terminal hydrophobic signal sequence. (In this respect, the shortest uncharged section in all known haemagglutinin signal sequences (A/Memphis/10/78[H1N1])[40] is 11 amino acids long, sufficient

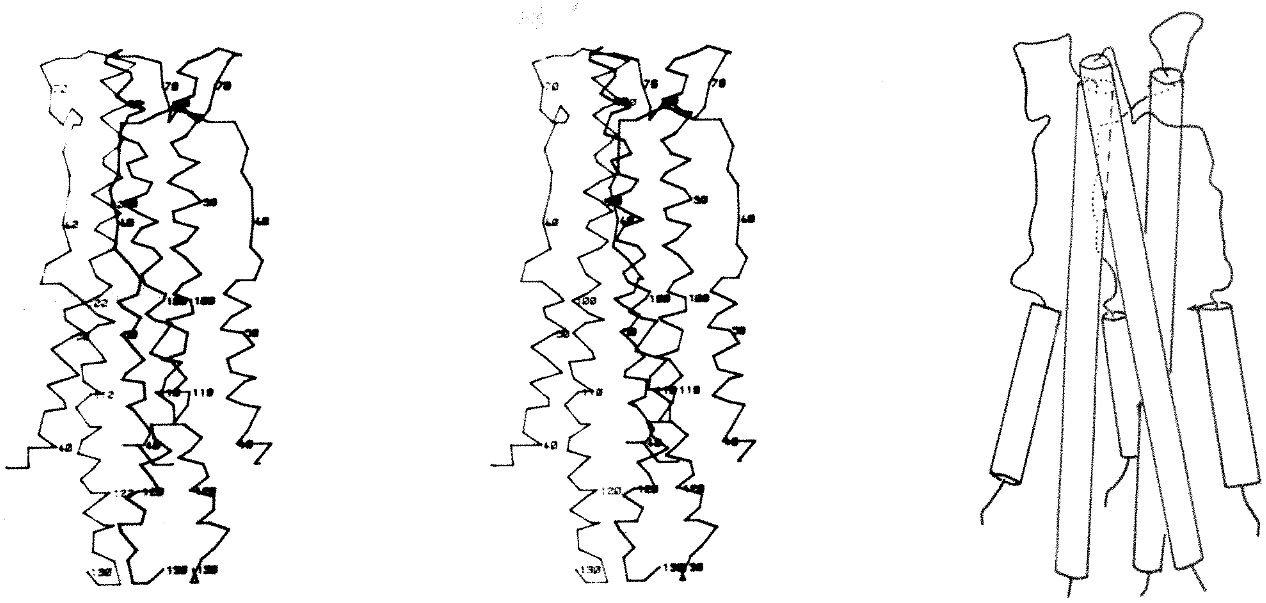

Fig. 4 Stereo drawing of amino acids 36–130 of the HA_2 chain, illustrating the triple-stranded coiled-coil core of the trimer. The schematic drawing on the right illustrates the same region with cylinders representing helices.

to span the lipid bilayer in an extended conformation.) Although the peculiar tertiary structure of the haemagglutinin could be generated without either of these suggestions, they emerge naturally from a consideration of the molecular form.

Quaternary structure

Coiled-coil. The major forces stabilizing the haemagglutinin's trimeric subunit interactions arise from a triple-stranded coiled-coil[41,42] in the fibrous region of the molecule. An α-helix (74–126) extends 76 Å along the molecular 3-fold symmetry axis. Three such helices, one from each subunit, pack together and twist 100° around each other in a left-handed superhelix (Fig. 4). The N-terminal (top) half of the coiled-coil is tightly packed (10 Å helix to helix) with many nonpolar residues in van der Waals contact around the 3-fold axis (Ile 77, Leu 80, Val 84, Leu 91, Leu 98, 99, 102). The C-terminal half of the coiled-coil is expanded away from the 3-fold axis (up to 22 Å helix to helix), with polar and charged residues interacting around the 3-fold axis (His 106, Asp 109, Asp 112, Ser 113, Asn 116, Glu 120, Arg 123). Some polar interactions may be mediated by solvent molecules.

Numerous buried charge pairs form intra-chain and inter-subunit salt bridges that contribute to the stability of the coil. The amino-terminal residues Leu and Phe of HA_2 pack around the 3-fold symmetry axis in the beginning of the open region of the coil (112–118).

The coiled-coil interactions agree with theoretical predictions of helix packing residues based on a heptad repeat[43], but the a, d contact region drifts through a, e, to b, e, by the end of the helices. Ward and Dopheide[44] predicted a coiled-coil in the approximately correct location from heptad repeats in their haemagglutinin sequence data.

Three short α-helices (HA_2, 38–56) pack almost hexagonally and antiparallel with the lower half of the three long helices (Fig. 4). The interactions again involve a twisting such that one end of the short helix lies between two long helices and the other end lies against the long helix of its own subunit.

Trimer assembly. Assembly of the trimeric 'spike' provides stabilizing interactions which seem to be crucial for the tertiary folding of regions in the fibrous stem of the individual subunits. The top half of the long α-helix (HA_2, 77–100) has very few interactions within its own subunit and in a monomer would expose a 36 Å hydrophobic exterior surface. Similarly, the extended chain, HA_2 65–77, and the β-loop of HA_1, amino acid 30, make most of their stabilizing contacts with an adjacent subunit. Thus the polypeptide chain folding in these regions of the monomer may only be completed on assembly of monomers to form the trimers. A corollary of these observations is that the molecule may only project off the surface of the membrane as a 'spike' when assembled as a trimer. Whether the possible flexibility in the monomer stem region in the absence of trimeric contacts may be exploited (by assembly–disassembly) for any biological role remains to be tested.

Membrane-associated region. The top half of the triple-stranded coiled-coil in the fibrous region of the haemagglutinin suggests a model for the quaternary interactions that may take place in the uncharged, predominantly hydrophobic, C-terminal peptide of the complete haemagglutinin (Fig. 1*a*), the domain that anchors the molecule into the virus membrane. This membrane-associated peptide (185–211) is probably α-helical. Twenty-seven uncharged amino acids are sufficient to cross the lipid bilayer in a helical conformation and the hydrogen bonding along the helix would prevent the unfavourable occurrence of unpaired carbonyl oxygen and amide nitrogen atoms in the lipid environment. Whether the three chains of the haemagglutinin trimer cross the membrane together as a unit or separately is unknown. A triple-stranded coiled-coil of α-helix crossing the membrane as a unit is suggested as it would facilitate trimerization on the internal side of the membrane, a property which may be important in the mechanism of budding or other transmembrane functions.

Globular region trimer contacts. The quaternary interactions of the globular region are far fewer than in the fibrous region. Residues from the eight-stranded β-structure are in contact but the interface is not extensive (Fig. 3*b*). The oligosaccharide attached at residue 165 (HA_1) spans the interface between the subunits, forming substantial contacts on both sides that would stabilize the oligomer in this region.

Carbohydrate

The carbohydrate (MW 13,000 per monomer) is located on the surface of the trimer, all along its length, with more in the half of the molecule nearest the membrane surface than at the distal end (Fig. 3). Seven Asn-X-Thr/Ser (six in HA_1) sequences occur in the Hong Kong haemagglutinin and all are glycosylated[6,11]. Two of the oligosaccharide moieties are simple and contain only *N*-acetyl glucosamine and mannose (HA_1, 165,285) whereas the others also contain galactose and fucose (HA_1, 8,22,38, and HA_2, 154). The absence of terminal sialic acids is due to the activity of the viral neuraminidase. The carbohydrate on residues HA_1 165 and 285 is clearly visible in the electron density maps, whereas residues 22 and 38 (HA_1) have less well defined carbohydrate density and residues HA_1 8, 81 and HA_2 154 have

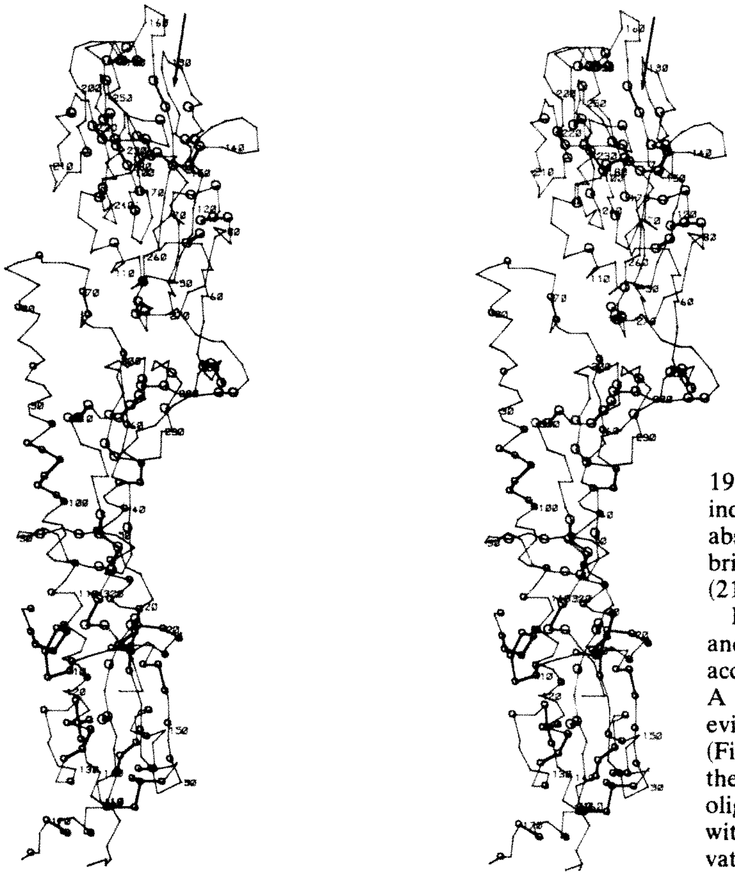

Fig. 5 Conserved amino acid positions from the known haemagglutinin sequences: ○, HA_1; ∘, HA_2. The pocket of highly conserved amino acids at the distal (top) end of the molecule, tentatively identified as the host-cell oligosaccharide receptor binding site, is marked by an arrow.

little or no visible carbohydrate in present maps, possibly due to positional disorder.

We have assigned preliminary positions to 63% of the hexose rings of the oligosaccharides. Our analysis is at present incomplete; for example, our placement of hexose rings is inconsistent with expected branch points at some locations (Fig. 3). Based on the experiences of Huber and colleagues with an oligosaccharide chain on IgG, we expect that when stereochemically precise model building and refinement are completed, these structures will be reliably determined[45,46].

The carbohydrate visible in the map covers 17–20% of the available surface and external residues of the trimer. Residues covered by the carbohydrate are mainly hydrophilic (60%), with Ser and Thr (33%) most frequently interacting with the sugars. Hydrophobic amino acids are often covered (33%) but no clusters of hydrophobic amino acids occur around any substituted Asn residue.

The role of carbohydrate in membrane antigens is largely undefined. Oligosaccharide chains on the haemagglutinin seem to have some structural roles, an observation also made for an IgG oligosaccharide[45]. Carbohydrate–protein interactions are involved in the subunit–subunit interface and inter- and intrachain contact regions. Thus these interactions may stabilize the monomer and the trimeric structure. We cannot assess the possibility that contacts between trimers on the viral surface could involve oligosaccharide chains. Two lysines, three arginines and five aromatic residues, potential tryptic and chymotryptic sites, are covered by oligosaccharide chains which suggests that carbohydrates may also stabilize the haemagglutinin by providing protection against degradative enzymes. The possibility that carbohydrate modulates recognition of the haemagglutinin by the immune system is discussed in the accompanying paper[28].

Structure comparison

Other influenza haemagglutinins seem to have structures very similar to that which we have found for the 1968 Hong Kong strain. The haemagglutinins from 12 strains of influenza have been sequenced (some partially) including viruses from 1957 to 1978 and an avian influenza[5–14,47]. Sequence comparison indicates that 22% of HA_1 and 45% of HA_2 residues are absolutely conserved—these residues include the six disulphide bridges and many structurally important residues such as proline (21 residues) and glycine (9 residues).

Furthermore, the structure reveals that all known insertions and deletions in the sequences of these different strains can be accommodated at the surface of the 1968 Hong Kong structure. A core of structurally important conserved residues is also evident in both the globular and fibrous regions of the molecule (Fig. 5). Similarly, all the carbohydrate attachment sites found in the known sequences are on the surface and could accommodate oligosaccharide side chains, and detailed structures associated with antigenicity also seem to be conserved[28]. These observations indicate that the 1968 structure is a good first-order model for haemagglutinins from many strains. Deviations from this structure will be important, however, in understanding the antigenic variation which the virus undergoes.

Biological activities

The distribution of conserved amino acids on the 3 Å structure reveals a highly conserved region in a surface pocket on the distal end of the molecule that seems well suited for a binding to host-cell oligosaccharide (Fig. 5). This tentative receptor binding pocket includes conserved residues Tyr 98, His 193, Glu 190, Trp 153 and Leu 194 (Fig. 5). It is similar to the wheat-germ agglutinin sialic acid-binding site[48]. No direct experiment has associated virus–cell receptor binding with specific amino acids in the haemagglutinin. Crystallographic data on the haemagglutinin in the presence of oligosaccharides are being collected to locate the receptor binding site directly.

The most highly conserved sequence in the haemagglutinin is the amino terminus of HA_2, where 1 substitution in the first 11 and only 5 in the first 23 amino acids have been observed. This sequence is associated with the activity by which the virus penetrates a host-cell membrane to initiate infection. Cleavage into HA_1 and HA_2 at this point is required for infectious penetration and for *in vitro* membrane fusion[26,27]. An homologous sequence is present at the cleavage-activation site on the Sendai virus fusion protein, where cleavage is required both for infectivity and membrane fusion activity[49]. The HA_2 N-terminal sequence is strongly nonpolar, the first charged side chain occurring at position 11 (Glu). It is unexpectedly rich in glycines (1,4,8 (ref. 12) and 13,16,20,23 (refs 4, 13, 14)) which could indicate flexibility or the presence of an unusual conformation. In the present structure, the first 11 amino acids form a contiguous series of sharp bends, with residues 2 and 3 buried, making 3-fold contacts at the centre of the molecule (Figs 3*b*, 5). (The series of glycine-rich bends in our unrefined model have not been identified with any known form of helix.) The α-amino group forms a salt bridge to an aspartic acid. The strong conservation of the apolar sequence is particularly striking when compared with signal or C-terminal anchoring hydrophobic sequences. In both the latter cases, almost every position has accepted conservation apolar substitutions

St. Groth and colleagues[15,16,23] has involved the selection of variants by growth of an H3 1968 virus (A/NT/60/68) and its derivatives in the presence of the most avid fractions of hyperimmune antisera and, similarly, Laver, Webster and colleagues[22,24,25] have selected variants of A/Memphis/1/71, a virus closely related to A/Hong Kong/1/68, by growth in the presence of monoclonal antibodies prepared against its haemagglutinin. After virus selection, amino acid sequence data were obtained for the haemagglutinins of the variants. Although only a partial sequence data are available, they indicate that variants selected using monoclonal antibodies contain single amino acid substitutions, which directly or indirectly alter an antigenic region of the haemagglutinin molecule sufficiently to prevent neutralization of the variant by the selecting antibody[22]. The locations of the amino acid substitutions in haemagglutinins of the laboratory-selected variants are summarized in Fig. 2*c*.

Suggested locations for the antigenic sites. An antigenic site is a region of a molecule involved in antibody binding[26]. Although there are no exhaustive immunochemical data such as those used in studies defining the antigenic sites on lysozyme and myoglobin[27,28], a combination of the amino acid sequence information and the three-dimensional structure of the 1968 haemagglutinin[1] allows identification of four regions of the Hong Kong haemagglutinin molecule in which amino acid substitutions seem to affect antibody binding.

Site A: an unusual protruding loop from amino acids 140 to 146, (see Fig. 2) which projects 8 Å from the local molecular surface, forms the centre of the most obvious antibody-binding site. Clearly the haemagglutinin of each antigenically distinct virus of epidemic significance has a mutation in this region (Fig. 2 and Table 1): A/Memphis/102/72: residue 144, Gly to Asp, and residue 122, Thr to Asn[4,6]; A/Victoria/1/75 and A/Victoria/3/75: residue 145, Ser to Asn, and residue 137, Asn to Ser respectively[9,12,13]. Furthermore, the haemagglutinins of a group of monoclonal antibody-selected variants neutralization by single amino acid substitutions in this region: 143, Pro to His, Ser, Thr, Leu; 144, Gly to Asp, and 133, Asn to Lys[22]. Conserved amino acids Gly 134, Ala 138, Cys 139, Phe 147 and Phe (Tyr) 148 occurring at each end of the antigenically variable loop provide the structural foundation of the site in all 10 haemagglutinins examined (including one Avian[3] and one Asian[7] subtype).

Site B: this comprises the external residues 187–196 of an *α* helix, and adjacent residues along the upper edge of a pocket tentatively implicated in virus receptor binding[1] (see Fig. 2). Two substitutions in the haemagglutinin of the 1972 virus, A/Memphis/102/72: 188, Asn to Asp, and 155, Thr to Tyr[4,6]; and two more in that of the 1975 virus, A/Victoria/3/75: 189, Gln to Lys and 193, Ser to Asn[9,12,13] characterize the site, but the lack of sequence information for this region of the haemagglutinins of several variants leaves the comparison incomplete[9]. The substitution 186, Ser to Ile in the haemagglutinin of the 30D virus[16], selected using 'avid-fraction' antisera, may also support the site designation. In addition, the existence of this structure in other haemagglutinins is suggested by the observed conservation of neighbouring residues. On the inward face of the helix residues 190 Glu, 191 Gln, 194 Leu and 195 Tyr are conserved in all the known sequences, as are 153 Trp and 154 Leu. However, because no amino acid substitutions in the haemagglutinins of variants selected by monoclonal antibodies comparable with those which support the delineation of site A have yet been reported, more direct evidence of antibody binding to this region is not available.

Site C: a bulge in the tertiary structure at the disulphide bond between Cys 52 and Cys 277, 60 Å from the distal tip of the molecule, comprises another antibody-binding site (see Fig. 2). The haemagglutinins of the viruses from both epidemic periods have substitutions clustered in this region:

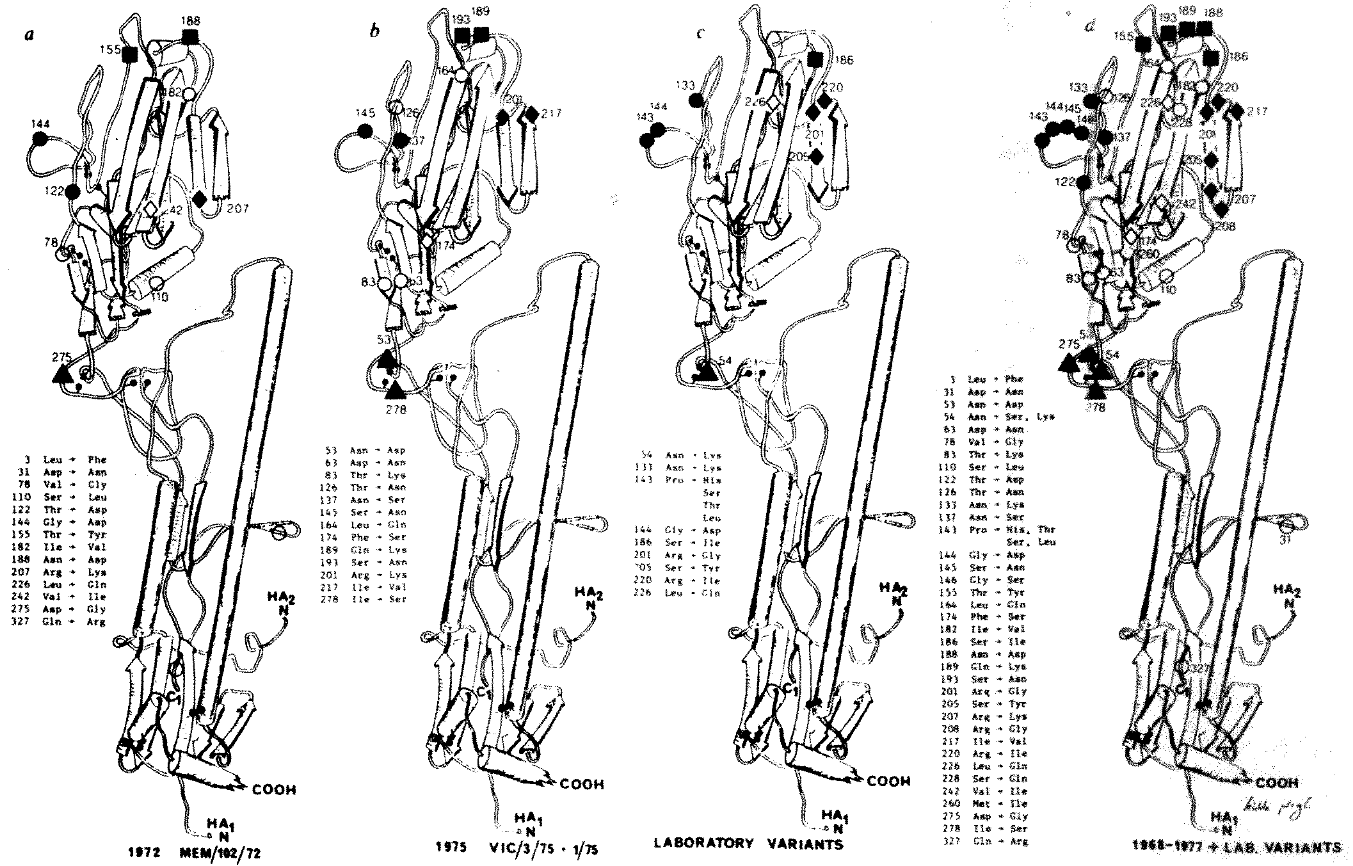

Fig. 2 Schematic drawing of a monomer of the AICHI-1968 haemagglutinin showing locations of amino acid substitutions on HA_1. ●, Site A; ■, site B; ▲, site C; ◆, site D (subunit interface); ◇, surface; ○, neutral. *a*, Amino acid changes from AICHI/2/68 to MEM/102/72 (refs 4–6, 10, 11). *b*, Amino acid changes from MEM/102/72 to VIC/3/75 (refs 12, 13). *c*, Laboratory-selected antigenic variants from growth in monoclonal or most-avid-fraction antibody[9,15,16,22]. (See Table 1 for details.) *d*, Summary of all known alterations from 1968 to 1977 including laboratory-selected variants[3–16,22]. A three-dimensional (stereo) drawing of the same view of the molecule is found in Fig. 3 of ref. 1.

Table 1 Antigenic drift residues

Strain	Residue	Replacement (from)	Replacement (to)	Probable antigenic site	Structural location and probable effects of replacement
MEM/102/72*	144	Gly	Asp	A	External loop. Substitution is both larger and charged. Change from glycine may restrict ϕ, Ψ angles of main chain, altering the loop shape.
	122	Thr	Asn	A?	External extended chain (β). Substitution is larger, 18 Å from residue 144, and may effect the edge of a contact region centred at the 144 loop.
	155	Thr	Tyr	B	4 Å from residue 193 (VIC) and the C-terminal end of the 187–196 α-helix. Substitution is considerably larger and would project over the 'pocket'.
	188	Asn	Asp	B	N-terminal exterior face of α helix 187–196, 18 Å from residue 155 altered charge.
	275	Asp	Gly	C	Near 52–77 disulphide bond bulge. Asp 275 was H-bonded to Asn 53, an interaction that would be lost by the Gly substitution.
	207	Arg	Lys	D?	Subunit interface near residues 99 and 100 of another subunit. Substitution is conservative but shorter and unbranched.
	242	Val	Ile	D??	At the surface but near residues 205 and 207 of same subunit and 221 and 222 of an adjacent subunit, also near the oligosaccharide chain attached at 165. Substitution is larger.
	226	Leu	Gln	?	External on the front of the 'pocket', 8 Å from residue 137 (A), 8 Å from 186 (B?), 16 Å from 242 (D?). Substitution increases size and changes polarity. Gln could reach Ser 136 or Asn 38 for H-bonds: Found in 29C 'avid-fraction' variant. Reverts in VIC/3/75.
	3	Leu	Phe	None	Near membrane, probably inaccessible to antibodies. Reverts in VIC/3/75.
	327	Gln	Arg	None	100 Å from distal tip. Reverts in VIC/3/75.
	31	Asp	Asn	None	82 Å from distal tip.
	78	Val	Gly	None (E?)	Probably buried by oligosaccharide at 81.
	182	Ile	Val	None	Buried residue near 220.
	110	Ser	Leu	None	Near Arg 261, buried. Reverts in VIC/3/75.
VIC/3/75† (VIC/1/75)‡	(145)	Ser	Asn	A	External loop. Substitution is larger and has more potential for H-bonding. If the Asn interacts with the 135/136 region the loop conformation might be altered (VIC/1/75).
	137	Asn	Ser	A?	External 7 Å from residue 145. Substitution is smaller, possibly near an edge of the A site.
	189	Gln	Lys	B	External face of 187–196 α helix. Substitution is larger and charged.
	193	Ser	Asn	B	External face of 187–196 α helix, 4 Å from 189 and 4 Å from 155. Substitution is larger with more H-bond potential. Possible new interaction with Tyr 155.
	278	Ile	Ser	C	Surface residue in 52–277 disulphide bulge. Substitution is smaller and polar and could H-bond to Asn 54.
	(53)	Asn	Asp	C	External in 52–277 disulphide bulge, next to 275. Introduces charge (VIC/1/75).
	201	Arg	Lys	D?	Packed in the subunit interface against 217 of the other subunit, below 188. Substitution is smaller and less bulky and could effect the fit between subunits or the site 'B' helix or be recognized directly if the subunit interface were exposed by a conformational charge.
	217	Ile	Val	D?	Packed in the subunit interface against 201 of the other subunit. Similar to the 201 change. Under 189 (B).
	174	Phe	Ser	D??	External after surface chain, 169 to 173: Pro, Asn, Asn, Asp, Asn. 14 Å from 242. 169 is next to 242.
	164	Leu	Gln	None	Buried next to 127. Substitution gets larger and polar.
	126	Thr	Asn	None	New oligosaccharide attachment site. Carbohydrate would cover a smooth face. Remote possibility that it could reach 133 or 122 and affect site A.
	327				Same as 1968 AICHI strain.
	3				
	226				
	110				
	63	Asp	Asn	None (E?)	New oligosaccharide attachment site, very near old site at 81.
	83	Thr	Lys	None (E?)	Destroys oligosaccharide attachment site at 81.
TEX/1/77§	146	Gly	Ser	A	External loop. Substitution increases size and potential for H-bonding to 135, 136 region, also limits Φ, Ψ angles of main chain (see MEM/102/72 residue 144).
	54	Asn	Ser	C	External as 53 above, next to 278 which is not yet sequenced in TEX/1/77.
	260	Met	Ile	None	Buried next to 177, near 174. Close to site D?.
ENG/187/70§	228	Ser	Gln	None	In pocket near 226. Substitution is much larger, and does not reappear after this strain.
ENG/42/72§	208	Arg	Gly	D?	Near subunit interface, residue 207. Substitution smaller and lacks charge.
Monoclonally selected variant‖	143	Pro	His, Ser Thr, Leu	A	Loop. All these residue 143 variations were selected with a single antibody. Selection with other antibodies has produced identical sequence changes.
	144	Gly	Asp	A	Loop. (See MEM/102/72 residue 144).
	133	Asn	Lys	A	Selected with the same antibody that 143 Pro–Ser was selected.
	54	Asn	Lys	C	External 52–277 disulphide bulge. Substitution is larger and charged.
	205	Ser	Tyr	D	Buried in the subunit interface near 221 and 220 (See VIC/3/75 residue 201).
Avid-fraction variant¶					
30D	186	Ser	Ile	B or D	Below 189 in B-site helix. Ser probably H-bonded to carbohydrate attached at 165. Ile may move carbohydrate affecting site D or directly affect site B.
30D	220	Arg	Ile	D	Subunit interface residue near 203 and 205 of an adjacent subunit 217, of the same subunit. Arg 220 probably H-bonds to Gln 210 of another subunit—the Ile substitution could not make such an interaction.
34D	201	Arg	Gly	D?	Refer to VIC/3/65 residue 201.
29C	226	Leu	Gln	?	Refer to MEM/102/72 residue 226.

A/Memphis/102/72: 275, Asp to Gly[4–6]; A/Victoria/1/75 and A/Victoria/3/75: 53, Asn to Asp and 278, Ile to Ser respectively[9,12,13]. The absence of amino acid sequences for the 275 to 278 region of HA_1 from a number of partial sequences may also mean that this list is incomplete[9]. A substitution at position 54, Asn to Lys, in a variant selected by monoclonal antibody prevents its neutralization[22] and variant 30D also fails to react with the same monoclonal antibody[16]. Again the variable amino acids seem to be anchored in a matrix of conserved residues: 50 Lys, 51 Ile (Leu), 52 Cys, 277 Cys, 281 Cys and 286 Gly. The variable residues at all four positions are in direct contact. In the structure of the 1968 haemaglutinin, Asp 275 is hydrogen-

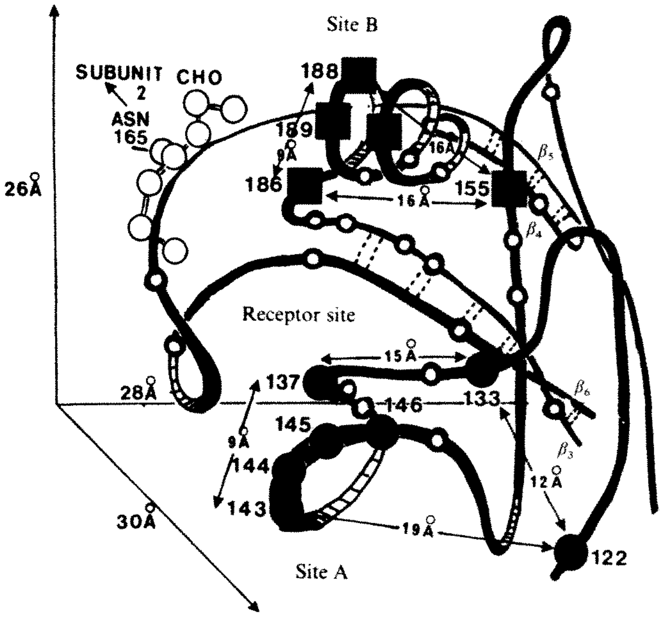

Fig. 3 Schematic drawing showing the size and shape of two of the proposed antigenic sites: ●, A and ■, B (see Fig. 2 and text). Their relationship to the pocket of conserved residues tentatively identified as the host sialic-acid-containing receptor binding site is shown.

bonded to Asn 53, Ile 278 is packed against Asn 54, and Cys 52 bonds to Cys 277. Changes in the types of contact between these residues (for details see Table 1) may be the structural alterations to which antibody binding is sensitive.

Site D: in the first three sites, the amino acid substitutions suggested as causing antigenic variation are external and, in principle, directly recognizable by molecules of the immune system. Site D departs from this apparently simple situation (site C may also). Several amino acid substitutions in the haemagglutinins of both natural and laboratory-selected antigenic variants occur in the interface region between subunits in the haemagglutinin trimer: A/Memphis/102/72: 207, Arg to Lys[4,6]; A/Victoria/3/75: 201, Arg to Lys and 217, Ile to Val[9,12,13]; monoclonal variant: 205, Ser to Tyr[22], and 'avid-fraction' variants 34C: 201, Arg to Gly, and 30D: 220, Arg to Ile[15,16] (see Figs 2, 4). These amino acids may be recognized directly as a result of a relative movement of the globular domains of HA_1 to expose the interface regions. However, it is also possible that the actual antibody binding site is remote from these amino acids but affected by the exact fit at the interface, which might be disturbed by the substitutions listed. A site which spans the monomer–monomer boundary or one near the oligosaccharide chain attached at residue 165, which overlaps that boundary, could be particularly sensitive to alterations in the subunit contact region. Residues 242, Val to Ile and 226, Leu to Gln in A/Memphis/102/72[4,5]; 174, Phe to Ser in A/Victoria/3/75[9,12,13,25] and 226, Leu to Gln (also near sites A and B) in laboratory variant 29C (refs 15, 16) are likely components of this area (see Fig. 2). The amino acid sequences of peptides in the 174 and 242 regions are absent from many partial sequences[9].

Other amino acid substitutions in HA_1 and HA_2 found in nature are considered to be antigenically neutral for reasons detailed in Table 1. For example, the substitution at residue 78, Val to Gly, in the A/Memphis/102/72 haemagglutinin, is buried by the oligosaccharide at position 81. Similarly, in A/Victoria/3/75 at residue 83, the Thr to Lys substitution destroys the oligosaccharide attachment site at residue 81, but the Asp to Asn change at 63 creates a new site—this means that the carbohydrate could occupy almost the same position.

The characterization of new variants may provide evidence for additional sites (for example, 122 and 126, site E?) or extend the size of those proposed.

Antibody interactions and neutralization. This analysis has not defined the extent of each site but only amino acid positions within sites that seem sensitive to substitution when examined serologically, Nevertheless, areas of the surface remain, not in the interfaces nor covered by oligosaccharide chains, that seem serologically unimportant. It is not clear why these regions are not immunogenic, although, for example, the concave shape of the pocket of conserved amino acids tentatively identified with receptor binding[1] probably prevents the production of avid antibodies against that region. The proximity of sites A, B and D to this tentative receptor site (Fig. 3) may be important in the mechanism of neutralization.

Table 1 summarizes changes in the size and/or change of the observed substitutions that would result in a decrease in the binding constant of antibody at a site as a result of steric repulsion or unfavourable charge interactions (the burying of an unpaired charge in the antibody–antigen complex). In addition to these mechanisms, the glycine-rich loop in site A protrudes in such a way as to make so few contacts with the rest of the structure that the effect of mutations in it may be amplified by altering the conformation of the entire loop. The more restricted range of torsion angles possible for amino acids replacing glycine and the potential for hydrogen and ionic bonds from the loop to adjacent regions of the molecule possible with polar or charged substitutions (Table 1) are candidates for such an alteration. (X-ray data on isomorphous crystals of singly substituted, monoclonally selected variant haemagglutinins prepared in collaboration with R. Webster are being collected to allow a direct visualization of these altered sites.)

Antigenic variation and disease incidence (1968–1975)

It seems from the above discussion that the haemagglutinins of both major disease-causing viruses of this period had at least one

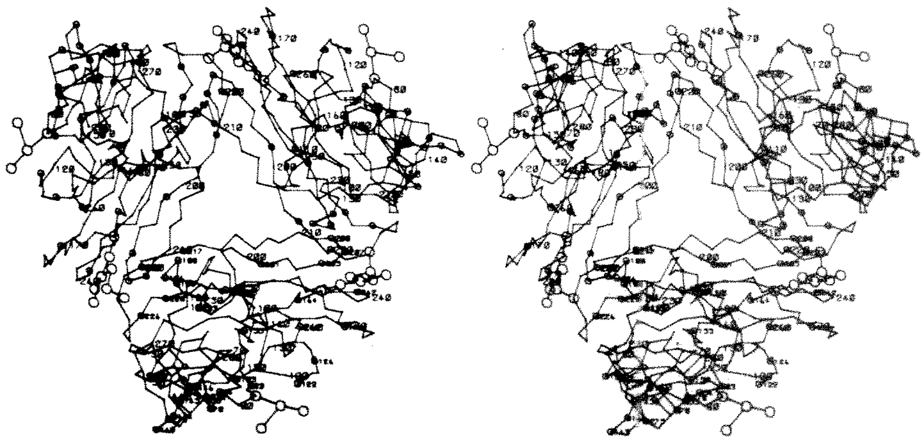

Fig. 4 Stereo drawing of the α-carbon tracing of residues 48–280 (HA_1) of the haemagglutinin trimer. Circled residues are natural and laboratory variations[3–16,22] (see Fig. 2*d*). Tentative (see ref. 1) carbohydrate positions are shown as large open circles for the attachment sites at Asn 81 and Asn 165. The view is down the trimer axis, viewed from the outside towards the membrane.

mutation in each of the four antigenic sites described, and may have required these to avoid virus neutralization. Thus, the viruses acquired the antigenic potential to cause a recurrence of disease in individuals previously infected with viruses of the H3 subtype. Because other characteristics of viruses such as transmissibility and virulence are important in the timing and impact of epidemics, antigenic potential (the recreation of a threshold of susceptible hosts) may, in general, only be a necessary condition for, but not capable of, the generation of epidemics.

The possibility has also been raised[25] that one locus may be more immunogenic than others and therefore, when altered, might be of greater advantage to the virus. Site A, due to its accessibility, seems to be ideally suited both for avid antibody binding and for accepting amino acid substitutions without affecting the main framework of the molecule. To establish the relative importance of the four antigenic sites, a definition will be needed of the spectrum of antibody molecules in human sera with regard to amount, avidity and site specificity.

The character and location of amino acids on the 1968 haemagglutinin structure conserved in three subtypes[3–14] indicates that the basic framework of the molecule is preserved[1]. Because strictly conserved amino acids are found flanking each of the proposed antigenic sites, these structures are also probably present in haemagglutinins from other subtypes. Whether or not the same sites are involved in the interaction of these other haemagglutinins with antibodies is unknown. In the haemagglutinin of other subtypes, these sites have not only varied considerably in amino acid sequence but probable points of oligosaccharide chain attachment are sometimes found within or near regions of the molecule sequentially equivalent to those proposed here as antigenic sites in the Hong Kong haemagglutinins: for example, in fowl plague virus[3] (Hav1) at 133 (site A), 158 (site B) and 240 (possibly site D), and in A/Japan/305/57 (H2) (refs 7, 14) at 169 (site D). It is therefore possible that the immune recognition of such sites in the haemagglutinins of other subtypes is sterically prevented by oligosaccharide chains.

We thank Colin Ward and Theo Dopheide for A/Memphis/102/72 and X:31 A/Aichi/2/68 sequences, Walter Fiers for the sequence of A/Victoria/3/75 and X:31, and Mary Jane Gething and Mike Waterfield for Japan/305/57. We thank Andrew Cherenson for assistance in sequence searches and comparisons, and acknowledge support from NIH grant AI 13654 (D.C.W.). Computing was supported by NSF PC-77-11398.

A gene chimaera of SV40 and mouse β-globin is transcribed and properly spliced

Gilbert Chu & Phillip A. Sharp

Center for Cancer Research and Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

A gene chimaera of the first exon from simian virus 40 (SV40) sequences coding for T antigen placed upstream from the third exon from mouse β-globin, and separated by the resultant new chimaeric intron, was cloned into a bacterial plasmid. When transfected into monkey cells, the gene chimaera was transcribed, polyadenylated and spliced using the donor splice site from SV40 and the acceptor splice site from mouse β-globin. This result suggests that a donor site from one gene can be spliced to an acceptor site from another gene.

THE finding of intervening sequences within mammalian genes has led to speculation that they take part in both phylogeny and ontogeny by facilitating the rearrangement of genes. These ideas are based on the assumption that the cell can properly splice together RNA from any two exons. Thus, evolution and differentiation may proceed in quantum jumps as a new gene is built by rearrangement of exons coding for functional protein domains from different pre-existing genes[1]. Differentiation of the immunoglobulin gene proceeds in such a manner[2]. Similarly, the regulation of a gene may be radically altered if a promoter sequence and short exon are introduced upstream from a series of exons coding for a complete protein. Insertion of this transposable promoter could occur thousands of nucleotides from the protein-coding exons.

If exons can be shuffled arbitrarily and the RNA is properly spliced, then there should be similarity among all donor sites and among all acceptor sites. In fact, the boundaries of intervening sequences are characterized by two consensus sequences, one for donor sites and one for acceptor sites[3]. Furthermore, there are examples of splicing pattern in which two or more donor sites

0028–0836/81/050378—05$01.00

are spliced to a common acceptor site (for example, the early region of SV40)[4,5]. The sequences of such donor sites seem to bear no special relationship other than their relationship to the consensus donor sequence. There are similar examples of splicing patterns in which two or more acceptor sites are spliced to a common donor (for example, the late mRNAs of adenovirus)[6,7]. These observations support, but do not prove, the hypothesis that a donor site from one gene can be spliced to an acceptor site from another gene. The experiment described here tests this hypothesis.

SV40–mouse β-globin chimaera

A gene chimaera of the first exon from SV40 T antigen placed upstream from the third exon from mouse β-globin (MβG), and separated by the resultant new chimaeric intron, was cloned into the plasmid vector pBR322 (see Figs 1, 2). The recombinant genome DNA was isolated from bacteria and transfected into African green monkey kidney cells (CV-1 cell line). RNA was collected from the cells and analysed by a modification of the S_1-endonuclease gel technique[8]—hybridization in 80% formamide to an end-labelled DNA probe, followed by digestion with S_1 endonuclease and electrophoresis on either neutral or denaturing gels.

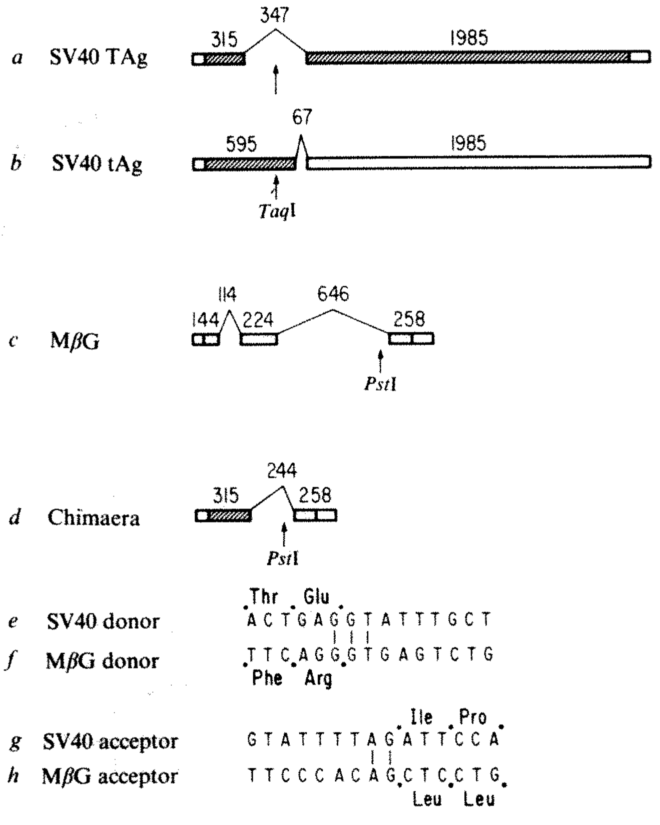

Fig. 1 mRNAs from early SV40, MβG and the gene chimaera. *a*, *b*, The two major SV40 mRNAs produced early in the lytic cycle, corresponding to large T and small t antigens. The coding regions are hatched[4]. *c*, The mouse β-globin mRNA where the coding regions are dotted[15]. *d*, The chimaeric mRNA which would be transcribed from a gene containing SV40 sequences upstream from the SV40 *Taq*I site and containing MβG sequences downstream from the MβG *Pst*I site. The ligation is achieved by introducing *Pst*I linkers (Collaborative Research) to the *Taq*I site in SV40 and annealing to the *Pst*I site in MβG. The chimaeric mRNA contains the first SV40 T-antigen exon and the third MβG exon, with the two exons separated by a chimaeric intron containing both SV40 and MβG sequences. *e*–*h*, The splice junctions from SV40 and MβG. The junction sequences from the SV40 T-antigen intron *e* and *g*[4], and the second MβG intron *f* and *h*[15] are shown. The chimaeric intron consists of SV40 donor and MβG acceptor. Note that the phase of the reading frame relative to the splice junction is the same for the SV40 and MβG introns. Thus the spliced chimaeric mRNA preserves the proper reading frame and permits the translation of a chimaeric protein.

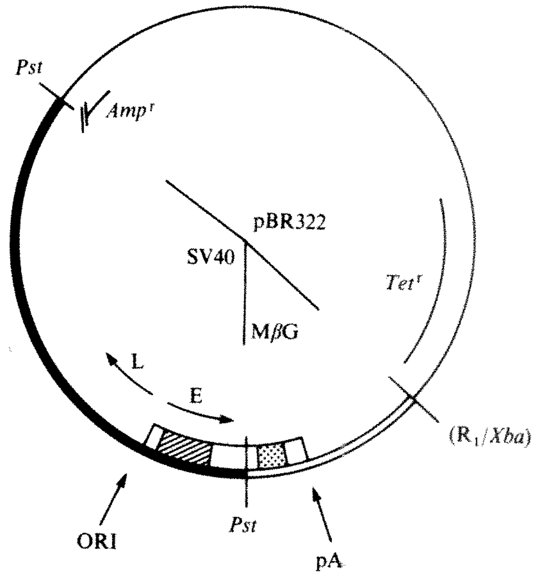

Fig. 2 Structure of the SV40–MβG–pBR322 recombinant genome. SV40 sequences (2,460 base pairs) are indicated by the solid bar, mouse β-globin sequences (~900 base pairs) by the double line and pBR322 plasmid sequences (3,607 base pairs) by the single line. The mouse β-globin (MβG) gene has been sequenced[15]. The SV40 DNA was made from strain 777. Strain 776 has been sequenced[21,22]. Strains 776 and 777 show no difference, by S_1 digestion, in the SV40 early region of interest in this work (G.C., unpublished data). The MβG–pBR322 junction was formed by the blunt-end ligation[23] of the *Xba*I site in the 3′-flanking sequence of MβG with the *Eco*R1 site in pBR322. The SV40–MβG junction was formed by cleavage of SV40 at the *Taq*I site, filling in the staggered end to form a blunt end by Klenow fragment of DNA polymerase I, attachment of *Pst*I linkers to the blunt end, digestion by *Pst*I and staggered-end ligation to the *Pst*I site in the second intron of MβG. The SV40–pBR322 junction was formed by the staggered-end ligation of the *Pst*I site at 0.04 map units in SV40 to the *Pst*I site in the ampicillin-resistance gene of pBR322. The structure was confirmed by analysis with restriction enzymes *Hin*dIII and *Bgl*I, and by double digests with *Hin*dIII and *Pst*I, *Bal*I and *Bgl*I, and *Hin*dIII and *Bal*I. The restriction patterns confirmed expectations from the construction. In particular, the region of the chimaeric intron was shown to contain a *Pst*I site and to be of the length predicted from the SV40 and MβG sequences, to an accuracy of 20 base pairs. The recombinant plasmid was grown in strain C600 of *Escherichia coli* under P2 containment. In SV40, the origin of replication (ORI) and the directions of early (E) and late (L) transcription are indicated. In MβG, the site of polyadenylation (pA) is shown[15]. The DNA sequences coding for the chimaeric mRNA are indicated by the broad bar. The hatched area indicates the coding region of the first exon in SV40 T antigen. The dotted area indicates the coding region of the third exon in MβG. The two coding regions are separated by a chimaeric intron. In pBR322, the ampicillin (*Amp*^{r}) and tetracycline (*Tet*^{r}) resistance genes are indicated by the solid lines. The *Amp*^{r} gene is no longer intact.

Chimaeric mRNA is transcribed, polyadenylated and spliced using the normal MβG acceptor site

The chimaeric genome was transfected into CV-1 cells by a modification of the calcium phosphate co-precipitate technique[9]. It was found that 15% of the cells could be routinely transfected with SV40 DNA in this manner (G.C., unpublished data). To obtain optimal levels of chimaeric mRNA, the chimaeric genome was co-transfected with DNA consisting of SV40 cloned into pBR322 at the *Bam*HI site. The *A* gene product is necessary for the replication of SV40 (ref. 10), and a 10-fold increase in early mRNA is observed between 9 h and 48 h after infection with SV40 virus[11,12]. The SV40–pBR322 recombinant contains an intact early region, and thus replication from the SV40 origin of replication will take place. As the chimaeric genome also contains the SV40 origin of replication, it was hoped that co-transfection would produce a similar increase in chimaeric mRNA, and such an increase was observed. RNA was collected 48 h after transfection. In some cases, poly(A)$^+$ RNA was selected by passage over an oligo(dT) column; all poly(A)$^-$ fractions were treated with DNase I. A DNA probe labelled at the 5′ end (see Fig. 3) was hybridized to the RNA preparations in 80% formamide at 47 °C, treated with S_1 endonuclease and the products electrophoresed.

The results of hybridization of the RNA with the DNA probe labelled at the 5′ end of the *Bal*I site are shown in Fig. 4 for a neutral 2% agarose gel (*a*) and for a denaturing 7 M urea 8% acrylamide gel (*b*). *Bal*I cleaves in the MβG sequences in the chimaera and thus a DNA probe labelled at this site will only hybridize to RNA complementary to globin sequences and not to RNA transcribed from the complementing SV40. The migration of a band on a neutral gel indicates the distance of the 5′ end of the mature RNA from the 5′-end label of the probe. RNA transcribed from the chimaeric genome that was spliced would generate a 415-base pair RNA/DNA hybrid (see Fig. 3). Some 315 and 100 base pairs of this hybrid are contributed by the exons from SV40 and MβG, respectively. Bands, generated by the poly(A)$^+$ fraction from cells transfected with the chimaeric genome after hybridization to DNA labelled at the *Bal*I site, are shown in Fig. 4*a*, lane 4. An RNA/DNA hybrid migrating at a rate expected for a 420 ± 10 base pairs is clearly present. No such band appears in either the poly(A)$^-$ fraction (Fig. 4, lane 5) or a mock transfection sample (Fig. 4, lane 3).

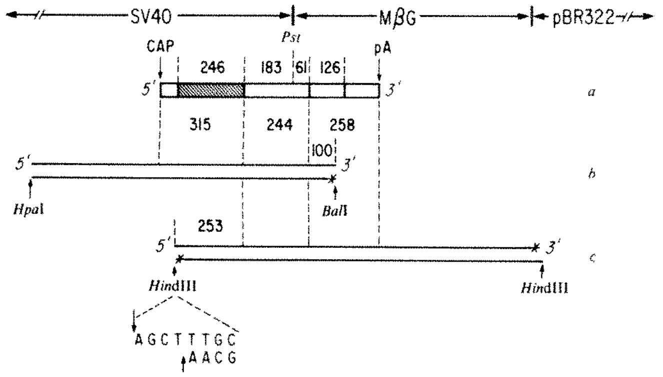

Fig. 3 Gene chimaera and the DNA probes used to analyse the chimaeric mRNA. *a*, The gene chimaera (817 base pairs) is shown from the major initiation site in SV40 (CAP) to the polyadenylation site in MβG (pA). The chimaeric intron is 244 base pairs long, containing 183 base pairs of SV40 sequence and 61 base pairs of MβG sequence. The two coding regions contain 372 base pairs, corresponding to a polypeptide of 124 amino acids. Note that both the coding region and the donor splice site of SV40 t antigen extend beyond the SV40–MβG junction. At the top of the figure the regions corresponding to SV40, MβG and pBR322 sequences are delineated. *b*, the 5′-end-labelled DNA probe was prepared by cutting the recombinant genome with *Bal*I, labelling with [γ-^{32}P]ATP in the presence of t_4 polynucleotide kinase, cutting with *Hpa*I and isolating the fragment by gel elution[24]. *c*, The 3′-end-labelled DNA probe was prepared by cutting the recombinant genome with *Hin*dIII. The DNA was then incubated with dCTP and T_4 DNA polymerase in 10 μl of a buffer of 50 mM Tris *p*H 8, 7 mM $MgCl_2$, 7 mM β-mercaptoethanol at 9 °C to allow the 3′→5′ exonuclease activity of the enzyme to remove nucleotides up to the first position containing a cytosine[25]. After 30 min, [α-^{32}P]dATP was added to allow the 5′→3′ polymerase activity of the enzyme to add labelled nucleotides. After labelling, the fragment was isolated by elution from an agarose gel. The left-hand sequence after *Hin*dIII cleavage is indicated.

The same experiment was done with RNA collected 9 h after transfection with chimaeric DNA alone. About one-tenth the amount of chimaeric RNA was observed in these conditions as compared to co-transfection with SV40. On a neutral gel, the same size band of 420 ± 10 base pairs was observed in both the total cytoplasmic sample and the poly(A)$^+$ fraction, but not in the poly(A)$^-$ fraction or in a mock transfection cytoplasmic sample (data not shown).

The migration of a band on a denaturing gel indicates the distance of the first acceptor splice site from the 5′-end label. Hybridization of DNA labelled at the *Bal*I site to RNA spliced at the acceptor sequences on the third MβG exon would yield a S_1-resistant segment some 100 nucleotides in length. A band migrating at this rate was generated by hybridization of the probe to globin mRNA (Fig. 4*b*, lane 9). A band of the same length, 100 nucleotides, was produced by hybridization to poly(A)$^+$ RNA extracted from a cell transfected with the chimaera. Because a sequencing ladder was run in parallel lanes and because hybridization of the probe to both chimaeric mRNA and MβG RNA produced co-migrating bands, we can assume that the acceptor sites for the chimaeric and MβG splices are identical, 100 nucleotides upstream from the *Bal*I site in the third MβG exon (see Fig. 3).

Chimaeric mRNA is polyadenylated at the normal MβG polyadenylation site and spliced using the normal SV40 donor site

Hybridization results with the probe (labelled at the 3′ end of the *Hin*dIII site in SV40 sequences) are shown in Fig. 5 for a neutral 2% agarose gel (*a*) and for a denaturing 7M urea 8% acrylamide gel (*b*). The migration of a band on a neutral gel indicates the distance of the 3′ end of the mature mRNA from the 3′-end label of the DNA probe. Hybridization of a probe labelled at the 3′ terminus of the *Hin*dIII site to a spliced chimaeric RNA would generate a 511-base pair RNA/DNA hybrid (see Fig. 3). As shown in Fig. 5*a*, lane 4, a band migrating as a 520 ± 20-base pair RNA/DNA hybrid resulted from hybridization to poly(A)$^+$ RNA extracted from cells transfected with the SV40 MβG recombinant.

Because the RNA in this experiment was collected from cells co-transfected with both cloned chimaeric DNA and cloned SV40 DNA, and because the probe is labelled at the 3′ end in the SV40 sequence, there are bands in Fig. 5*a*, lane 4, corresponding to the early SV40 mRNAs for small t and large T antigens. This can be seen by comparing lane 4 with lane 13, which is the result of hybridization to RNA from cells infected with SV40 virus alone. The bands in Fig. 5*a*, lane 4 for small t and large T antigen are much lighter than the band for the chimaeric mRNA because the T_m for the region of SV40 between the origin of replication and *Taq*I sites is ~36 °C (ref. 5) and the T_m for the chimaeric DNA segment is 46 °C. The hybridization was done at 47 °C and therefore strongly favoured the detection of chimaeric mRNA over SV40 early mRNAs.

The migration of a band on a denaturing gel indicates the distance of the first donor splice site from the 3′-end label. The *Hin*dIII site of SV40 is some 256 nucleotides from the donor site in the mRNA for the large T antigen. The denaturing gel in Fig. 5*b* shows that the position of the donor site for the chimaeric splice is at the usual position of the donor for SV40. Part of the same sample analysed on the neutral gel in Fig. 5*a*, lane 4, was loaded on to the denaturing gel in Fig. 5*b*, lane 4. Hybridization of the probe to both chimaeric (Fig. 5*b*, lane 4) and SV40 mRNA (Fig. 5*b*, lane 6) produced bands which co-migrated at a rate consistent with 254 ± 5 base pairs from the donor splice site to the 3′ end of the probe. The markers in lane 1 include a doublet at 276 and 284 base pairs. Comparison of the co-migrating bands with the distance separation of the doublet shows that the donor sites for the chimaeric and SV40 splices are the same, up to an uncertainty of two nucleotides.

Note that Fig. 5*b*, lane 4, is the result of hybridization of the chimaeric probe to RNA from cells co-transfected with both cloned chimaeric and cloned SV40 DNA. When the heteroduplexes are run on a denaturing gel, the bands corresponding to chimaeric mRNA and SV40 large-T mRNA should co-migrate and there will be a second band corresponding to SV40 small-t mRNA. We conclude that the band in Fig. 5*b*, lane 4, is almost entirely due to chimaeric mRNA and only receives a small contribution from SV40 large-T mRNA for two reasons. First, the result in Fig. 5*a*, lane 4, shows that the level of hybridization to chimaeric mRNA is much higher than that for mRNA for either SV40 large T and small-t antigens. Second, the small t and large T mRNAs are present in roughly equal amounts in Fig. 5*a*, lane 4, and the small-t mRNA is repreented by a very faint band in Fig. 5*b*, lane 4.

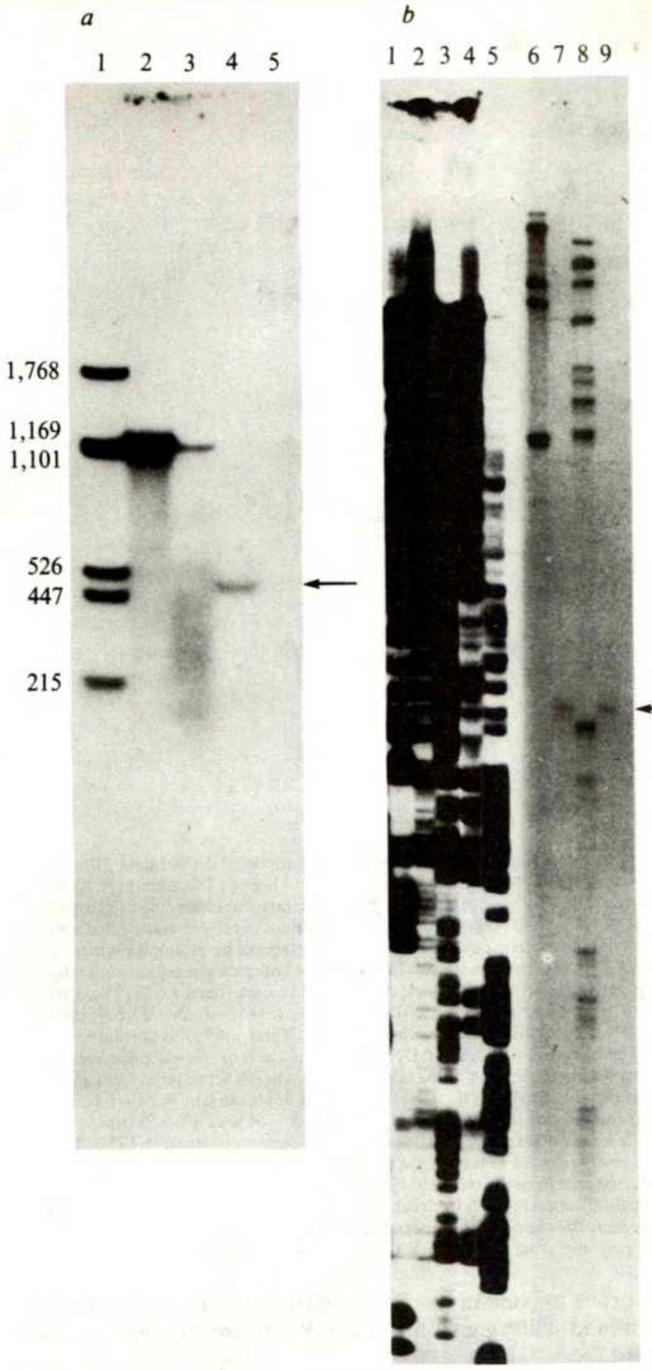

Fig. 4 Analysis with 5′-end-labelled probe of the RNA from cells co-transfected with the gene chimaera and cloned SV40 DNA. The probe is labelled at the *BalI* site of the chimaeric clone with polynucleotide kinase (see Fig. 3*b*) and hybridization was performed in 80% formamide at 47 °C (ref. 8). The transfection procedure is a modification of that used by Graham and van der Eb[9] and Frost and Williams[26]. Here, the cells are exposed to a calcium phosphate/DNA co-precipitate while in suspension (G.C., in preparation). *a*, Neutral 2% agarose gel. Lane 1 shows DNA markers, SV40 DNA cleaved by *Hin*dIII resulting in fragments of length 1,768, 1,169, 1,101, 526, 447 and 215 base pairs. Lane 2 shows intact probe. Lane 3 is the result of hybridization to the cytoplasmic RNA from mock-transfected cells. Lanes 4 and 5 are the poly(A)$^+$ and poly(A)$^-$ cytoplasmic fractions of cells co-transfected with the gene chimaera and cloned SV40 DNA, collected after 48 h. The band in lane 4 corresponds to a heteroduplex of 420 ± 20 base pairs. This value is determined by analysis with heteroduplex markers, as RNA–DNA heteroduplexes migrate slightly slower than DNA–DNA duplexes on a neutral gel (see data in Fig. 5). *b*, 7 M urea 8% acrylamide gel. Lanes 1–5 show a sequencing ladder used as markers. Lane 6 is a marker lane (SV40 cleaved with *Hin*dIII). Lane 7 is the result of hybridization to RNA from co-transfected cells. Lane 8 is a marker lane. Lane 9 is the result of hybridization to MβG mRNA. The bands in lanes 7 and 9 are co-migrating, with an uncertainty of less than one base pair on the sequencing ladder. Because the sequencing ladder in lanes 1–5 contained much more specific activity than the experimental data in lanes 6–9, the gel was photographed to give optimal exposure in lanes 6–9, while preventing overexposure in lanes 1–5.

Analysis of nuclear RNA from co-transfected cells reveals the existence of RNA which is unspliced and which migrates with a size consistent with that expected for the unspliced precursor to the chimaeric message. The RNA observed appears in both poly(A)$^+$ and poly(A)$^-$ fractions and is not observed in the cytoplasm (Fig. 5*a*, lane 11). In addition, two other species of RNA are observed, one which protects the full length of the 5′-end-labelled probe, terminates at the MβG polyadenylation site and is unspliced, and the other which migrates as if it were the spliced product of the first, with the proper chimaeric intron excised (data not shown). These RNA species represent transcripts which must initiate upstream of the *HpaI* site, either in SV40 or pBR322. As before, the spliced mRNA is found only in the poly(A)$^+$ fraction, whereas the unspliced RNA is found in both poly(A)$^+$ and poly(A)$^-$ fractions. Interestingly, neither spliced nor unspliced species accumulate in the cytoplasm.

RNA splicing

We have shown that a gene chimaera of SV40 and MβG is transcribed and spliced with the proper use of the SV40 donor and the MβG acceptor. Because the exons used were obtained from such different sources, monkey virus and mouse, and because the sequences show so little homology between the two donors and between the two acceptors (see Fig. 1), we conclude that splicing can occur over a wide range of donors and acceptors. In the particular case studied here, the spliced mRNA conserves the reading frame (see Fig. 1), and it remains to be seen whether proper splicing will occur if a chimaera is constructed where the spliced mRNA does not conserve the reading frame.

Recent studies of expression of mutated transcription units have suggested the interchangeability among donor sites or among acceptor sites. The mouse κ-chain immunoglobulin gene consists of three exons. In an aberrant κ gene, the donor site at the second exon is deleted and the transcribed message is formed by joining the first and third exons. This message translates into a polypeptide as the two exons have the same reading phase relative to the site of splicing[13]. Similarly, some mRNAs expressed after infection of cells with an Ad2–SV40 hybrid virus, Ad2$^+$ND4, seem to be the product of splicing adenovirus RNA sequences to SV40 sequences[14]. (The term 'chimaeric splice' was used in the title of this article.)

Interchangeability among donor sites and among acceptor sites raises several questions. The two donors from the first and second intervening sequences in MβG show considerable homology to each other[15], and similarly the two acceptors. But the improper splice from the first exon to the third exon has not been observed[16,17]. If in the chimaeric gene the MβG acceptor is spliced to the SV40 donor, which bears little resemblance to the usual MβG donor, why does the improper splice in MβG not occur?

The most attractive explanation is that splicing activity operates in a processive way. That is, it starts at one end of the intervening sequence, for example, at the acceptor site, and completes the splice when it reaches the first donor sequence. This restricts RNA splicing to an intramolecular process and insures against production of a nonfunctional protein by skipping an exon. A paradox immediately arises as there are transcription units with multiple donor sites for a single acceptor site, for example, the two SV40 early messages[4,5]. Also, the adenovirus late mRNAs have multiple acceptor sites for a single donor site[6,7]. A processive splicing mechanism is consistent with such splicing patterns only if splicing activity either (1) reaches the first possible splice termination site and then restarts the splice, or (2) always begins at the donor site in some transcription units and at the acceptor site in others.

The excision of a single intervening sequence may proceed in a processive manner, but it is clear from studies of ovalbumin[18] and vitellogenin nuclear RNA[19], that the excision of a series of intervening sequences does not necessarily proceed in a specific

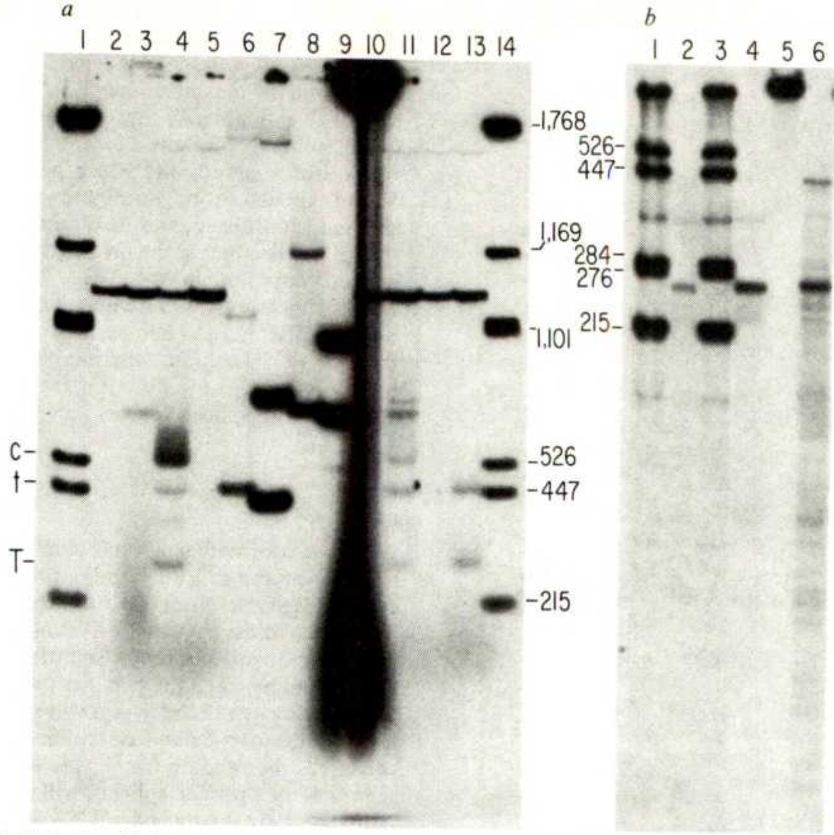

Fig. 5 Analysis with 3′-end-labelled probe of the RNA from cells co-transfected with the gene chimaera and cloned SV40 DNA. The probe is labelled at the *Hin*dIII site of the chimaeric clone with T_4 DNA polymerase (see Fig. 3*c*) and hybridization was done at 47 °C. *a*, Neutral 2% agarose gel. Lane 1 shows DNA markers, SV40 cut by *Hin*dIII. Lane 2 shows intact probe. Lane 3 is cytoplasmic RNA from mock-transfected cells. The band in lane 3 migrating at a rate corresponding to 710 base pairs is an artefact sometimes observed in this series of hybridizations. Lanes 4 and 5 are the poly(A)$^+$ and poly(A)$^-$ cytoplasmic fractions of cells co-transfected with the gene chimaera and cloned SV40 DNA, collected after 48 h. Marked by arrows to the left of the gel are the expected migration patterns of heteroduplexes formed with chimaeric mRNA (c), SV40 small t antigen mRNA (t) and SV40 large T antigen mRNA (T). Note the three bands in lane 4 which migrate at the predicted rates for c, t and T. Lane 10 is nuclear RNA from mock-transfected cells. Lanes 11 and 12 are the poly(A)$^+$ and poly(A)$^-$ nuclear fractions of co-transfected cells. There are bands present corresponding to the artefact in lane 3, and to c, t and T. There is also an extra band migrating at 750 ± 20 base pairs, consistent with the 755 base pairs predicted for an unspliced RNA terminating at the MβG polyadenylation site. Lane 13 is RNA from cells infected with SV40 virus. There are bands present which correspond to mRNAs for t and T. Lane 14 shows the same markers used in lane 1. Lanes 6 and 7 are results with SV40 DNA labelled at the *Bcl*I site and subsequently cleaved with *Pst*I. Lane 7 shows intact DNA prepared in this way and lane 6 shows the result of hybridization of the labelled DNA to cRNA prepared from SV40 DNA with *E. coli* DNA polymerase. Note that the DNA–RNA heteroduplex in lane 6 migrates slightly slower than the DNA–DNA duplex in lane 7. Lanes 8 and 9 show a similar effect to that of lanes 6 and 7, but with SV40 DNA labelled at the *Bcl*I site and subsequently cleaved with *Hin*dIII. *b*, 7 M urea 8% acrylamide gel. Lanes 1 and 3 show DNA markers, SV40 cut by *Hin*dIII, end-labelled by T_4 polynucleotide kinase and recut by *Pst*I, resulting in fragments of length 1,402, 1,101, 911, 526, 447, 284, 276 and 215 base pairs. Lane 2 shows the poly(A)$^+$ nuclear fraction of co-transfected cells from the same hybridization sample loaded on to the neutral gel in Fig. 5*a*, lane 11. Lane 4 shows the poly(A)$^+$ cytoplasmic fraction of co-transfected cells from the same hybridization sample loaded on to the neutral gel in Fig. 5*a*, lane 4. Lane 5 shows the 3′-end-labelled DNA probe. Lane 6 shows the result of hybridization to RNA from cells infected with SV40 virus. (The probe used in lane 6 was the probe used for the hybridization in lanes 2 and 4, but cleaved with *Taq*I. Because the region of SV40 between the *Bgl*I and *Taq*I sites has a T_m of only 36 °C, the hybridization was done at 40 °C.) The bands in lanes 2 and 4 are co-migrating to an accuracy of less than two base pairs.

order. Thus the RNA splicing activity must be capable of interacting in a processive manner in the middle of a long RNA chain containing multiple intervening sequences.

A general model for splicing of pre-messenger RNA would consist of the recognition by a molecular structure of a set of RNA sequences, the consensus sequence, near either the donor or acceptor site, and then translocation of the structure along the intervening sequence until termination occurs at either the acceptor or donor site, respectively. The obvious similarity between this process and translation of mRNA by ribosomes is striking. Perhaps a nuclear analogue of the ribosome, that is, an entity containing both structural RNA and multiple proteins, will prove to contain the RNA splicing activity. The studies of Steitz and colleagues on nuclear RNPs are pertinent in this regard[20].

Andrew Buchman and Paul Berg (personal communication) have constructed a chimaeric gene similar to that described here and have obtained similar results from the study of RNA transcribed from it.

Estimates of the vertical mass eddy diffusion coefficient K are necessary to understand the dynamics and photochemistry of a planetary atmosphere. Most previous estimates for the atmosphere of Venus[1–10], pertain to the upper atmosphere. In the lower atmosphere ($\leq$80 km), information on small-scale ($\leq$1 km) temperature fluctuations has been provided by radio scintillations observed during radio occultation by the atmosphere[11–18]. Here we relate the vertical mass eddy diffusion coefficient to these radio scintillation observations so that reliable estimates can be obtained near the tropopause level of 60 km for the first time. Using the recent Pioneer Venus radio occultation measurements[16], and assuming that the turbulence is generated by shear instability, we find that $K = 4\times10^4$ cm^2 s^{-1}, the energy dissipation rate $\varepsilon = 20$ cm^2 s^{-1}, and the dissipation rate of temperature fluctuations $N_\theta = 10^{-3}$ K^2 s^{-1}. These results indicate that small-scale turbulence probably plays a major part in vertical transport near the tropopause of Venus.

Two regions of intense small-scale temperature fluctuations located near 45 and 60 km and coinciding with highly statically stable regions of the atmosphere of Venus have been identified by the radio scintillation measurements[14,15]. We will study the upper region of turbulence. The turbulent eddies are anisotropic and elongated in the horizontal direction, and their wavenumber spectrum is approximately Kolmogorov. The Pioneer Venus orbit 18 entrance radio occultation measurements have been analysed in detail both for the mean temperature profile[19] and for fluctuations in the upper region of turbulence[16] situated above the tropopause. The estimate of structure constant c_T for the temperature fluctuations in the vertical direction is 0.15 K m$^{-1/3}$. This estimate is reliable because: first, the wave propagation theory used to interpret the radio scintillations is the most comprehensive to date[20]; second, contrary to earlier results, the radio scintillations observed by entry probes and orbiting or fly-by spacecraft now show good agreement with each other[21]; and third, temperature fluctuations inferred from the radio measurements agree closely with the Pioneer Venus *in situ* results[16]. The latter were obtained by estimating the deviations from a linear fit to the temperature profile.

For the Kolmogorov spectrum, the structure constant c_T is related to the energy dissipation rate ε and the dissipation rate of temperature fluctuations N_θ by[22,23]

$$c_T^2 = bN_\theta\varepsilon^{-1/3} \tag{1}$$

where b is an empirical constant which is ~2.8 (ref. 24). The eddy diffusion coefficients (diffusivities) for momentum and heat, K_m and K_h respectively, are given by[25–27]

$$\varepsilon = K_m\left(\frac{\partial u}{\partial z}\right)^2(1-R_f) \tag{2}$$

$$N_\theta = K_h\left(\frac{\partial\theta}{\partial z}\right)^2 \tag{3}$$

where R_f is the flux Richardson number, θ is the potential temperature, u is the horizontal wind speed and z is the vertical direction. K_m and K_h are also called eddy viscosity and eddy conductivity respectively. The flux Richardson number is related to the gradient Richardson number Ri by

$$R_f = \frac{K_h}{K_m}Ri \tag{4}$$

and

$$Ri = \frac{g}{\theta}\left[\frac{\partial\theta}{\partial z}\Big/\left(\frac{\partial u}{\partial z}\right)^2\right] \tag{5}$$

where the acceleration due to gravity g is 8.9 m s^{-2} for Venus. The eddy Prandtl number which is K_m/K_h has been found to be close to unity in the Earth's atmosphere[23,28]. If we assume this to be the case of Venus as well and call $K = K_m = K_h$ the eddy diffusion coefficient, we obtain from equations (1)–(5)

$$c_T^2 = b\frac{\theta}{g}\frac{\partial\theta}{\partial z}\varepsilon^{2/3}\frac{Ri}{1-Ri} \tag{6}$$

a result which has been presented by Ottersten[29], and

$$K = \left[\frac{g}{\theta}\left(\frac{1-Ri}{Ri}\right)\right]^{1/2}\frac{c_T^3}{b^{3/2}(\partial\theta/\partial z)^{5/2}} \tag{7}$$

Equation (6) indicates that the scintillations are caused by temperature fluctuations (in the case of Venus, the effect of water vapour fluctuations is negligible) which are directly related to both the mean vertical gradient of potential temperature and ε, a measure of the intensity of the velocity fluctuations. For a neutrally stable atmosphere, even if large velocity fluctuations are present, no scintillations would be detected as $\partial\theta/\partial z = 0$. Thus, although scintillations were not detected in the middle cloud region of the Venus atmosphere near 50 km (ref. 16), it cannot be concluded that mechanical turbulence is absent because the stability of the atmosphere is very close to neutral[30].

The fact that the scintillations are observed in regions of high static stability where high wind shears are also present suggests that the turbulence is produced by wind-shear instability[16]. At 60 km, the Pioneer Venus measurements[30,31] of θ and u yield $Ri = 1.7$ ($\partial\theta/\partial z = 1.6\times10^{-2}$ K m^{-1} and $\partial u/\partial z = 10^{-2}$ s^{-1}). Although Ri is small, it falls short of 0.25 which is the critical value for initiation of dynamic-shear instability indicated by both theoretical and experimental studies[32]. This is, however, not surprising as the Pioneer Venus measurements of temperature and wind velocity lack the spatial resolution to measure the local gradient Richardson number adequately. In the case of the terrestrial free atmosphere, estimates of Ri decrease substantially with decrease in scale over which they are measured[33]. Typically, $Ri = 0.25$ only in thin layers[34] and generally escapes detection unless the spatial resolution is of the order of 100 m. In analysing the scintillation observations of Venus we will therefore assume that $Ri = 0.25$.

Note that when $Ri = 0.25$ and $K_h = K_m$, equations (2)–(5) yield

$$\varepsilon = 3N^2K_h \tag{8}$$

where $N = (g/\theta)\ (\partial\theta/\partial z)^{1/2}$ is the Brunt–Väisälä frequency. Equation (8) is the relationship used by Lilly *et al.*[35] to deduce K_h in the Earth's stratosphere.

Let us now estimate K for Venus at 60 km using equation (7). For $c_T = 0.15$ K m$^{-1/3}$, $b = 2.8$, $Ri = 0.25$, $\partial u/\partial z = 2.6\times10^{-2}$ s^{-1} and $\partial\theta/\partial z = 1.6\times10^{-2}$ K m^{-1}, we obtain $K = 4\times10^4$ cm^2 s^{-1}. In comparing the tropopause regions of the Earth[28,35] and Venus

0028–0836/81/050383—02$01.00

we find that the eddy diffusion coefficients are similar. Note that the assumed wind shear corresponding to $Ri = 0.25$ is $2.6 \times 10^{-2}\ \mathrm{s}^{-1}$, which is a factor of 2.6 higher than the observed value. These strong shears are not unusual in the Earth's free atmosphere and have been observed over altitude intervals of several hundred metres[36].

For $K = 4 \times 10^4\ \mathrm{cm}^2\ \mathrm{s}^{-1}$, equations (2) (3) give $\varepsilon = 20\ \mathrm{cm}^2\ \mathrm{s}^{-3}$ and $N_\theta = 10^{-3}\ \mathrm{K}^2\ \mathrm{s}^{-1}$. The energy dissipation rate ε deduced from the Pioneer Venus radio scintillations can be compared with estimates obtained from the wind measurements. The latter can be obtained using the relationship[22-25]

$$\varepsilon = \frac{(\sigma_v)^3}{L} \tag{9}$$

where σ_v is the r.m.s. velocity and L is the characteristic spatial scale. In the case of the Pioneer Venus measurements[31], we estimate that at 60 km $L \sim 5$ km and $\sigma_v \sim 2\ \mathrm{m\ s}^{-1}$ which is consistent with the Venera 9–12 results[37,38]. This leads to $\varepsilon = 18\ \mathrm{cm}^2\ \mathrm{s}^{-3}$ which agrees well with the radio results. Kerzhanovich *et al.*[38] have analysed the Venera 11 and 12 wind measurements and obtained 50–180 $\mathrm{cm}^2\ \mathrm{s}^{-3}$ for ε above 40 km. All these estimates of ε for Venus fall within the range measured near the Earth's tropopause using *in situ*[28,35] and radar[39,40] observations.

Turbulence in the upper troposphere and lower stratosphere of Venus seems to be similar to that found near the terrestrial tropopause which is due primarily to the Kelvin–Helmholtz instability[41,42]. It is produced in the region of high wind shear[43] which exists above 40 km (ref. 31). Temperature fluctuations are generated in the highly statically stable regions near 45 and 60 km (ref. 30) and these in turn give rise to the radio scintillations that are observed. In the vicinity of 50 km (middle cloud region), the stability of the atmosphere is nearly neutral so that temperature fluctuations are substantially reduced and no scintillations occur. Covey and Schubert[44] have recently discussed the eddy diffusion coefficient for the middle cloud region near the sub-solar point.

Turbulence near the terrestrial tropopause generally takes the form of thin horizontal layers[39-41]. The radio occultation measurements of Venus do not have enough resolution to determine whether the patchiness of terrestrial turbulence also exists in the atmosphere of Venus. However, because the radio scintillation observation is a path-integrated measurement, the estimate of eddy diffusion coefficient obtained in this study is representative of the average atmosphere at 60 km. The equations which were used to estimate K are based on isotropic turbulence and strictly speaking do not apply to the anisotropic turbulence probed by Pioneer Venus. On the other hand, the structure constant c_T used to deduce K is that in the vertical direction and accounts for the fact that the turbulence is stronger in the vertical than in the horizontal direction.

We have found that K is $\sim 4 \times 10^4\ \mathrm{cm}^2\ \mathrm{s}^{-1}$ at 60 km, and believe that this is a good order-of-magnitude estimate. Note that this result is close to the value often assumed in dynamical studies of the atmosphere of Venus[46,47]. Although the scales measured by scintillations are small[16] (≤ 1 km), they are substantially larger than those in the terrestrial troposphere that have been measured and studied extensively with radar[39,40] (≤ 10 m). The fact that the eddy diffusion coefficient estimated from the radio scintillations is consistent with that expected on the basis of vertical cloud-particle distribution[4] and photochemical[10] considerations, implies that small-scale turbulence is probably the dominant mechanism for vertical transport near the tropopause (~ 60 km) in the Venus atmosphere. This is not the case in the Earth's atmosphere[39,48].

Clearly, the radio scintillation technique provides a useful means for determining the eddy diffusion coefficient in regions of the atmosphere where measurements have not yet been made. These radio measurements are applicable to the outer planets, and would yield not only details of the small-scale turbulence in the lower atmosphere, but information on the static stability of the atmosphere as well.

We thank J. W. Armstrong, E. M. Dewan and R. E. Young for useful discussions. This research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under contract NAS7-100, sponsored by NASA.

Optical observations of OV−236

D. Wills & Beverley J. Wills

McDonald Observatory, Department of Astronomy,
University of Texas, Austin, Texas 78712

Dent and Balonek[1] recently reported a large outburst in the radio source OV−236 (=1921−293). We have made optical observations of the associated optical object, and report here that it has a high degree of linear polarization, optically variability of ~1 mag in 25 days, and an emission-line spectrum at a redshift $z = 0.3525$. It thus belongs to the small class of extragalactic objects whose properties are intermediate between those of 'classical' QSOs and BL Lac objects.

There has been considerable confusion about the correct optical identification of OV−236. Dent and Balonek[1] refer to the red stellar object suggested in ref. 2, and give an optical

0028-0836/81/050384—03$01.00

position, apparently from ref. 3, but neither is correct. Accurate radio positions that agree within 0.2 arc s have been measured[4,5], but the red object noted in ref. 2 is 37 arc s away, and is therefore definitely excluded as the optical identification. The optical object is correctly identified in ref. 3 and in ref. 5, where its radio and optical position agree within ~1 arc s. We have also measured the 1950.0 optical position from glass plate copies of the Palomar Sky Survey, and find RA = 19 h 21 min 42.26 s, dec = −29°20′27.0″, with r.m.s. uncertainties of ~0.4 arc s; this position is within 0.3 arc s of that given in ref. 5. The optical position given in ref. 3, and repeated in ref. 1, is probably a misprint—there is no object visible there on the Sky Survey plates. The correct identification appears stellar, and about 18 mag, on two pairs of Sky Survey plates (epochs 1954.72 and 1958.53). It may be slightly brighter, and again appears stellar, on the SRC IIIa–J Schmidt plate J2597 (epoch 1976.71), which reaches fainter magnitudes and has better resolution. The object appears to be red on the Sky Survey plates, at least in part because of galactic extinction—its galactic coordinates are $l = 9.3°$, $b = -19.6°$. It has a history of optical variablity[5]. Unfortunately, the radio outburst described in ref. 1 occurred at a time of year when the object was becoming inaccessible to ground-based optical telescopes.

We obtained polarimetry of the object on 12.4 June 1980 UT, using the McDonald Observatory 2.1-m Struve reflector, and the polarimeter described in ref. 6. Visually, the object was estimated to be ~1 mag brighter than on the Sky Survey plates, and equal in brightness to the star 19 arc s following; that is, ~17 mag. The degree of linear polarization was found to be 8.0±0.5% r.m.s., in position angle 149±2°. The galactic reddening that we adopt below implies a contribution of <1% polarization due to the interstellar medium[7].

Spectrophotometry was obtained between 3,900 and 6,900 Å on 14 July 1980 UT, and between 3,400 and 5,700 Å on 8 August 1980, with ~7 Å FWHM resolution, using the McDonald 2.7-m NASA reflector and the instrument described in ref. 8. Figure 1 shows the spectra, calibrated by observations of standard stars to an accuracy of ~10% r.m.s. The difference in continuum levels indicates a fading of nearly 1 mag during the 25 days separating the two sets of observations (J. T. Pollock found a decrease of ~0.7 mag in $m_{\rm pg}$ between 16 July and 7 August).

The first spectrum shows two narrow (~15 Å FWHM) emission lines at 5,042.5 and 6,770.5 Å, which can be unambiguously identified as [O II] and [O III] $\lambda\lambda$3,727, 5,007 at an observed redshift $z = 0.3525 \pm 0.0005$ r.m.s. This spectrum also show an emission line at the expected wavelength of [O III] λ4,959, but no clear sign of Hβ. The second spectrum again shows [O II], at 5,042.9 Å, and a narrow feature at the position of Mg II λ2,798. Although the spectrum is noisy near the position of Mg II, the width of the feature is consistent with those of the forbidden lines. Neither spectrum shows evidence of absorption lines that might indicate the presence of a galaxy.

In the first spectrum the rest-frame equivalent widths of the [O II] and [O III] lines are 3.7 and 9.2 Å, respectively, while in the second one the values for [O II] and Mg II are 9.0 and 4.1 Å, respectively (with r.m.s. uncertainties of typically 10%). The large and significant change in the equivalent width of (O II] is independent evidence for a continuum level change, because the intensity of this line appeared to change by only ~25% between the two observations, a difference that is within the uncertainties in the absolute levels of the two spectra (~10% r.m.s. per observation). The [O II] emission arises in a large low-density region and is not expected to change significantly on a time scale of 25 days (18.5 days at the object). Based on the latter assumption, the fainter spectrum in Fig. 1 has been scaled by a factor of 0.734 so as to equalize the intensities of [O II].

The two spectra in Fig. 1 have the same shapes, with spectral indices $\alpha = 1.3$ and $\alpha = 2.4$ over 5,300–6,750 Å and 3,800–5,300 Å, respectively, after applying a correction for galactic reddening, using $A_{\rm V} = 0.5$ mag (see for example, ref. 10), and defining the spectral index α by $f_\nu \propto \nu^{-\alpha}$. The steepening below 3,600 Å may have been exaggerated by the use of a 2.8 (NS) by 4.5 (EW) arc s aperture and the large zenith distance (~60°) of the object, but we do not believe that these factors contribute to the spectrum curvature between 3,800 and 6,750 Å (this is supported by the good agreement between the spectral shapes in the wavelength region that is common to both spectra). The difference between the two spectra obtained in July and August in the region of overlap is well-represented by a power-law spectrum having $\alpha = 2.1 \pm 0.1$ r.m.s. ($\alpha = 2.9$ before de-reddening); power-law spectra were also derived for the variable components in the variable QSOs 0736+01 and 3C345 (ref. 9).

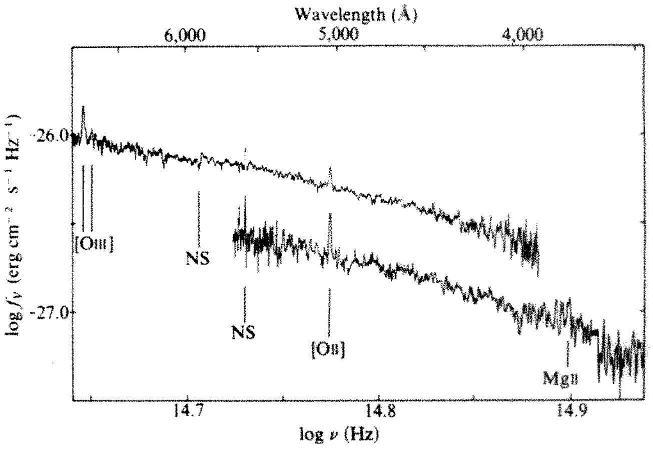

Fig. 1 Spectra of the optical object associated with OV−236, obtained with the McDonald Observatory IDS. The difference in continuum level represents real variability of the object during the 25 days that separate the two observations. Emission lines of Mg II λ2,798, [O II] λ3,727 and [O III] $\lambda\lambda$4,959, 5,007 are marked. NS indicates the positions of incompletely cancelled night sky lines ($\lambda\lambda$5,577, 5,892).

The high degree of linear polarization, the neutral colour and the emission-line spectrum form an unusual, but not unique, combination, placing OV−236 intermediate in properties between the BL Lac objects and QSOs. Most of the objects that are strongly variable at radio and optical frequencies, and that have high (>5%) optical polarization, have optical spectra that show no emission lines when observed with the sensitivity and wavelength resolution appropriate to the present observations. Had the object been 1.5 mag brighter than in July (as it was in mid-1979, ref. 5), with the emission lines retaining their intrinsic strength[9], the lines would have been barely detectable (1–3 Å equivalent width), and we would probably have classified OV−236 as a classical BL Lac object.

Perhaps the object that is most similar to OV−236 is 1400+162 (refs 11, 12), which is neutral in colour, has high optical polarization, and even weaker emission lines than those in OV−236 (from Fig. 2 of ref. 11 we estimate the rest-frame equivalent width of [O II] λ3,727 in 1400+162 to be 1.0 Å, and the intrinsic luminosity of the [O III] λ5,007 line in OV−236 is about 45 times that in 1400+162 (ref. 12)). No radio maps of OV−236 are yet available, but the fact that its 408 MHz flux density[13] is close to the pre-eruption value at high frequencies[1] suggests that the source does not possess extended components with steep radio spectra like those of 1400+162 (ref. 11).

Other possibly similar objects are 0752+258, which has a high degree of linear polarization[14,15], although much stronger emission lines[16,17], and 3C446, with its history of radio and optical variability, its high polarization and its rather weak emission lines[18]. Further observations of this small group of objects may eventually help to elucidate the connection between BL Lac objects and QSOs.

We thank J. T. Pollock for information about the recent optical variability of OV – 236, and the NSF for support.

Excited ozone is a possible source of atmospheric N_2O

Sheo S. Prasad

Jet Propulsion Laboratory, California Institute of Technology,
4800 Oak Grove Drive, Pasadena, California 91109

In the formation of ozone from O and O_2 in the ground state, the products of the reaction may include electronically excited forms of ozone (O_3^*) which are spectroscopically recognizable in pulsed radiolysis and flash photolysis experiments[1–4]. Indeed, it has been suggested that in the three-body recombination reaction

$$O + O_2 + M \rightarrow O_3^* + M \qquad (1)$$

there is a 62% chance that the ozone product will be in an excited form. Although the identity of these excited precursors of ozone is not known, excited $^3B_2$, $^3A_2$ and $^1A_2$ states of bent ozone and the cyclic ozone have been suggested[5–7], and the existence of electronically excited states of bent ozone below its dissociation limit has been corroborated by large-angle electron scattering experiments[8]. Thus, more than one form of internally excited ozone precursor may be involved. It has been estimated[9] that $\Sigma n(O_3^*) \approx (100-1{,}000)\cdot n(O^1D)$ in the stratosphere. Consequently, even with moderate reactivity, O_3^* may be chemically significant in the stratosphere. We now hypothesize that some of the internally excited ozone, probably that which is electronically excited, may be a potential source of N_2O through the gas-phase reacton (2*a*),

$$O_3^* + N_2 \rightarrow N_2O + O_2 \qquad (2a)$$

$$\rightarrow O_3 + N_2 \qquad (2b)$$

Previously, N_2O was considered[10–12] to form by the reaction

$$O_3 + N_2 \rightarrow N_2O + O_2 \qquad (3)$$

involving unexcited ozone, for which a rate coefficient $k_3 = 5\times10^{-28}\,\mathrm{cm^3\,s^{-1}}$ at 292 K has been reported[13]. This rate constant was estimated by mixing nitrogen and ozone in an absorption tube, measuring ozone disappearance from the absorption in Chappuis band and nitrous oxide formation from the intensity in the 7.8 μm band. However, such a slow reaction between two quite stable molecules is unlikely to proceed without substantial activation energy. In the colder upper atmosphere, therefore, k_3 will probably be much smaller than $5\times10^{-28}\,\mathrm{cm^3\,s^{-1}}$. Hence reaction (3) is not expected to be a significant atmospheric source of N_2O. On the other hand, reaction (2*a*) seems more likely in view of Goody and Walshaw's results[13], because there are many known instances where internal excitation (either vibrational or electronic) in one reactant significantly enhances the reaction.

The wavelength dependence of the quantum yield for N_2O formation, $\phi(N_2O)$, from photolysis of dilute solutions of O_3 in liquid N_2 at 77 K (ref. 14), and the wavelength dependence of $O(^1D)$ quantum yield in gas-phase photolysis of O_3 (refs 15–19) may be interpreted to suggest the possibility of reaction (2*a*). Relevant experimental data are presented in Fig. 1, where $\phi(N_2O)$ obtained by DeMore and Raper[14] is shown with $\phi(O^1D)$ obtained in gas-phase experiments. Over most of the wavelengths used in DeMore and Raper's experiment, $\phi(N_2O)$ is synonymous with $\phi(O^1D)$ in ozone photolysis. Thus, $\phi(N_2O)$ in this experiment begins to decrease rapidly at about 300 nm in agreement with the behaviour of $\phi(O^1D)$ in gas-phase experiments. However, $\phi(N_2O)$ in DeMore and Raper's experiment is perceptible even at 334 nm where $\phi(O^1D)$ is most probably zero according to other experiments. This implies that an additional, low activation energy mechanism of N_2O formation exists, which comes into prominence in DeMore and Raper's experiments at longer wavelengths where $\phi(O^1D)$ vanishes and the reaction

$$O(^1D) + N_2 + M \rightarrow N_2O + M \qquad (4)$$

becomes inoperative. We conjecture that reaction (2*a*) may be this new mechanism. We therefore augmented DeMore and Raper's reaction scheme by including our reactions (1) and (2), and a new expression for N_2O quantum yield is derived:

$$\phi(N_2O/\lambda) \approx \frac{\phi_1(\lambda)}{1 + k_6/k_4} + 0.62\phi_2(\lambda) f_1 f_2 \qquad (5)$$

where 0.62 is the probability of internal excitation in nascent ozone as explained before; f_1 is that fraction of internally excited nascent ozone which could produce N_2O; $f_2 = k_{2a}/k_2$ applicable in their case; ϕ_1 is the quantum yield for $O(^1D)$; ϕ_2 is the same for $O(^3P)$ and k_6 is the rate coefficient for the reaction

$$O(^1D) + N_2 \rightarrow O(^3P) + N_2 \qquad (6)$$

At $\lambda < 300$ nm, $\phi_1 = 1$ and $\phi_2 = 0$, and at 334 nm, $\phi_1 = 0$ and $\phi_2 = 1$, so that $f_1 f_2 \approx 4.2\times10^{-3}$ on the basis of the observed N_2O quantum yields in DeMore and Raper's experiments[14]. On the other hand, failure to detect N_2O, clearly above the background

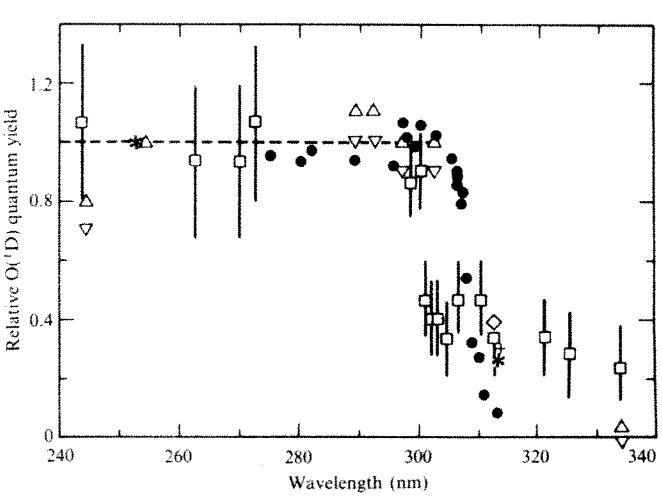

Fig. 1 Relative $O(^1D)$ quantum yields at various wavelengths in the photolysis of ozone. □, Ref. 14; ●, ref. 15; ▽△, ref. 16; +, ref. 17; ◇, ref. 18; *, ref. 19. DeMore and Raper[14] report $\phi(N_2O)$ which is synonymous with $\phi(^1D)$ over most of the wavelengths used by these authors.

0028-0836/81/050386—03$01.00

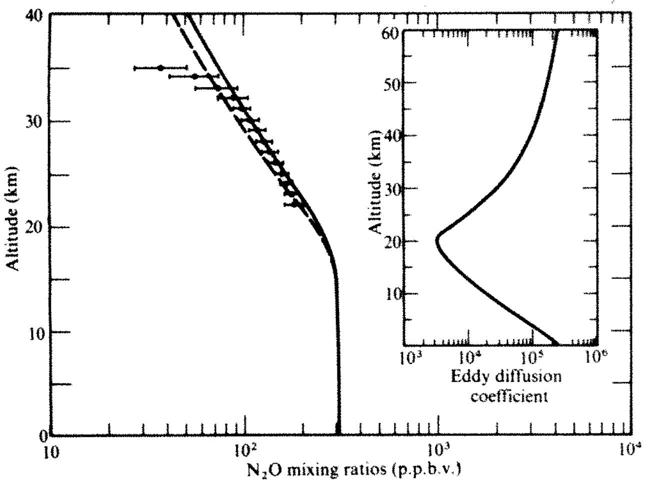

Fig. 2 Theoretical N_2O mixing ratios. Solid line, with the new N_2O source involving excited ozone; dashed line, without this source; |—●—| represent atmospheric measurements of Farmer *et al.*[23]. The inset shows the profile of eddy-diffusion coefficients used in this study.

level, in the experiments of Simonaitis *et al.*[20] places an approximate upper limit of $f_1f_2 \approx 10^{-4}-10^{-5}$ in their experiments conducted at 292 K. Considering widely different experimental conditions and the uncertainties, the difference between the two estimates of f_1f_2 is quite understandable, for example, in terms of possible inverse temperature dependence of f_1f_2. However, because the present study is exploratory we have ignored details, such as the temperature dependence, and have arbitrarily used $f_1f_2 = 10^{-5}$. This choice is consistent with Simonaitis *et al.*'s experiment which was in the gas phase and at a temperature close to the stratospheric temperatures.

The production rate of N_2O through reaction (2*a*) may now be written as:

$$q(N_2O) = \frac{6.2\times10^{-6}k_1n(O)n(O_2)n(M)}{k_2n(M)+1/\tau}k_2n(N_2) \qquad (7)$$

$$\approx \frac{6.2\times10^{-6}(J_{O_3}+2J_{O_2})}{k_2n(M)+1/\tau}k_2n(N_2). \qquad (8)$$

where J_{O_3,O_2} is the number of O_3 (or O_2) photodissociated per second. Approximate equality between reactions (7) and (8) becomes increasingly invalid above about 60 km. But this is immaterial because O_3^*-related source of N_2O is very small at these higher altitudes. As a first approximation, $k_2(=k_{2a}+k_{2b})$ may be assumed to be the same for all internally excited ozone, so that $k_2 \sim (7-0.6)\times10^{-14}\,cm^3\,s^{-1}$ on the basis of several experimental data[1-3]. There are no direct experimental data on the lifetime, τ, of internally excited ozone against non-collisional destruction. We have therefore tried several estimates ranging from a few microseconds to a millisecond. Atmospheric concentrations and fluxes of N_2O corresponding to its production through reaction (2*a*) were then calculated. These calculations were made for the US Standard Atmosphere, 1976, using one-dimensional photochemical-dynamical modelling. We assumed that N_2O molecules were lost by photodissociation and by reaction with $O(^1D)$. $O(^1D)$ concentrations were obtained on the basis of local chemical equilibrium between its production from O_3 photodissociation and loss by quenching collisions with N_2 and O_2. Ozone distribution needed for this and for estimating the solar UV attenuation was taken from US Standard Atmosphere. The empirical method of Shimazaki *et al.*[21] was used to calculate the absorption of solar UV in the O_2 Schuman–Runge bands. We assumed a N_2O mixing ratio of 3.1×10^{-7} at the lower boundary[22] and a zero flux at the upper boundary at 90 km. Calculations were done for a latitude of 30°.

The results in Fig. 2 were obtained by using $\tau = 9\times10^{-6}$ s, $k_2 = 2.0\times10^{-14}\,cm^3\,s^{-1}$ for the excited ozone able to react with N_2 (the eddy-diffusion coefficient, k_{eddy}, profile used is shown as an inset). Our small value of τ is not inconsistent with the experimental data of refs 1–4, because it applies to only a small fraction f_1 of excited ozone which may approach 10^{-5} if f_2 approaches unity. Measurements of the N_2O mixing ratio at 32°N are also shown in Fig. 2 for comparison with our theoretical results. Our theoretical profile using the assumed excited ozone source of N_2O clearly agrees with Farmer *et al.*'s[23] data better than the profile without this source, if we ignore the data points at 34 and 35 km which have significantly larger experimental error bars. This performance of our theory is, of course, dependent on various factors in the calculations, such as the profile of k_{eddy}, and the properties of excited ozone precursors. Nevertheless, with a reasonable choice of k_{eddy}, the assumed N_2O production from excited ozone has reproduced certain observed nitrous oxide mixing ratios as satisfactorily as the theory without this assumed new source. Nitrous oxide mixing ratios exhibit great variability. Naturally, other observed profiles of nitrous oxide mixing ratios may not agree as well with our new theoretical profile. Use of other k_{eddy} profiles, particularly those determined from observed N_2O mixing ratios and the assumption that there is no atmospheric source for this species, will also spoil the good performance of the new theory evident in Fig. 2. These, however, do not contradict the new theory. The present spread in measured N_2O mixing ratios and estimates of k_{eddy} profiles do not allow a conclusive choice between the new theory and the current theory which links atmospheric N_2O solely to microbiological activity on the Earth's surface. Experimental investigations of reaction (2*a*) are needed.

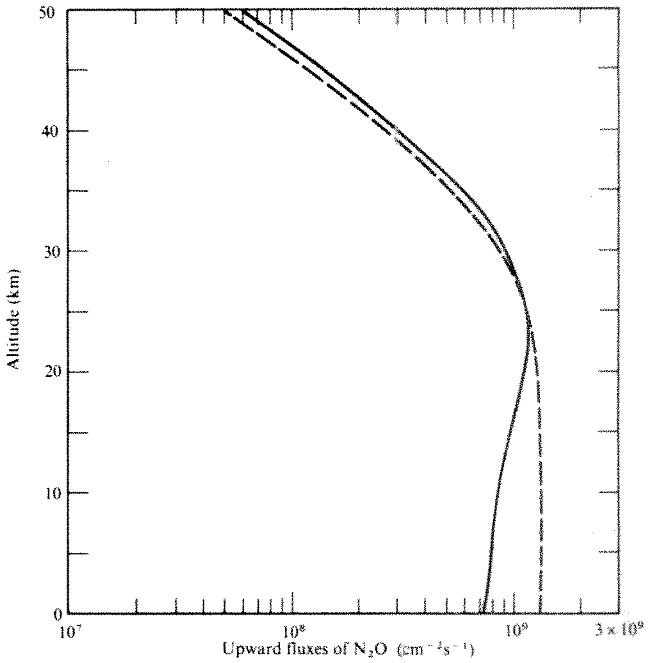

Fig. 3 Upward flux of N_2O corresponding to the profiles of nitrous oxide mixing ratio and eddy-diffusion coefficients shown in Fig. 2.

Fluxes of nitrous oxide in the two limits with and without the new source are presented in Fig. 3. The new source of N_2O implies that the net upward flux of N_2O due to microbiological activities at the Earth's surface may be significantly smaller than the currently accepted value of $(1.3-1.4)\times10^9$ N_2O molecules $cm^{-2}\,s^{-1}$. Thus, this new source tends to strengthen a recent conjecture[24] that the main impact of human beings on the stratospheric N_2O level may not be through the indirect mechanism of increased nitrogen fixation, but through the direct anthropogenic production[25] of N_2O. Besides, the assumed new source of N_2O has two more attributes: (1) it provides a possible new physical basis for latitudinal and temporal variations in N_2O, because upper atmospheric ozone itself has these variations; and (2) this source could impart an additional stability to the ozone layer against external perturbations. Any perturbation which produces an increase in ozone will result in increased N_2O from the new source and thereby in increased NO_x. The increased NO_x will exert a stabilizing effect by arresting further increase in ozone. Similar arguments, but in the opposite sense, would apply to perturbations which produce initial decrease in the ozone layer.

This study represents one phase of research carried out at the Jet Propulsion Laboratory, California Institute of Technology, under contract no. NAS7-100, sponsored by NASA.

Flexural strength and porosity of cements

J. D. Birchall, A. J. Howard & K. Kendall

Technical Department, ICI Mond Division, PO Box 8, The Heath, Runcorn, Cheshire WA7 4QD, UK

A curious feature of hydraulic cements, such as those based on calcium silicate, calcium aluminate and calcium sulphate, is that they exhibit similarly low flexural strengths, typically between 3 and 10 MPa, despite their differing chemical composition, varying degrees of hydration and contrasting setting mechanisms[1-3]. Because of these low strength values, unreinforced cements are never used in flexure or tension, and studies of cement strength are usually confined to compression. Those few studies which have considered flexural or tensile failure have concluded that hydraulic cements have an intrinsic maximum tensile strength of about 20 MPa[4,5]. Here we demonstrate that the commonly observed flexural weakness of cement is due to the presence of large voids which are largely undetected by conventional methods of pore analysis such as gas adsorption and mercury porosimetry. The removal of such macro-defects results in flex strengths up to 70 MPa, despite the large volume of gel pores remaining in the material. These strength figures, comparable with those of sintered ceramics, have been achieved without the use of elevated pressures or temperatures, and without fibrous reinforcement.

Much previous work on the fracture of cement has been concerned with compressive failure and with attempts to relate total volume porosity and compressive strength. From such studies, empirical laws such as those of Feret, Abrams and Powers have been derived[6-9]. However, the mode of failure in compression is complex and the relationship of compressive strength to porosity is unlikely to be adequately described by a single equation[10]. On the other hand the tensile and flexural strengths of brittle materials are more amenable to analysis[11-13] and in the Griffith equation,

$$\sigma = (ER/\pi c)^{1/2} \tag{1}$$

tensile cracking stress (σ) is related to an effective critical crack length (c) (which may be a pore); Young's modulus (E), and fracture surface energy (R) being taken as material constants.

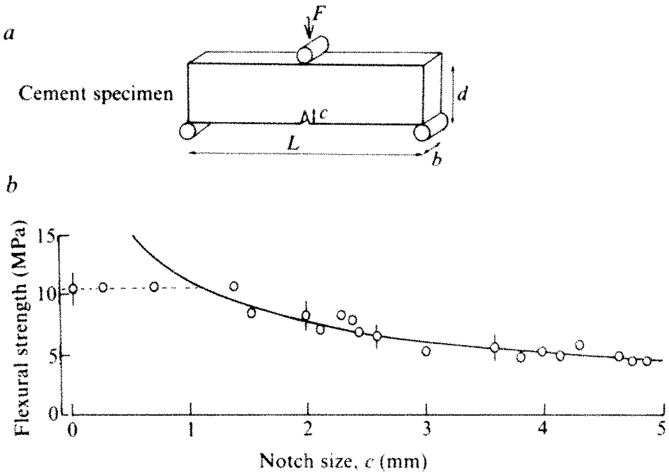

Fig. 1 *a*, The flexural testing arrangement. *b*, Results of flexural testing of notched, Ordinary Portland Cement paste.

The porosity of Portland cement paste is complex and involves a very wide range of pore sizes. Most of the porosity volume is associated with the hydrate gel structure (<100 nm) but larger porosity defects are present. There is a continuing debate as to which microstructural features limit the strength of cement pastes[9]. We have measured the flexural strengths of such pastes and related these through the Griffith equation to the sizes of the largest natural, or artificially-introduced 'pores' within the material. Finally, we have prepared cement paste specimens from which these macroscopic voids have been largely eliminated with a consequent, and dramatic, increase in strength.

The flexural strength testing arrangement is shown in Fig. 1*a*. Bars of cement paste were cast from a slurry containing 100 parts of Ordinary Portland Cement and 22 parts water, cured for 7 days and dried for a further 7 days. In some of the specimens, transverse notches of various depths were cut in the centre of one face using a diamond wheel. Notched and un-notched samples were then bent until cracking occurred. The data are presented in Fig. 1*b* as a Griffith plot of failure stress against

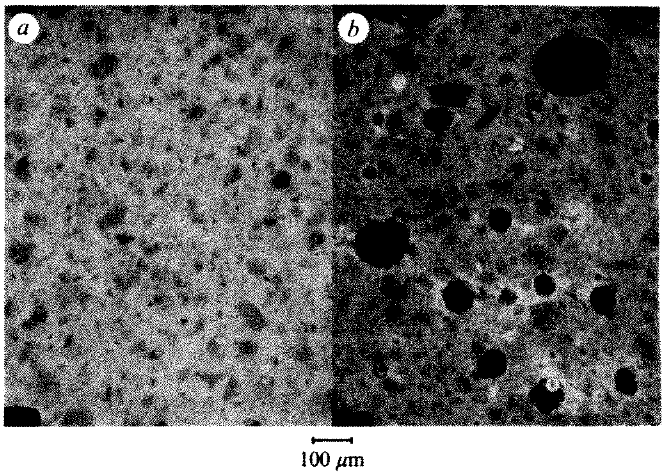

Fig. 2 Optical photomicrographs of polished cement paste sections. *a*, MDF cement. *b*, Ordinary Portland Cement paste. Voids are filled with Indian Ink to improve contrast, and appear black. The grey features are the residues of unhydrated cement grains. ×50.

0028-0836/81/050388—03$01.00

notch depth, the stress σ being calculated from the fracture force F using the relation $\sigma = 1.5\,FL/bd^2$, as the flaw lengths were sufficiently small to avoid significant error[14]. The results gave a reasonable fit to the Griffith curve for notches exceeding 1.1 mm in length. Having calculated E from the flex measurements (20 GPa), the fracture energy $R = 19\ \mathrm{J\,m^{-2}}$ was determined from equation (1). This value, typical of strong, brittle ceramics, indicates that the weakness of cement does not stem from low toughness. The results point to flaw size c as the cause of the weakness. For small notches, the strength was found to be essentially constant at 10.5 ± 2 MPa, the same as un-notched samples. It was inferred that this deviation from the Griffith curve was caused by large natural flaws in the cement.

To investigate this, the porosity of the samples was measured both by mercury porosimetry[15] and by quantitative microscopy[16]. Mercury porosimetry showed the pattern obtained by other workers[17,18], with a median pore diameter of 40–60 nm, a large proportion of gel pores (<7.5 nm diameter) and only 0.1% volume porosity above 15 μm diameter. In contrast, quantitative microscopy of polished sections of the cement demonstrated the presence of significant numbers of large holes, the maximum hole size being measured at 0.83 ± 0.17 mm which agreed satisfactorily with the natural flaw size of 1.1 ± 0.2 mm obtained from the fracture measurements shown in Fig. 1. Furthermore, the volume associated with pores greater than 15 μm diameter was found to be about 5%, far greater than that given by mercury porosimetry, presumably because the mercury method cannot distinguish the pore diameter from the pore entrance diameter, or because the pores are effectively closed[19].

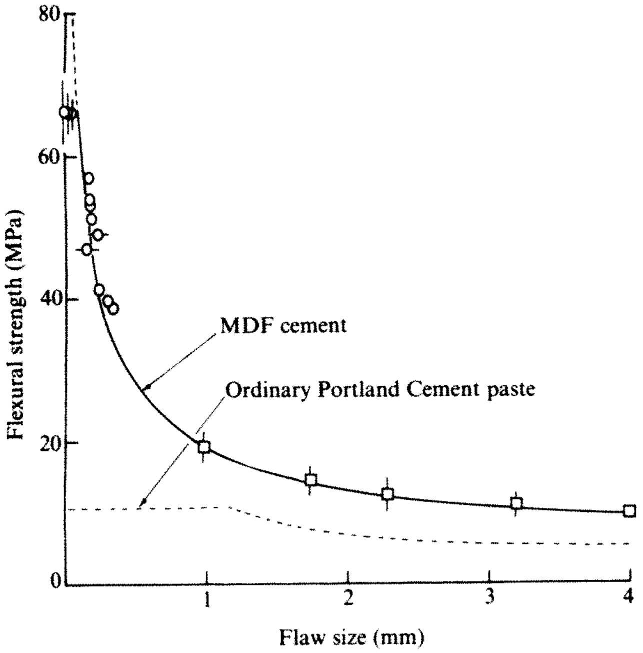

Fig. 3 Results of flexural testing of notched MDF cement (solid line) compared with Ordinary Portland Cement paste (dashed line). □, Flaws introduced by diamond saw; ○, flaws introduced by air bubbles or glass micro-balloons.

Samples of cement paste were then prepared[20] in which the size of large included voids was reduced by a combination of rheological control and efficient mixing. Rheology was controlled, for example, by attention to particle size distribution and the use of rheological aids at low water/cement ratios (<0.2). Such methods reduced the size of the large voids whilst not necessarily reducing the total porosity volume as calculated from true and apparent density. A polished cross-section of a typical product, shown in Fig. 2a, illustrates the freedom from holes exceeding 15 μm in length, contrasting with the ordinary cement paste shown in Fig. 2b. Such preparations, (macro-defect-free (MDF) cement) were subjected to the bend test as previously described. Macrodefects were artificially re-introduced as indicated in Fig. 3 which presents the results together with the data for the ordinary cement samples.

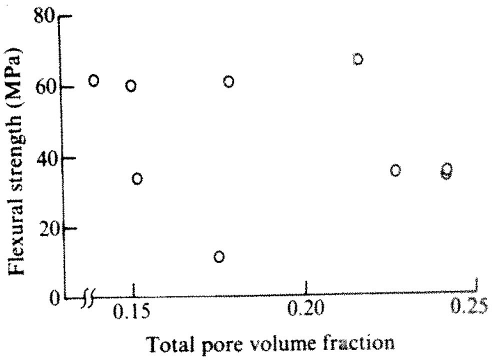

Fig. 4 The lack of correlation of flexural strength of cement paste with total pore volume. (Measured by mercury displacement and helium pycnometry.)

The results fitted the Griffith theory reasonably well but were different in two respects from the original cement. First, the strength at any given flaw size was higher. This was explained by the higher elastic modulus of MDF cement (~40 GPa) and its higher fracture surface energy of $30\ \mathrm{J\,m^{-2}}$. The second difference was that MDF cement followed the Griffith curve to much higher stresses and lower flaw sizes than ordinary cement. When the largest visible holes were ≤90 μm in length (as measured by quantitative microscopy) the samples ceased to fit the Griffith curve but gave the same strength (66 ± 5 MPa) as material containing no holes visible in the optical microscope. Presumably, some flaws other than visible holes, perhaps grain interfaces, dominated at this juncture.

The experiments demonstrate that Griffith theory applies adequately to ordinary cement pastes and that the low flexural strengths normally found are associated with macroscopic flaws rather than microscopic or mineralogical features of the gel. It follows that total pore volume measurements will not correlate with strength except by accident, when pore size distribution remains constant over a series of samples. Figure 4 shows the lack of correlation of total porosity and strength in our experiments. Any attempts to relate flexural strength to gel microstructure, or to seek improved strength by altering microstructure will need to recognize the dominant role of large defects arising during preparation and not necessarily detected by conventional porosimetry.

We have shown that, by removing macroscopic flaws during preparation, cement pastes can be made having flexural strengths (at 60–70 MPa) comparable to sintered ceramics, without the need for fibrous reinforcement or high pressure compaction. This principle is not limited to Portland cement but gives similar improvements when aluminous or sulphate cements are used. Indeed, it should apply generally to all hydraulic cements. Nor is the strengthening limited to tensile fracture; compressive strengths are elevated, being typically greater than 200 MPa.

Conductive polymer: reticulate doping with charge-transfer complex

Jeremiasz K. Jeszka, Jacek Ulański & Marian Kryszewski

Polymer Institute, Technical University of Łódź, 90-924 Łódź,
Żwirki 36, Poland

Additives which can form charge-transfer (CT) complexes enhance the photoconductivity of polymers. In contrast, the dark conductivity of polymers containing this type of additive increases only slightly. Several crystalline CT complexes exhibit high dark conductivity. When introduced into polymer matrix these smuld therefore significantly increase its conductivity provided that the CT complexes are ordered, because their high conductivity is related to the strong interactions between donor and acceptor stacks in the crystal. We describe here a new method of introducing microcrystalline CT complexes into polymers. It consists of growing microcrystals during film casting. The system, poly (bisphenol A carbonate)/(PC) with microcrystals of the CT complex of 7,78,8-tetracyanoquinodimethane (TCNQ) with tetrathiotetracene (TTT), reaches the dark conductivity of 3×10^{-2} Ω^{-1} cm^{-1} at room temperature at 1 wt% of the complex. This conductivity is only slightly temperature dependent.

PC is a polymer with very low electrical conductivity but with good mechanical properties. The crystalline complex of TTT and TCNQ of stoichiometry 1:2 has a conductivity of 10^2 Ω^{-1} cm^{-1} at 300 K measured using a no-contact method at 10^{10} Hz (ref. 1). Casting of a 4 wt% solution of PC and appropriate amounts of TTT and TCNQ on *o*-dichlorobenzene on to hot (390 K) glass substrate produces high-conducting polymer films containing microcrystalline precipitations of the CT complex[2].

Micrographs of the film containing 1 wt% of the complex and that of its cross-section are shown in Fig. 1*a* and *b* respectively. Clearly the microcrystallites are not distributed at random but form dendrite-like paths penetrating the polymer matrix. The microcrystallites disappear irreversibly when a sample is annealed above 450 K, they are not observed in samples cast at temperatures higher than 450 K and in both cases no high conductivity is observed.

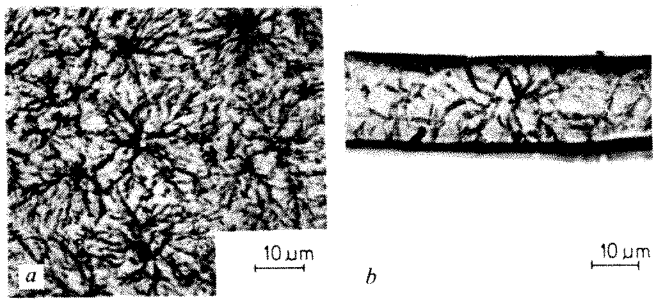

Fig. 1 Micrograph of the PC film containing 1 wt% of the TTT:TCNQ CT complex (*a*) and of its cross-section (*b*). Solutions of PC and TTT and of PC and TCNQ in *o*-dichlorobenzene were prepared separately, and after dissolving the additives at ~420K were mixed together and cast on to glass substrate at 390 K. To preserve appropriate conditions for microcrystallite growth and densification of the polymer matrix, the rate of solvent evaporation has to be controlled. PC (BDH Chemicals, laboratory reagent) was used as received, TTT and TCNQ were purified by recrystallization and the solvent was redistilled before use.

The dependence of the specific conductivity of the films on the content of the CT complex in the sample is shown in Fig. 2. This dependence has a yep-like characteristic and for ~1 wt% of the additive, the conductivity is increased by more than 17 orders of magnitude. When the additive content is higher, a saturation effect is observed. The microscopic investigation of these samples shows that for concentrations below 0.75 wt% the network of microcrystallites does not penetrate all the sample, while for concentrations higher than 1.5 wt% needle-like crystallites of uncomplexed TCNQ and TTT are observed.

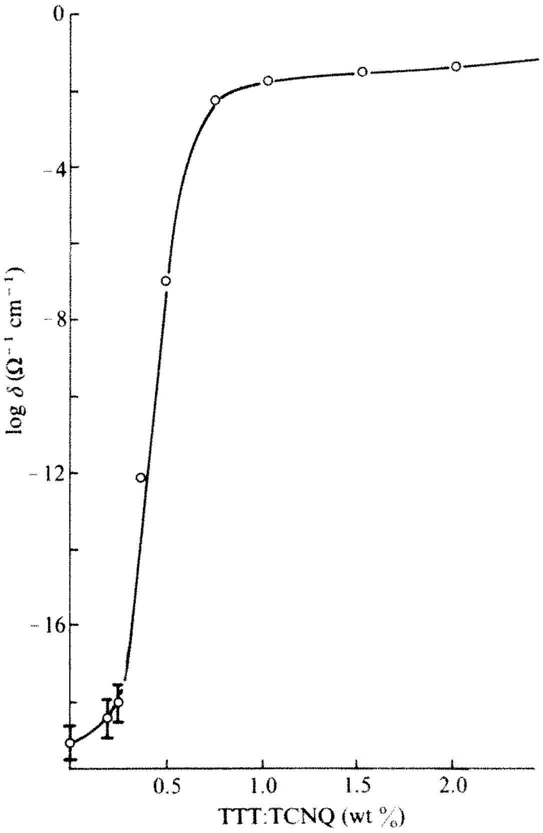

Fig. 2 The dependence of the specific conductivity of the system on the content of the TTT:TCNQ CT complex. Measurements were carried out in a vacuum chamber. For samples having high conductivity (0.5–2.0 wt% of the complex), the four-probe technique was used. Samples having higher resistivity were sandwich-type with evaporated gold electrodes and a guard ring. For samples with intermediate conductivity, both techniques give equivalent results.

The conductivity of homogeneous films obtained by casting at 450 K or by heating conducting samples above 450 K does not exceed 10^{-17} Ω^{-1} cm^{-1} even when the highest concentrations of additives are used. This indicates that the existence of the network of microcrystallites is a prerequisite for the high conductivity of the investigated material.

The temperature dependence of conductivity for samples containing 0.5, 1.0 and 2.0 wt% of TTT:TCNQ is presented in Fig. 3. Contrary to the metal-like temperature dependence of the electrical conductivity found for good conducting CT complexes of TCNQ so-called organic metals, the conductivity of the systems under study shows a weak increase with increasing temperature, diminishing with increasing content of the CT complex.

Current–voltage characteristics of highly conducting samples (concentrations above 0.75 wt%) are ohmic in the investigated temperature range up to the field strength 10^4 V m^{-1}. For higher

0028–0836/81/050390—02$01.00

fields the evolved heat causes overheating of some regions which leads to destruction of the crystals and the samples becoming nonconductive. When the CT complex content is lower, the conductivity seems to be field dependent for the field strength 10^5 V m^{-1} and higher.

To find the real stoichiometry of the complex being formed in these conditions, samples with different donor-to-acceptor molar ratios were investigated. For samples containing 1 wt% of the additives, the molar ratio of TCNQ to TTT changed from 0.45 to 3.0. The conductivity measurements have shown that the highest conductivity is obtained when the molar ratio is 1.0. Also, the microscopic observations of the samples with donor-to-acceptor ratio different from one showed the presence of crystallites characteristic of an excess of uncomplexed component. This suggests that the stoichiometry of the adduct formed within the polymer is 1:1, which differs from the 1:2 stoichiometry of the naked adduct[1].

A relatively high conductivity of the samples containing 1% or more of the CT complex means that the Hall effect may be observed. The experiment was carried out at room temperature in a magnetic field of 10 T for samples containing 1% of additives. The effect was weak, but it could be determined that the excess charge carriers were electrons and their mobility could be estimated to be of the order of 10^{-1} cm^2 V^{-1} s^{-1}.

The step-like dependence of conductivity on the amount of additive present suggests that high conductivity of this material is related to the existence of a microcrystallite network of TTT:TCNQ complex which forms conducting paths, while electrical properties of the polymeric matrix change by only a small extent. On the other hand, the fact that the temperature dependence of conductivity differs from that of highly conducting TCNQ salts indicates that there are some energetic barriers in the paths. These can arise from a separation of some crystallites by the polymer, in which case the increase of conductivity with temperature would be limited by thermal expansion of the polymeric matrix. This effect is, of course, more pronounced for smaller concentrations of the complex (see Fig. 3). It can also explain deviations from Ohm's law in current–voltage characteristics observed for complex concentrations lower than 0.5%.

The value of mobility, which is very high even compared with the mobility in the best polymer photoconductors[3], can be accepted assuming the predominant role of conducting paths and taking into account high values of mobility in organic metals. Assuming one carrier per TTT:TCNQ molecule and full 1:1 complexing, one can calculate for the samples with 1 wt% of additives the density of charge carriers of the order of 10^{19} cm^{-3} and the mobility about 10^{-2} cm^2 V^{-1} s^1, while from the Hall effect we find 10^{18} cm^{-3} and 9×10^{-2} cm^2 V^{-1} s^{-1} respectively which, as the full complexing does not take place, seems to be a reasonable value.

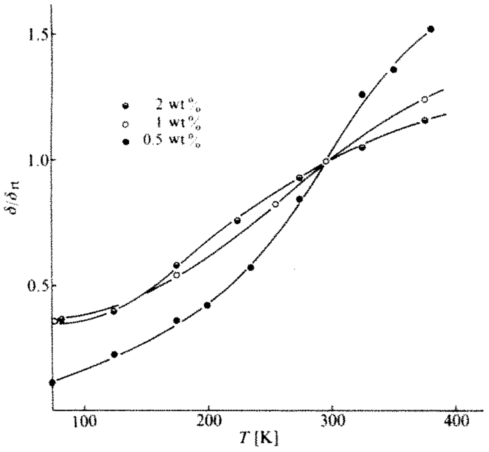

Fig. 3 The temperature dependence of electrical conductivity for the samples with different content of the CT complex. ◒, 2 wt%; ○, 1 wt%; ●, 0.5 wt%

Finally, note that mechanical mixing of polymers with microcrystalline powder of conducting material is much less effective because in this case the amount of conductive additives must usually exceed 20% to achieve comparable values of conductivity[4]. The origin of this difference may be partially explained by a simple geometrical argument: for a needle of length 10 times its other dimensions, the volume is about 50 times smaller than that of a sphere of diameter equal to the needle length. If the needles are perfectly aligned, something of the order of 50 times as much weight of powder would be needed to produce the same effect as oriented needles. In our system, considerable local orientation of microcrystals is obtained by the crystallization of the complex in the polymer matrix in suitable conditions. This orientation is not perfect but a factor of ~10–20 may be expected on the basis of this argument.

The discussed mixtures, due to their high conductivity obtained at low concentration of the CT complex, combine the good application properties of commercial polymers (in contrast with polyacetylenes or $(SN)_x$) with the relatively high conductivity, and form a new class of polymeric materials.

Interlayer formation of humin in smectites

P. Cloos, C. Badot & A. Herbillon

Groupe de Physico-Chimie Minérale et de Catalyse, UCL, and
Section de Physico-Chimie Minérale, MRAC Place Croix du Sud 1,
B-1348 Louvain-la-Neuve, Belgium

The stability of humin, the alkali-resistant part of humic matter in soil[1–4], is usually accounted for by its intimate association with inorganic soil colloids, especially swelling clays and iron compounds. Although the stability of these organo-clay complexes has been explained by interlamellar intercalation, there is evidence[2–4] that large-sized humic acid nuclei are unlikely to penetrate layer silicates in normal soil conditions. The ability of clay minerals to promote polymerization of organic monomers has long been recognized[5], and has been confirmed recently[6–8]; however, the conditions in which these catalytic properties were exhibited were unlike those existing in natural soils. We now report the results of preliminary investigations suggesting that humin-like substances may form between layers of silicate clays from smaller aromatic molecules in conditions that resemble those occurring naturally.

To approach field conditions, we percolated an aqueous aniline (50 p.p.m.) solution through columns containing a 9:1 (w/w) mixture of fine sand and clay. Homoionic Fe(III), Al and Ca exchanged forms of raw montmorillonite from Camp-Berteau (Morocco) were used. An appropriate percolation velocity and clear effluents were obtained by alternating in the columns (height, 140 mm; diameter, 45 mm) ~1-cm thick layers of the sand–montmorillonite mixture and of neat sand, deposited on a 3–4 cm-thick bottom layer of sand supported by glass wool. Apart from interruptions at the weekends, a 50-ml portion of the dilute aniline solution was daily percolated through each column.

During the first treatment, similarly to observations[9] made on 1% clay suspensions, light-green trails and spots developed in the top Fe(III)–clay/sand layers. They turned progressively to green-blue, then to dark greenish-grey whilst increasing in size and extending slowly towards the bottom of the column as more aniline was added. The Al and Ca saturated samples did not

† Treated with a 0.1 M solution of $Na_4P_2O_7$.

‡ After HF attack of the aniline–Fe(III)–montmorillonite complex.

show any change in colour; after a few percolations, the aniline concentration of the effluents equalled that of the treating solution, and washing with distilled water removed most of the organic added. In contrast, no aniline could be detected in the effluents of the column containing Fe(III)–clay, the bottom layer of which had not yet been reached by the green-grey zones at the end of six weeks, when the experiment finished.

After air-drying the column at room temperature, the dark-coloured material was collected and the colloidal organo-clay fraction was separated by sedimentation and freeze-dried. Treating it with a 0.1 M solution of HCl or a 0.1 M alkaline solution of $Na_4P_2O_7$ did not modify either its colour (7.5 GY 4/1 to 10 GY 4/1 on the soil colour chart) or its carbon content (Table 1). Hence, according to the conventional solubility criteria[1–4], the dark-coloured organic substance firmly held by the clay may be termed humin-like material.

Several attempts to extract this humin-like material with various organic solvents failed. Only with dimethyl sulphoxide (DMSO) could we extract part of it from a sample previously attacked with a dilute HF solution. The dark grey to black powder, left after evaporation of the solvent, still had an ash content of 23% for a carbon content of nearly 40% (Table 1).

Assuming interlamellar intercalation, the amount of aniline (Table 1) fixed as a monomolecular layer would cover less than 10% of the internal clay surface[8]. Nevertheless, the basal spacings (Table 1) determined on oriented clay films in a vacuum camera, are systematically higher for the increasingly dehydrated organo-clay complex than for the corresponding neat clay.

A stronger argument for interlamellar intercalation is provided by the IR and ESR spectra (Fig. 1) of the aniline–Fe(III)–montmorillonite complex. The IR spectra, recorded on self-supporting clay films, show evidence of hydration water (ν_{OH} near 3,500, δ_{OH} near 1,640 cm^{-1}), and are characterized by broadening of the aromatic ring vibrations in the 1,600–1,500 cm^{-1} range, by the development of bands near 1,320 and 1,255 cm^{-1} and of a broad charge-transfer absorption extending from roughly 2,000 to beyond 4,000 cm^{-1}. The ESR spectra exhibit a sharp radical signal near the position of a free spinning electron (reference), superimposed on the broad Fe(III) signal. These features are typical for the so-called Type II complexes[10–13], which reportedly form exclusively in the interlayer space of smectites[14]. Their formation generally occurs in dehydrating conditions, through a π interaction between certain aromatic compounds and some transition metal cations occupying exchange sites. This interaction leads to electron transfer resulting in the reduction of the metallic cation and the formation of aromatic radical cations able to participate in polymerization reactions[6–8].

The typical bands of the aniline–Fe(III)–montmorillonite Type II complex persist in the IR spectrum of the DMSO extract (Fig. 1). An additional absorption near 1,665 cm^{-1}, compatible with quinonoid C=O stretching, suggests further oxidation, as do the enhancement of the radical signal (Fig. 1) and the relative decrease in nitrogen content (Table 1) on treating the organo-clay complex with $Na_4P_2O_7$ or DMSO. Similarly, the relative increase in nitrogen content of the acid-treated sample is explainable by partial oxidative hydrolysis, the protonated amino moiety being retained on the clay by exchange wih Fe(III).

Ferric iron was present mostly as hydroxycations ($(Fe(OH)^{2+}$, $Fe(OH)_2^+$) or polymeric species of these, as indicated by the apparent cation exchange capacity of 184 mEquiv. per 100 g, instead of 100 mEquiv. per 100 g when determined on NH_4–montmorillonite at *p*H 7. Ageing for more than 10 months, in aqueous suspension or in ambient conditions, did not prevent Fe(III)–montmorillonite from interacting with aniline as described above. Moreover, aniline seemed to be the first aromatic compound to form a Type II complex on a smectite in aqueous medium, evolving to polymeric species in near-pedogenic conditions.

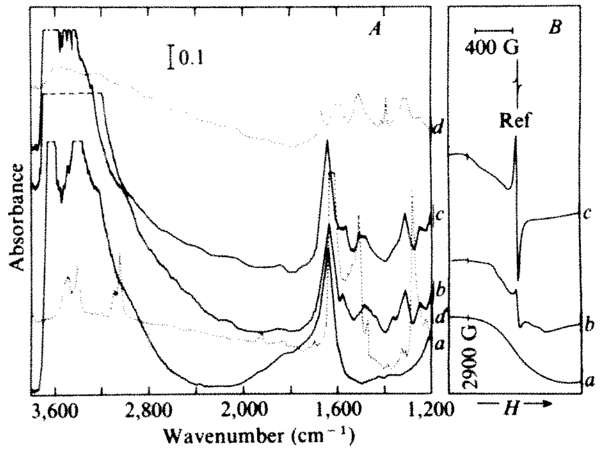

Fig. 1 IR (*A*) and electron spin resonance (*B*) spectra for: *a*, neat Fe(III)–montmorillonite; *b*, aniline–Fe(III)–montmorillonite complex; *c*, same after $Na_4P_2O_7$ treatment. Spectra *a'* and *d* refer to aniline (in CCl_4 solution) and to the DMSO extract of the aniline–Fe(III)–montmorillonite complex (in KBr pellet), respectively.

The above observations demonstrate that interlayer humin formation in smectitic soils or sediments can take place through Type II complexes at the expense of small-sized aromatic molecules. Although aniline is not very representative of biologically generated, natural aromatics—much less than phenolic compounds[1,3], for instance—its behaviour is probably not unique. The important result is the interlamellar polymerization of a simple aromatic monomer, at low concentration in aqueous solution and at low temperature on a smectite containing Fe(III) exchange forms. This type of reaction might well be an alternative for the intercalation of large-sized, polymeric humic acid nuclei, highly improbable in natural conditions.

Compositional convection and stratification of Earth's core

David R. Fearn* & David E. Loper

Geophysical Fluid Dynamics Institute, Florida State University,
Tallahassee, Florida 32306

Traditionally, studies[1,2] of the possible stratification of the outer core of the Earth have been based on thermal buoyancy, with the effects of composition being implicitly ignored. However, recent work[3,4] has demonstrated the importance of compositional buoyancy in providing the power necessary to sustain the geodynamo. It seems likely, therefore, that the effects of composition are also important in determining the stratification of the core. We present here a study of the relative importance of thermal and compositional buoyancy in the core. We briefly review the idea that the growth of an iron-rich inner core leads to the release of material which is depleted in iron and therefore buoyant. We then calculate the density profile which results if both this light material and the latent heat released as the inner core grows are redistributed by diffusion. It is found that not only are compositional effects important, they dominate thermal effects in determining the stratification of the core. Finally, using parameter estimates relevant to the core, we show that the diffusive density profile is unstable throughout the outer core except for a layer some 70 km deep adjacent to the mantle–core boundary. We therefore expect that convection fills the entire outer core with the possible exception of a thin layer below the mantle–core boundary.

It has long been believed that the Earth is in thermal equilibrium, with the internal generation of heat by radioactive decay balancing the surface heat flux. Recently, Stacey[5] pointed out that such an equilibrium cannot be maintained because the strength of the radioactivity decays with time and he argued that a significant portion of the surface heat flux is due to the gradual cooling of the entire Earth. This idea is strongly supported by studies[6–8] using parameterized models of thermal convection.

If the Earth is cooling, there will come a time when the core fluid reaches its freezing temperature and solid begins to freeze out. If the freezing temperature gradient is steeper than the actual temperature gradient, then freezing will first occur at the centre of the core, and the frozen solid will accumulate to form a solid inner core[9]. The freezing process results in the release of light material as well as of latent heat. Both are sources of buoyancy and have been proposed[10,11] as the cause of the convective motions necessary for dynamo action.

The core is not a pure material but is composed mainly of iron together with a significant fraction (8–20%) of some lighter material[12]. The precise nature of this material is not important for our purposes and it is sufficient to model the core as a binary alloy of a heavy metal and a light non-metal. We shall assume the mass fraction ξ of light material to be less than that required for an eutectic mixture ($\xi < \xi_e$) as the case $\xi > \xi_e$ proposed by Braginsky[11] has been shown to be geophysically implausible[13]. Metallurgical studies[14] have shown that the solid which freezes out when $\xi < \xi_e$ contains more of the heavy component and is therefore more dense than the surrounding liquid. By conservation of light material, the freezing process must, therefore, leave a light, compositionally buoyant residue in the liquid adjacent to the freezing interface. Thus, as the inner core grows, light material is released and it is this compositional buoyancy which Braginsky[11] proposed as the source of the energy for the geodynamo.

The energetics of Braginsky's proposal have been calculated[3,4] by estimating the rate of release of gravitational potential energy resulting from the net motion of light material upward and heavy material downward, assuming the inner core to have grown at a constant rate over the lifetime of the Earth. This mechanism was found to be capable of supporting a large toroidal magnetic field through dynamo action. Here we study the dynamics of Braginsky's proposal by estimating the relative strengths of the buoyancy forces produced by temperature and compositional differences within the core.

If the inner core is growing at a mass rate $\dot{M}$ and the change in composition on freezing is denoted by ξ_i, Loper and Roberts[15] have shown that the upward flux I of the light material and the thermal diffusive flux Q of heat into the outer core are given by

$$I = \xi_i \dot{M} \quad \text{and} \quad Q = L\dot{M}, \tag{1}$$

where L is the latent heat. The light material must be redistributed throughout the fluid outer core (causing a gradual increase in the mass fraction of light material) and the heat must be transported up to the mantle–core boundary. There are two possible mechanisms for redistribution: diffusion and convection. The mechanism which occurs is determined by the density gradient. A necessary condition for the diffusive state to be unstable to a convective instability is that a parcel of fluid displaced upward isentropically and without change of composition be less dense than its surroundings;

$$(\partial\rho/\partial r)_{S,\xi} < \mathrm{d}\rho_o/\mathrm{d}r \tag{2}$$

where r is the radial coordinate and a subscript o denotes the static diffusive state. Loper and Roberts[15] have shown that for the large length scales in the core, the density difference required to overcome diffusive processes associated with convective motions is very small and to a good approximation equation (2) is also sufficient for convective instability.

Let us adopt equations of state for density and entropy of the form

$$\mathrm{d}\rho = \beta\rho\,\mathrm{d}p - \alpha\rho\,\mathrm{d}T - \bar{\delta}\rho^2\,\mathrm{d}\xi$$

and

$$\mathrm{d}S = -(\alpha/\rho)\,\mathrm{d}p + (C_p/T)\,\mathrm{d}T + \bar{s}\,\mathrm{d}\xi$$

(see ref. 16). We may now rewrite equation (2) as

$$\alpha\rho\,\mathrm{d}T_o/\mathrm{d}r + \bar{\delta}\rho^2\,\mathrm{d}\xi_o/\mathrm{d}r < (\alpha^2 T/C_p)\,\mathrm{d}p/\mathrm{d}r \tag{3}$$

where C_p is the specific heat capacity at constant pressure, α is the thermal expansion coefficient, and $\bar{\delta}$ is the specific volume change with composition.

In the diffusive state the radial fluxes Q_o of heat and I_o of light material are related to the diffusive gradients by

$$I_o = -\rho DA[\mathrm{d}\xi_o/\mathrm{d}r + (\bar{\delta}/\bar{\mu})\,\mathrm{d}p/\mathrm{d}r] \tag{4}$$

and

$$Q_o = -kA\,\mathrm{d}T_o/\mathrm{d}r \tag{5}$$

The constitutive laws (4) and (5) are equivalent to equations (58.11) and (58.12) of Landau and Lifshitz[17] with $Q_o = A\hat{\mathbf{r}}\,.\,[\mathbf{q} - (\bar{\mu} + \bar{s}T)\mathbf{i}]$ and the coefficient k_T set equal to zero. Here $A = 4\pi r^2$ is the area of the sphere of radius r, k is the thermal conductivity, D is the material diffusion coefficient and $\bar{\mu}$ is the energy of mixing. At the inner-core boundary I_o and Q_o are given by equation (1), whereas at the mantle–core boundary we assume there is no flux of light material ($I_o = 0$), and a specified heat flux Q_m. The flux Q_m results from the diffusion of the latent heat $L\dot{M}$ across the outer core, plus the heat capacity released by the cooling of the core and any heat generated by radioactive decay, ohmic heating, and so on. If we assume the internal heat sources to be uniformly distributed throughout the outer core,

0028–0836/81/050393—02$01.00

then

$$Q_o = [(r_m^3 - r^3)L\dot{M} + (r^3 - r_i^3)Q_m]/(r_m^3 - r_i^3) \qquad (6)$$

where r_m is the radius of the outer core and r_i is the radius of the inner core. Similarly, assuming the material flux I_o distributes the light material uniformly throughout the outer core, we have

$$I_o = \xi_i\dot{M}(r_m^3 - r^3)/(r_m^3 - r_i^3). \qquad (7)$$

Combining equations (3)–(7) and assuming a hydrostatic balance, $dp/dr = -\rho g$ we obtain

$$\frac{\alpha^2 T}{C_p} + \frac{(\bar{\delta}\rho)^2}{\bar{\mu}} < \frac{\left[(r_m^3 - r^3)\dot{M}\left(\frac{\alpha L}{k} + \frac{\bar{\delta}\xi_i}{D}\right) + (r^3 - r_i^3)\frac{\alpha}{k}Q_m\right]}{4\pi r^2(r_m^3 - r_i^3)g} \qquad (8)$$

The terms on the left-hand side of equation (8) represent the stabilizing effects of the conduction of heat down the adiabat and the diffusion of material induced by the pressure gradient (barodiffusion), respectively, while the terms on the right-hand side represent the destabilizing effects of the release of latent heat and of light material associated with the freezing process and the heat flux out through the mantle–core boundary. This is a generalization of equation (14) of Loper and Roberts[18].

The instability criterion (8) can be considerably simplified for parameter values thought to be relevant to the core. Loper and Roberts[18] have shown that $\alpha^2 T/C_p \ll (\bar{\delta}\rho)^2/\bar{\mu}$ and $\alpha L/k \ll \bar{\delta}\xi_i/D$ at the inner-core boundary. Using the same sources as Loper and Roberts[18] for the parameter estimates, it can be shown that these inequalities hold good throughout the outer core. We can also obtain a measure of the importance of the term involving Q_m by comparing its maximum value (at $r = r_m$) with the left-hand side of equation (8). Using parameter estimates appropriate at the mantle–core boundary, with $Q_m = 5 \times 10^{12}$ W, we find that $[\alpha Q_m/gk4\pi r_m^2]/[(\bar{\delta}\rho)^2/\bar{\mu}] \simeq 6 \times 10^{-2}$. Thus we may conclude that thermal effects are not of primary importance in determining the stability of the core. To a first approximation, the thermal terms may be neglected and equation (8) reduces to

$$\frac{(\bar{\delta}\rho)^2}{\bar{\mu}} < \frac{(r_m^3 - r^3)\bar{\delta}\xi_i\dot{M}}{4\pi r^2(r_m^3 - r_i^3)gD}. \qquad (9)$$

This is the condition for the diffusive state to be unstable to convective overturning. It depends only on compositional effects and is equivalent to the condition $d\xi_0/dr < 0$.

The diffusive flux of light material has two components (see equation (4)). The first is the familiar flux down the compositional gradient which acts to make the composition homogeneous (minimizing chemical potential energy). If this were the only component, instability would occur throughout the core for any positive growth rate $\dot{M}$. The second component is the barodiffusive flux which acts to separate out the light component from the heavy component (minimizing gravitational potential energy). Together the two fluxes act to redistribute light material in such a way as to minimize the total (gravitational plus chemical) potential energy. If $\dot{M} = 0$ and the net flux of light material in the core is zero, we can see from equation (4) that the compositional gradient $d\xi_o/dr = -(\bar{\delta}/\bar{\mu})\, dp/dr > 0$ is stable. The mass rate of growth $\dot{M}$ must exceed some critical value before the compositional gradient changes sign. As $\dot{M}$ is increased we can see from equation (9) that this happens first at the inner-core boundary ($r = r_i$). As $\dot{M}$ is further increased a layer $r_i \leqq r \leqq r_t < r_m$ develops in which $d\xi_o/dr < 0$. Within this layer, the diffusive solution is unstable and convection occurs.

Loper and Roberts[18] have shown that at $r = r_i$, inequality (9) is satisfied by a wide margin, implying convection in the lower part of the outer core. On the other hand, at $r = r_m$ the right-hand side of equation (9) vanishes so the diffusive density profile must be stable in a layer adjacent to the mantle–core boundary. We determine the depth $h = r_m - r_t$ of this stable layer by finding that value r_t of the radius for which the left- and right-hand sides of equation (9) are equal. Solving for h we find

$$h = \rho^2\bar{\delta}DgV/\xi_i\dot{M}\bar{\mu}, \qquad (10)$$

where $V = 4\pi(r_m^3 - r_i^3)/3$ is the volume of the outer core and we have assumed $h \ll r_m$. Using parameter estimates relevant to the vicinity of the mantle–core boundary (with $D \simeq 6 \times 10^{-9}$ m^2 s^{-1}) we find the depth of the stably stratified layer to be ~70 km. The uncertainties in the estimates of the various parameters (particularly D and $\bar{\mu}$) mean that this figure should be regarded as only an order-of-magnitude estimate of the depth of the stable layer.

A simple calculation equating the kinetic energy of a convecting fluid parcel to the potential energy gained as this parcel penetrates the stable layer suggests that convection will penetrate only a few metres into the stable layer if it is already established. However, if the stable layer were forcibly mixed by some cataclysmic process (such as core formation), the combined action of barodiffusion and the normal diffusive process would act to re-establish the layer, but only very slowly. In fact, it would take a length of time equal to the age of the Earth to establish a layer several tens of kilometres thick by these processes. Further, this process might be severely inhibited if convective motions disrupt the newly forming stable layer before a strongly stabilizing gradient can be established. In view of these caveats, the recent claim[19] that the top of the outer core is stably stratified must be treated with caution.

We thank Paul Roberts for his helpful discussions. This work was supported by the NSF under grant no. EAR78-00818 and is contribution No. 160 of the Geophysical Fluid Dynamics Institute, Florida State University, Tallahassee, Florida.

Significance of contrasting magmatism in North East Africa and Saudi Arabia

N. B. W. Harris & I. G. Gass

Department of Earth Sciences, The Open University, Walton Hall,
Milton Keynes MK7 6AA, UK

The Red Sea is a north–south rift that split the Arabian–Nubian shield into eastern (Arabian) and western (Egypt and Sudan) segments by seafloor spreading less than 30 Myr ago[1]. Because geological studies in the region have generally have confined by national frontiers, a comparative study of magmatic evolution on either side of the Red Sea has not, so far as we are aware, previously been undertaken, and current models for Arabian–Nubian shield evolution suggest broadly similar histories for the basement on both sides of the Red Sea. However, although the igneous rock geochronology on both sides of the Red Sea indicate that Precambrian magmatic histories were broadly similar, since then they have been quite distinct in that the African crust has been invaded episodically by quartz syenites, nepheline syenites and peralkaline granites between 500 and 80 Myr; no such igneous activity is evident in Arabia (Fig. 1). We propose here that the Red Sea line has had structural significance from at least the end of the Cambrian though whether it defines a line of contrasting upper mantle or lower crust geochemistry, or of contrasting crustal rigidity cannot yet be established.

0028-0836/81/050394—03$01.00

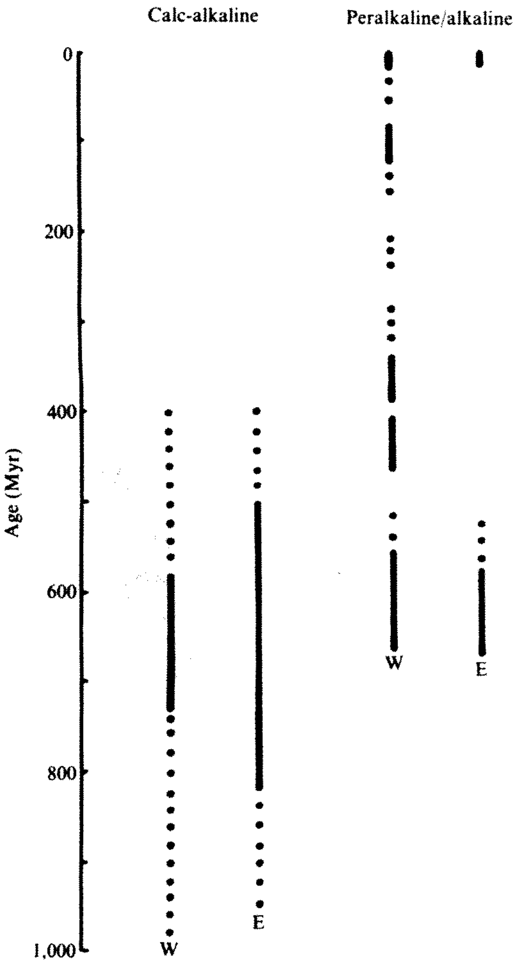

Fig. 1 Age spans of calc-alkaline and peralkaline/alkaline magmatism in the Arabian–Nubian shield. Solid lines from U–Pb zircon or Rb/Sr isochron ($N > 3$) data with $2\sigma < 10\%$. Dotted lines from K/Ar or other Rb/Sr data. E, Eastern shield (Saudi Arabia and Sinai). W, Western shield (Egypt and Sudan). All ages have been recalculated to IUGS recommended constants[2].

Nearly 600 age determinations have been published from the Arabian–Nubian shield, about two-thirds of which are from Saudi Arabia. Although most of these are isolated K/Ar or Rb/Sr ages, and cannot be considered reliable indicators of geological events, available U–Pb zircon and Rb/Sr isochron ages with low errors indicate that on both sides of the Red Sea calc-alkaline igneous activity was more or less continuous between 840 and 500 Myr, being initially dioritic or tonalitic in character until about 700 Myr when granitic magmatism became predominant. There is evidence of sporadic magmatism as early as 980 Myr, and a single three-point isochron of Saudi Arabian metabasalt at 1,165 Myr (ref. 3). Due to daughter isotope leakage, the age of cessation of calc-alkaline magmatism is difficult to define, and some activity may have occurred between 500 and 400 Myr on either side of the Red Sea. However, in contrast to calc-alkaline magmatism, peralkaline and alkaline magmatism have differing age distributions in Africa and Arabia (Fig. 2). In north-west Arabia, excluding Tertiary magmatism associated with Red Sea rifting, peralkaline magmatism seems to be restricted to a geologically brief period[3–6] between 640 and 540 Myr whereas in north-east Africa alkaline intrusions were not only emplaced between 600 and 540 Myr (refs 7, 8), but continued to be so at irregular intervals until 80 Myr ago[8–10]. Many of the available dates for this magmatism are from the K/Ar method, but eight have been confirmed by Rb/Sr isochrons and six more by Rb/Sr mineral ages.

Although the data bank of reliable ages of alkaline intrusions Arabia is not as large as in north-east Africa, there are two independent indications that magmatism did not occur in the eastern shield between 540 and 30 Myr.

(1) In Egypt and north-east Sudan, the mainly Mesozoic Nubian sandstone is intruded by alkaline ring complexes[11,12], whereas peralkaline intrusions in Saudi Arabia are not known to penetrate Phanerozoic sedimentary formations.

(2) In the western shield there is a critical change in magma composition at ~500 Myr. Pre-500 Myr peralkaline granites with smaller volumes of quartz syenites and peralkaline granites were emplaced[7,9,13]. After 500 Myr the dominant rock-type is nepheline syenite with smaller volumes of quartz syenite and peralkaline granite[9,13,14]. This depletion in silica of the younger intrusives indicates a change of either depth or volatile content in the source environment. Analyses from 17 separate alkaline intrusions from Saudi Arabia[15,16] indicate peralkaline granites which are strongly quartz normative which therefore correlate with the pre-50 Myr group from Saudi Arabia. Moreover nepheline-bearing plutons have not been recorded in Arabia so far as we are aware. The absence of silica undersaturated magmas from Saudi Arabia supports the conclusion that the post-500 Myr group from Egypt and Sudan have no equivalent in Saudi Arabia.

Therefore, although there was little if any magmatic activity in Saudi Arabia and Sinai between 500 and 30 Myr, in Egypt and north-east Sudan there were spasmodic and seemingly random high level injections of peralkaline and alkaline magmas throughout this period.

Geochemical considerations of peralkaline granites in general and of Arabian peralkaline granites in particular indicate that such magmas originate by partial melting at depth in the presence of non-hydrous volatiles[16,17]. Of the 16 available Rb/Sr ioschrons of peralkaline and alkaline granites from both sides of the shield, 12 indicate initial $^{87}Sr/^{86}Sr$ ratios between 0.701 and 0.704 implying a source in the upper mantle or lower crust. Four remaining isochrons show ratios between 0.705 and 0.710 which suggest either crustal contamination or a source of high Rb/Sr ratio.

However, as most, if not all, peralkaline magmatism from the shield originates from either the lower crust or upper mantle, its absence in the Arabian segment after 500 Myr may be attributed to: the westward migration of an upper mantle thermal energy source; a more rigid crust to the Arabian segment; or variation in upper mantle geochemistry. These alternatives are now briefly evaluated.

If there has been a westward migration of a high heat-flow region in the upper mantle it could result in an east–west age trend of peralkaline intrusions within the African crust. No such trend is observed and intrusions with age differences of 300–500 Myr are found in juxtaposition[9,13].

Alternatively, it is possible that the Arabian crust became impervious to magmas. Although magma can rise through most of the crust by stokesian diapiric movement, its emplacement into the upper crust is greatly facilitated by the presence of active fractures. It is relevant therefore that fault trends differ in the two segments. In Egypt and the Sudan, an EW–ENE trend is most obvious and controls the emplacment of alkaline intrusions[13], whereas in Arabia the dominant NW–SE Nadj system[18] was active up to 500 Myr ago and is associated with the emplacement of peralkaline granites in Saudi Arabia[15,16]. So, as both segments are cut by faults which were active during the periods of magmatic emplacement, crustal imperviousness to magmatic penetration seems an unlikely explanation for the lack of Phanerozoic peralkaline magmatism in Arabia.

The formation of silica undersaturated alkaline intrusions in the western shield implies the existence of a deep source region low in H_2O and possibly rich in CO_2 (ref. 19). The absence of similar intrusions in the eastern shield may indicate a distinct upper mantle geochemistry and, if this proves to be the case, the distinction existed 450 Myr before the opening of the Red Sea. Although it is possible that the boundary between two upper mantle regions of distinct geochemistry coincidentally become the site of lithospheric rupture, the following model seems to provide a more obvious link between upper mantle heterogeneity and subsequent rifting.

There is strong and increasing evidence[20,21] that the continental crust of the Arabian–Nubian shield was produced by the evolution and accretion of originally intra-oceanic island arc systems during the Upper Proterozoic. This process was complete by about 500 Myr at which time the region attained a continental character, but this was obviously reached in some places before others[16]. The presence of peralkaline granites on both sides of the shield before 500 Myr indicates that the upper mantle or lower crust was able to provide magmas which were emplaced as peralkaline granite melts. Structural and geochemical evidence suggests the Arabian shield was underthrust by one or more Upper Proterozoic, easterly dipping subduction zones[3,21]. In this event, a mantle wedge beneath Arabia and above the subduction zones would be hydrated due to seawater being expelled from the subducted oceanic plate which in time would lower the liquidus temperature of the sub-Arabian peridotite mantle, and the melts produced would be enriched in H_2O and therefore be of calc-alkaline affinity. Peralkaline magmatism, which requires conditions of low P_{H_2O}, would only be initiated after subduction had ceased. However, the sub-Arabian mantle and lower crust would be depleted in components contributing to low temperature melts, and therefore could not provide peralkaline melts after ~500 Myr until the opening of the Red Sea. In contrast, the sub-African mantle, which had not been extensively depleted by such late stage calc-alkaline magmatism retained its low melting point components and continued to produce small quantities of alkaline magma throughout the Phanerozoic. During the Tertiary the Red Sea rift developed along the line separating depleted and non-depleted upper mantle, which in turn may coincide with a Proterozoic suture zone.

Solar energy conversion by chloroplast photoelectrochemical cells

Ravindra Bhardwaj, Rong L. Pan & Elizabeth L. Gross

Department of Biochemistry, The Ohio State University,
484 West 12th Avenue, Columbus, Ohio 43210

Solar energy can be captured by photochemical or photoelectric processes in which a gradient of chemical potential can be generated using photochemical redox reactions. Photosynthesis is the most efficient system for quantum conversion and storage of solar energy[1]. Various biomimetic systems have been constructed as models for the conversion of light to electrical energy[2–11]. These biological photoelectrochemical cells have utilized microcrystalline chlorophyll *a* (Chl *a*)[2], chlorophyll liquid crystals deposited on the electrodes[3–5] or incorporated into filters[6], bilayer lipid membranes[7], chloroplast membranes[8], chloroplasts[9] and bacterial reaction centres[10,11]. The power conversion efficiencies are mostly very low (≈0.002%). We describe here a chloroplast photoelectrochemical cell which generates large photovoltage and photocurrent, and has a power conversion efficiency close to 1%.

We have previously developed a solar cell using photosystem I (PSI) particles[12]. Our rationale was that charge separation occurs within the reaction centre of PSI particles and produces a

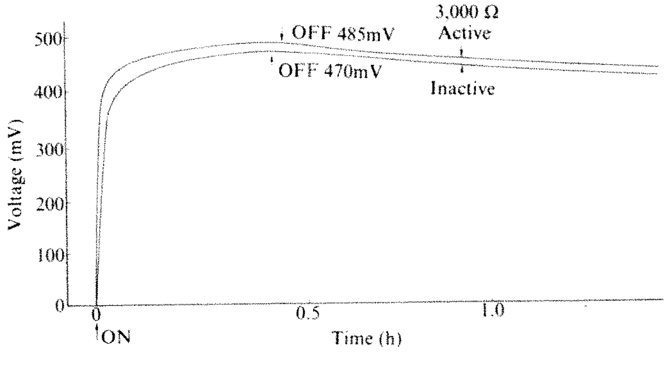

Fig. 1 Time course of potential development. Chloroplasts containing 80 μg Chl were aspirated onto a 1-cm^2 area (1.2-μm pore diameter) Metrical filter. The cell contained 80 mM Tricine (*p*H 7.0) + 100 mM NaCl + either 3.0 mM FMN or 0.5 mM DCIP. The FMN side (front surface area = 8 cm^2) was illuminated with white light ($I = 4,600$ W m^{-2}). The potential was measured across a 3,000 Ω load resistance.

FMN (3.0 mM) and AQS (1.5 mM) were used as acceptors. DCIP (0.5 mM) was the donor. (+) and (−) indicate active and inactive (killed) chloroplasts respectively.

strong reductant (reduced P430)[13] and a weak oxidant (P700$^+$)^{5}g3[14]. The reductant and oxidant then interact with exogenous electron acceptors and donors producing a gradient of chemical potential which can be converted into an electrical current. Also, the electron acceptor used (flavin mononucleotide, FMN) is photoreducible either directly by the electron donor (Fe^{2+}) in the case of potassium ferrocyanide[15] or by Tricine[16]. Thus, both photosynthetic reduction of FMN mediated by PSI and FMN photochemistry (FMN photoreduction) contribute to the power developed. In the case of FMN, photodestruction also occurs. Using isolated chloroplasts in place of the PSI particles in the photochemical cell has proved advantageous because of their ease of preparation and their power conversion efficiency of close to 1%.

Isolated PSI particles or broken chloroplasts (Type C) were placed on a filter between two compartments containing the electron donor and the electron acceptor, respectively. Platinum electrodes were placed in each compartment and the photovoltage was observed across a load resistance (see ref. 12 for experimental details and design). Initially[12], we obtained an open circuit photovoltage (V_{oc}) of 360 mV, a short circuit current (I_{sc}) of 108 μA and a maximum power (W_{max}) of 20 μW.

We determined the characteristics of our chloroplast photoelectrochemical cell in the presence of two photoactive electron acceptors, FMN and AQS (anthroquinone 2-sulphonate) in optimal conditions of donor (dichlorophenol indophenol, DCIP) and acceptor concentrations, *p*H and buffer strength (Table 1). In all cases, the chloroplasts contribute at least 30% of the power observed. The two acceptors have different *p*H optima: 7.0 for FMN and 8.2 for AQS. Both Tris and Tricine buffers increased the power observed because they act as electron donors for the photoreduction of FMN[16] and AQS[17]. The increase in power with increasing buffer concentration is not a salt effect because increasing NaCl concentration from 100 to 200 mM had no effect. The AQS system did not generate greater power in phosphate buffer because, unlike FMN, there is no photodestruction which also contributes to the power developed. FMN was a better electron acceptor than AQS because of its greater absorption cross-section in the visible region of the spectrum and the fact that photodestruction could contribute to the potential developed. A maximum power of 400 μW was observed across a 100 Ω resistance. The open circuit voltage and short circuit current were 510 mV and 3.5 mA respectively.

The time course of the photoresponse is shown in Fig. 1. A photovoltage of 485 mV was observed across a 3,000 Ω resistance. That the potential persisted for 1–2 h even after the light was turned off, illustrated the system's ability to store energy. The ability of the cell to generate a voltage is equivalent to a generator in series with a source resistance (R_s) whose magnitude is a reflection of the ability of the cell to generate current. The R_s in a photoelectrochemical cell is a function of rate of electron transport through PSI during illumination and the rate of photoreduction of the acceptor (FMN or AQS) by the reducing agents. The more efficient these processes, the lower R_s will be. Because both photosynthetic and photochemical reduction of the acceptor depend on light, R_s should very high in dark and low in light. R_s also operates in parallel with membrane resistance (R_m). To develop and store energy, R_m has to be very high to limit the dissipation of the reduced photoproducts through the membrane. We have measured the R_m and the differences in the internal resistance in the dark and during steady state illumination (Fig. 2). The R_m was calculated to be of the order of 1.5×10^5 Ω (Fig. 2, curve 1). In the dark, the internal resistance was 5×10^4 Ω (curve 2) which decreases to 150 Ω (curve 3) after steady state photovoltage is achieved during illumination. The

Chloroplasts (containing 80 μg Chl were aspirated onto 1-cm^2 filter of 1.2 μm pore diameter. Conditions included 80 mM Na-tricine (at the indicated *p*H). The light intensity at the front of the cell was 5,000 W m^{-2}.

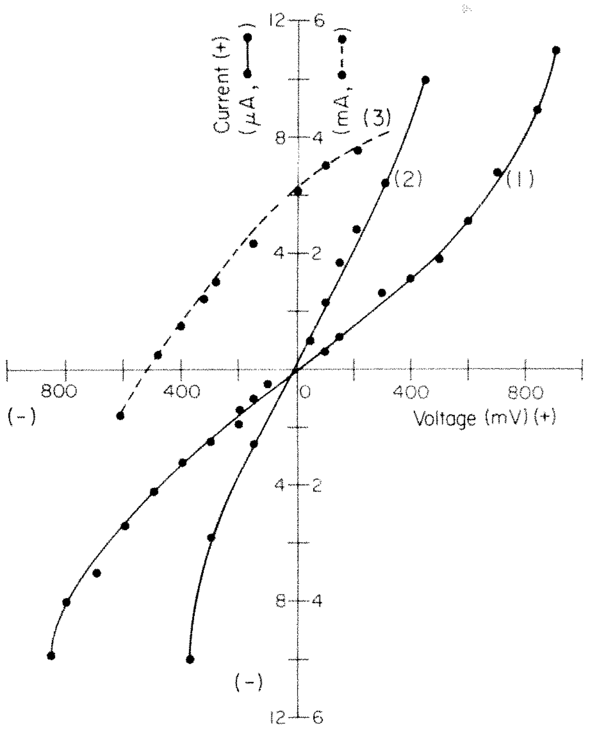

Fig. 2 Current–voltage curves of PSI impregnated membrane in absence of any dye (curve 1), in presence of dyes in dark (curve 2) and during illumination in presence of dyes after steady state potential was developed. Controlled potential was applied using a battery and a potentiometer and the current was measured. Membrane resistance (R_m) (curve 1) was measured only in salt solution. Other conditions as in Fig. 1. Light intensity was 2,000 W m^{-2}.

current–voltage curve shows that in light (curve 3) the V_{oc} is 520 mV and I_{sc} is 3.1 mA.

Table 2 shows that the chloroplasts can effectively substitute for the PSI particles. The power and short circuit current obtained is marginally higher in the case of PSI particles. This may be due to a permeability barrier in chloroplasts.

We calculated the power conversion efficiency for the FMN system assuming a total front surface area of 8 cm^2. The efficiency increased as the incident light intensity was lowered from 0.08% at 5,000 W m^{-2} to 0.4% for 30 W m^{-2}. The contribution of the chloroplasts to the total power also increased as the light intensity was lowered from 30% at 5,000 W m^{-2} to 50% at 30 W m^{-2}. If we calculate the efficiency for 30 W m^{-2} based on the 1 cm^2 area of chloroplasts illuminated rather than the 8 cm^2 of FMN solution, we obtained an efficiency of 3.2%. The true efficiency lies between the two estimates. By subtracting the photochemical contribution from the total power an efficiency of 2.3% was obtained for the chloroplast contribution. This may not be correct, however, as the two contributions are synergistic.

Liquefaction of biomass as a source of fuels or chemicals

Ian J. Miller & S. Kevin Fellows

Chemistry Division, Department of Scientific and Industrial Research, Petone, New Zealand

Although biomass is one of the few renewable sources of liquid fuels and chemicals, relatively little work has been carried out on its direct liquefaction. Here, we report that wood or cellulose can be almost totally converted to liquids or gases when heated under pressure to 350 °C in the presence of phenol, water, an acid or base catalyst, and either hydrogen or nitrogen. The resultant liquids were separated into a neutral fraction, which was partly characterized by gas chromatography–mass spectrometry (GC–MS) and found to contain mainly aromatic compounds with or without an oxygen-containing ring, and a phenolic fraction. The nature of these compounds was found to be dependent on the catalyst, but not appreciably on the physical conditions used.

Previous attempts at liquefying biomass have tended to consider it as a substitute for coal. Thus liquids have been obtained by pyrolysis under hydrogen[1], by pyrolysis in wood tars, by reaction with carbon monoxide[2], by hydrogenation with iodine[3] or nickel[4] as a catalyst, or by hydrogenation with a 'donor solvent'[5]. These processes, however, fail to take advantage of the depolymerization of carbohydrate fraction at least at ~350 °C to monomer units such as 1,6-anhydroglucose[6]. This is followed by degradation and condensation reactions which, if unchecked, lead to the formation of char. These intermediates need therefore to react or to be rearranged before they can condense.

A preliminary objective is to slow down the condensation reactions, which is best done by providing a solvent to slow down the higher order solid state reactions. We used phenol because as the hydrogenation of lignins produces mainly phenols[7] they would be a significant by-product of the process, and phenol with certain catalysts such as zinc chloride, dissolves cellulose. To interrupt condensation reactions we first tried hydrogenation, and then simple acid–base catalysed rearrangements.

In a typical qualitative reaction 2 g of the cellulosic material, 2 g of phenol, 2.5 g of water, and 0.5 g of other reagents were placed in a glass liner which in turn was placed in a 15 cm^3 capacity pressure vessel. This was pressurized to 3.4 MPa with either hydrogen or nitrogen, and heated to 350 °C within 30 min for times between a few minutes and several hours. After cooling, the liquid products were separated into phenolic and non-phenolic fractions, and the major components of the latter characterized by GC–MS. Some of the phenolic fraction was also characterized, and was similar overall to that reported from the hydrogenation of lignin[7].

The composition of the neutral fraction did not depend appreciably on the source of the biomass. When heated with zinc chloride and nitrogen, cellulose (filter paper, cut into squares), softwood (*Pinus radiata*, chips ≤6×6×2 mm) or hardwood (aspen, powdered, similarly to Masonite process, by steam explosion) gave products of almost identical composition.

The biomass was required to remain in contact with the solvent. If the volume of solvent was reduced below that outlined above, charring occurred. Only 1 g of wood chips could be used as they did not pack very well. The powdered aspen was used for most experiments because it packed better, and it could be slurried with the two phases of the liquid. To mimic green biomass, aspen with 40% dry solids, 60% moisture was used.

Liquefaction of powdered aspen was essentially complete after a few minutes at 350 °C. The composition of the neutral fraction was unaffected by reaction time, although the yield was

lower at shorter times (with evidence of cellulose pyrolysates present), and at times appreciably longer than an hour, when tarring occurred. Reactions below 325 °C led mainly to char formation, and the time between 250 and 325 °C had to be minimized. This problem could be alleviated by shaking and by having larger amounts of phenol present. Reactions over 400 °C led to tarring.

Representative results using aspen are shown in Table 1. If zinc chloride was used with nitrogen, the main non-phenolic products were as listed in the first row of Table 1. If small amounts of nickel were added, there were increases in the amounts of 2-methyl benzofuran and xanthone, and a decrease of xanthene (Table 1). This may indicate that some hydrogenation occurs even without the addition of hydrogen gas, hydrogen presumably coming from the lignin. If hydrogen were used instead of nitrogen, the same products occur, but in significantly different proportions, and other compounds could be tentatively identified. About 3% of aromatic hydrocarbons, including toluene, ethyl benzene, and xylenes were also formed.

Replacing the zinc chloride with either sodium dihydrogen phosphate or sodium carbonate also gave complete liquefaction. Results and the conditions used are given in Table 1. Copper, cobalt, iron, and chromium were also used in place of nickel, and all gave liquefaction, with varying proportions of the same products.

For quantitative experiments, 2.5 g oven dried aspen, 10 g phenol, 13.5 g water, 0.8 g of a reagent and, if required 0.4 g $Ni(OH)_2$ were slurried, and placed in a glass liner for a larger reactor, which was pressurized to 4 MPa and heated to 350 °C in 40 min. The reagents used, and the recovered yields of neutrals were: zinc chloride/N_2, 0.76 g; zinc chloride/Ni/H_2, 0.74 g; NaH_2PO_4/N_2 0.55 g, and K_2CO_3/N_2, 0.65 g.

Positive yields of phenol were obtained in two reactions, namely $ZnCl_2/H_2/Ni$ (10.2 g recovered), and K_2CO_3/N_2 (10.15 g recovered). The phosphate reacted with the glass, and there was extensive char formation on the exterior of the liner. This was assumed to have come from phenolics reacting with alkaline glass, but in any case is irrelevant to further process development. That the phenol could be recycled was shown by reacting 1-inch squares of filter paper with zinc chloride, nickel, and hydrogen. The phenol was recycled three times before handling losses made it unlikely that the cellulose would dissolve properly. In these conditions 25 g of cellulose gave 12 g of neutral liquids which distilled between 50 and 400 °C.

If cellulose alone is converted to the products in Table 1 by the abstraction of oxygen atoms, the maximum yield is ~60% by weight, whereas if the conversion proceeds by the elimination of carbon dioxide, the maximum yield is ~40%. With a lignin content of 25%, the carbohydrates of aspen would give ~1.1 or 0.7 g of products if each conversion were totally efficient. The maximum yield of phenolics from the lignin would be ~0.7 g, although polyhydroxy phenols would not have been recovered in this study. Handling losses with the original solvent also prevent a proper assessment of phenol yield. The observed recoveries do establish, however, that the reaction is a net producer of phenols.

In conclusion, cellulosic material can be liquefied in conditions which, compared with those required for coal liquefaction, are relatively mild and fast. For a given set of catalysts, ~75% of the non-phenolic products consist of less than eight chemical compounds, and in some cases even fewer. Furthermore, a change in the catalysts can significantly alter the nature of the products. Thus cellulosic feedstocks could be the basis of a significant range of chemical products. Also, because hydrogen is not a necessary component of the liquefaction process for some products, it is possible that crude feedstock for a fuels or chemical industry could be manufactured in many small satellite reactors, thus obviating the large transport costs incurred if an equivalent amount of biomass were processed at one site. The satellite reactors could be low in cost, while the central processing unit could still manage the economies of scale necessary for product costs comparable with materials such as coal.

We thank Steven Gwyn for GC–MS analyses and assistance with product identification.

Endosperm cell number in barley

M. P. Cochrane & C. M. Duffus

Department of Agricultural Biochemistry, University of Edinburgh, West Mains Road, Edinburgh EH9 3JG, UK

Grain weight is one of the major components of grain yield and it has been suggested that in wheat, final grain weight may be a function of endosperm cell number[1]. If grain weight is to be increased by increasing the rate and/or duration of endosperm cell division, it is important to establish the stage of development at which maximum endosperm cell number is attained. Evers[2] reported that no cell division occurred in the endosperm of wheat later than 16 days after anthesis and other workers[3,4] have come to a similar conclusion using cell counts. However, biochemical analyses[5] have shown that the maximum DNA content of wheat endosperm is not reached until 25 days after anthesis and both Donovan[6] and Radley[7] have suggested that endosperm cell division may continue until about 30 days after anthesis. We have estimated the number of endosperm nuclei in developing caryopses of barley and have examined transverse sections of endosperms of different ages. We report here that cell division in barley endosperm continues until 28–30 days after anthesis.

Fig. 1 The number of nuclei per endosperm during barley caryopsis development. Bars indicate confidence limits at $P = 0.05$.

In the present investigation, as in previous work in this laboratory[8], barley (*Hordeum vulgare* var. *distichum* L. cv. Midas) was grown in a greenhouse, and caryopsis ages were estimated on a scale based on the normal development of field-grown barley in Scotland, which takes 60 days from anthesis to harvest-ripeness. The parameters used to estimate developmental age include pericarp shape and colour, endosperm shape and colour, and embryo length. The middle three or four grains were removed from each of several of the first-maturing ears in two or more pots. The developmental age of each caryopsis was determined and the endosperm dissected out, taking care to remove the testa and embryo and leave the aleurone intact. It was not possible to sample caryopses older than 33 'days' after anthesis because at this stage of development, the aleurone adheres to the testa and peels off with it. Endosperms were fixed overnight in 1 : 3 v/v acetic acid/ethanol and then stored in 70% ethanol. Endosperms of the same developmental age were pooled and three samples of 10 were stained using Feulgen reagent and digested in cellulase[9]. Cells were suspended in 0.5 M sorbitol and nuclei were counted in a haemocytometer. Caryopses from the same ears were prepared for light microscopy[8].

The number of nuclei per endosperm increased during the period 16–28 'days' after anthesis (Fig. 1). Transverse sections of mid-grains (Fig. 2) show that the aleurone layer of a 15-'day' caryopsis is one to two cells thick, with cell division occurring in both anticlinal and periclinal planes. The cells in the inner and outer layers of the testa are similar in size and the cells of the nucellus are fully expanded and thin-walled. The endosperm of the 15-'day' caryopsis is flat and greyish-white, and the embryo cannot be seen with the naked eye. In 23-'day' caryopses the aleurone is two to three cells thick and cell division can be observed (Fig. 2). The cells in the outer layer of the testa are thinner than those in the inner layer, and the nucellar cells are thick-walled. At this stage the endosperm is white and rounded and the embryo is ~0.25 mm long. By 33 'days' after anthesis, three to five layers of aleurone are established and clearly differentiated from the sub-aleurone and the starchy endosperm. The inner testa cells are large and have osmiophilic contents, and the nucellus is represented only by a layer of compressed wall material. In 33-'day' caryopses the endosperm is yellowish, firm and well rounded, the embryo is ~2.1 mm long and the aleurone layer peels off with the testa.

These observations on developing barley caryopses differ from those reported for wheat in that the number of nuclei per endosperm in barley increased up to about 30 'days' after anthesis, whereas in wheat, increase in the number of nuclei per endosperm stopped 16–20 days after anthesis[3,4]. In addition, evidence of endosperm cell division was observed at a later stage of development in barley than that reported for wheat[2]. These differences may be due to: (1) some assays being done on wheat endosperms contaminated with testa or stripped of their aleurone cells; (2) comparisons being made on the basis of strict chronological age, taking no account of variation in morphological development due to environmental factors; (3) the fact that the aleurone layer in wheat caryopses is only one cell thick whereas that in barley is at least three cells thick and so cell division in barley may continue for some time after the last starchy endosperm cells have been initiated. Note, however, that there is evidence of anticlinal divisions in the meristematic aleurone of 23-'day' barley endosperms and the cells thus produced presumably contribute to an increase in the surface area of the endosperm and hence to an increase in endosperm volume. It seems unlikely that similar anticlinal divisions in the aleurone of wheat cease as early as 16 days after anthesis[2].

Perhaps, therefore, more attention should be paid to the suggestions of Donovan[6] and Radley[7] that cell division in wheat endosperm continues up to 25–30 days after anthesis and to

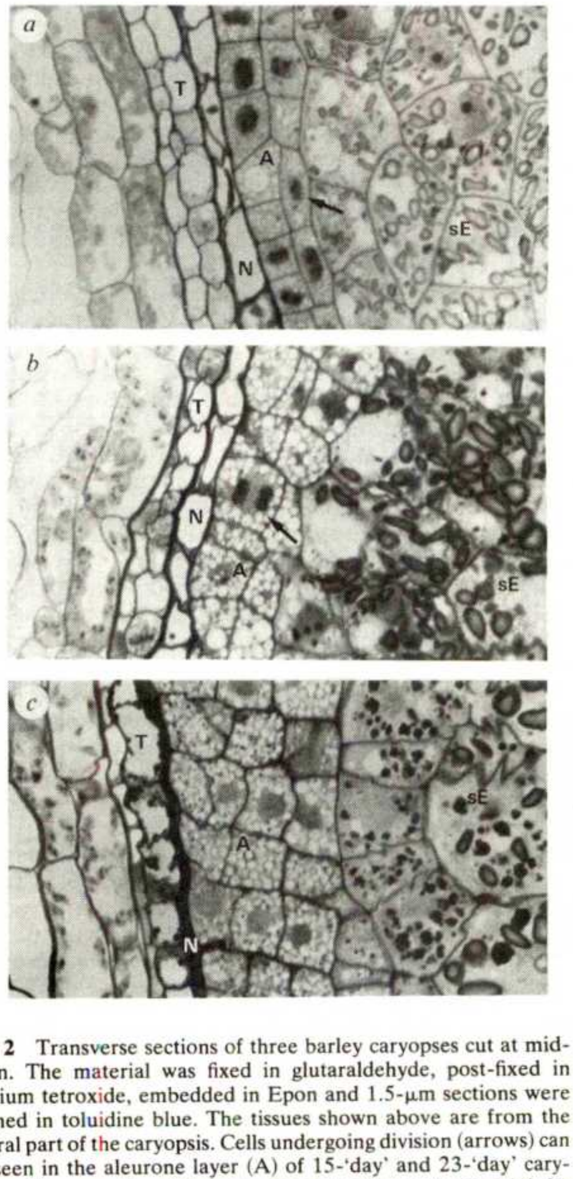

Fig. 2 Transverse sections of three barley caryopses cut at mid-grain. The material was fixed in glutaraldehyde, post-fixed in osmium tetroxide, embedded in Epon and 1.5-μm sections were stained in toluidine blue. The tissues shown above are from the lateral part of the caryopsis. Cells undergoing division (arrows) can be seen in the aleurone layer (A) of 15-'day' and 23-'day' caryopses. These sections illustrate the state of development of the nucellus (N), testa (T) and starchy endosperm (sE) as the number of endosperm nuclei increases (Fig. 1). *a*, 15-'day'; *b*, 23-'day'; *c*, 33-'day'. ×400.

Sandstedt[10], who observed that cell divisions occurred in the endosperm of wheat, grown in Nebraska, up to 16 days after anthesis, that is, half-way between anthesis and maturity in those climatic conditions. If attempts are to be made to increase the weight of cereal grains by applying chemicals which increase endosperm cell number, it is important to establish the pattern of cell division in the developing grain. The timing of the application of any such chemicals could be particularly critical in barley because it seems that cell division taking place after a certain stage of development produces mainly aleurone cells and therefore does not provide further capacity for carbohydrate storage. Thus, stimulation of endosperm cell division early in development could increase the yield of carbohydrate, whereas stimulation of cell division at a later stage could improve the nutritional quality of the grain by increasing the yield of the proteins, fats, minerals and vitamins which are found in aleurone cells.

Activation of brown adipose tissue thermogenesis by the ventromedial hypothalamus

Martin N. Perkins, Nancy J. Rothwell, Michael J. Stock & Trevor W. Stone

Department of Physiology, St George's Hospital Medical School,
Tooting, London SW17 0RE, UK

It is well established that electrical stimulation of the ventromedial hypothalamus (VMH) causes a reduction in food intake, whereas electrolytic or chemical lesions in this area result in hyperphagia and obesity in the rat. This has led to the suggestion that either the ventromedial nucleus itself, or nerve fibres passing close by, are important in the control of food intake. However, obesity due to VMH lesions occurs in weanling rats in the absence of hyperphagia and can develop in adult rats pair-fed with controls, indicating that destruction of this area also causes an increased metabolic efficiency (that is, a reduced energy expenditure). In normal rats, hyperphagia induced by feeding a highly palatable cafeteria diet is often accompanied by a large increase in heat production (diet-induced thermogenesis) which tends to prevent excessive weight gain and obesity[1]. This diet-induced thermogenesis is due to sympathetic activation of brown adipose tissue (BAT) and we have now investigated the possibility that the VMH is involved in the activation of this process. We found that electrical stimulation of this area produced increased BAT thermogenesis, which suggests that the VMH exerts a dual influence in the regulation of energy balance—an inhibitory effect on energy intake and a stimulatory effect on thermogenesis and energy output.

BAT thermogenesis can be monitored by recording the tissue temperature, as Flaim *et al.*[2] did when stimulating the sympathetic nerves supplying interscapular BAT. This is the largest and most accessible BAT depot and recordings can be made with minimal surgery. We therefore used the same approach to investigate the effects of electrical stimulation of the VMH on the temperature of interscapular BAT. At the same time we recorded core (rectal) and muscle (quadriceps) temperatures.

Male Sprague–Dawley rats (250–290 g) were maintained on a pelleted stock diet (PRD, Christopher Hill Group) and housed in a metabolism room at 24 ± 1°C. They were anaesthetized with urethane (0.12 g per 100 g) and an array of three coaxial stimulating electrodes ~400 μm apart in the lateral plane was stereotaxically located in the VMH (De Groot's[3] coordinates AP 5.4, L 0.6–0.7, V 9.0 mm), the position of all electrodes being later verified histologically. A small incision was made above the scapulae and a thermocouple probe (Comark 1604) was placed between the two lobes of the interscapular BAT and secured by closing the incision with surgical clips. A similar plastic-coated thermocouple was inserted 5 cm into the rectum and a needle thermocouple (0.5 mm o.d.) was inserted into the left quadriceps muscle. Experiments were carried out in a room kept at 24–25 °C and core temperature remained between 35.5 and 37.5 °C in all animals.

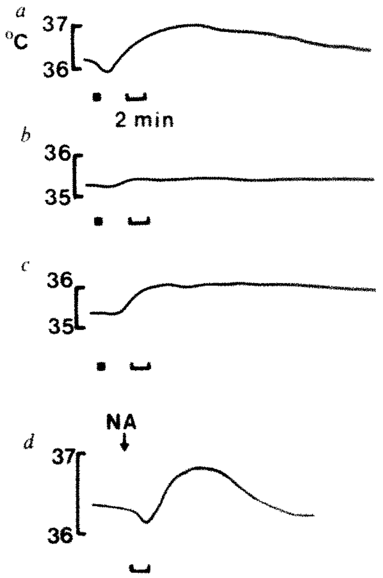

Fig. 1 Records of interscapular BAT temperature following unilateral stimulation of the VMH (■). The electrical stimulus was a 30-s train of monophasic square-wave pulses (0.5 ms, 50 Hz, 60 μA), and histological examination later confirmed that electrodes were located in the lateral and posterior regions of the VMH. *a* Shows a normal response with BAT temperature falling from 36.2 to 36.0 °C 1 min after stimulation, followed by a rise to a peak value of 37.0 °C 9 min later. During this period, rectal and muscle temperatures remained at 36.2 and 35.5 °C, respectively. *b* Shows that treatment with the β-adrenergic antagonist propranolol (0.3 mg per kg, intravenously) reduces the rise in the BAT temperature response to less than 0.2 °C. This effect of propranolol was reversible, as a normal temperature response could be elicited 2 h after treatment (*c*). *d* Shows the temperature response of BAT in a rat given an intravenous injection of noradrenaline (NA, 3 μg per kg). The initial fall in temperature (0.2 °C) and the subsequent rise (0.9 °C above pre-stimulation value) are similar in magnitude and duration to the response to VMH stimulation shown in *a*.

Electrical stimulation of the VMH at hourly intervals produced a biphasic response in interscapular BAT temperature (Fig. 1*a*). The initial decrease in temperature (mean ± s.e.m. = 0.16 ± 0.05 °C, *n* = 5) occurred after 1 min and was followed by a rise (0.86 ± 0.25 °C) which was maximal at 8 ± 2 min and had returned to the pre-stimulation value after 20 ± 4 min. Rectal and skeletal muscle temperatures either did not change or increased slightly (0.25–0.35 °C) after a delay, and on each

0028-0836/81/050401—02$01.00

occasion BAT temperature increased above rectal temperature by 0.3–0.5 °C. The response of BAT to VMH stimulation was remarkably similar to the effects of direct sympathetic nerve stimulation reported by Flaim *et al.*[2]. They also noted an initial small decrease in temperature after 1 min which they ascribed to an α-adrenergic vasoconstrictor effect, and a subsequent large and prolonged increase due to β-adrenergic stimulation of BAT thermogenesis. In our study the α-antagonist phentolamine inhibited the initial decrease in temperature but did not affect the secondary increase produced by VMH stimulation. However, β-adrenergic blockade (using propranolol, Fig. 1*b*) almost abolished the increase in BAT temperature (0.15 ± 0.09 °C, $P < 0.01$ compared with normal response). This confirms the findings of Flaim *et al.*[2] and suggests that VMH activation of BAT thermogenesis also involves β-adrenergic receptors. These findings are consistent with the observation that the increase in metabolic rate of animals exhibiting non-shivering or diet-induced thermogenesis is inhibited by β-receptor blockade but less affected by α-antagonists[1,4].

It is difficult to denervate completely a tissue with a sympathetic supply as rich as that of BAT, and so we used a local anaesthetic to test whether activation by the VMH was mediated by neural or humoral signals. Topical application of tetracaine (1% solution) to the interscapular area abolished the response of BAT to stimulation of the VMH, although the tissue responded to injection of noradrenaline (40 µg per 100 g intraperitoneally) with biphasic temperature responses (Fig. 1*d*) similar in magnitude and duration to stimulation of either sympathetic nerves[2] or the VMH. Central stimulation of thermogenesis by BAT therefore seems to be mediated by the sympathetic nerve supply.

The functional specificity of the VMH has been a matter of debate because, in terms of food intake, the noradrenergic fibres running through this area are apparently more important than the ventromedial nucleus[5]. This may also be true for the effects of VMH stimulation on thermogenesis but, nevertheless, the focus for successful stimulation of BAT thermogenesis can be precisely located in this area. Moving the stimulating electrodes out of the VMH by only 0.5 mm, dorsally or laterally, abolished the response of BAT to central stimulation, and normal responses could be elicited only by moving the electrodes back to their original position. Electrical stimulation in the adjacent lateral hypothalamus had no effect on BAT temperature. Others[6,7] have noted that electrical stimulation of the VMH led to an increase in plasma glycerol and lipogenesis in BAT without affecting lipid synthesis in white adipose tissue, whereas stimulation of the lateral hypothalamus was ineffective. These findings support our suggestion that the VMH is involved in BAT thermogenesis, for diet-induced thermogenesis results in increased BAT lipolysis[1], and lipogenesis in this tissue is considerably increased during exposure to cold[8,9].

The importance of these findings in the regulation of energy balance depends on our proposal[1] that diet-induced thermogenesis has its origins in BAT, and we have demonstrated that the greater thermogenic capacity of hyperphagic rats fed the cafeteria diet[1] is due entirely to increased oxygen utilization by BAT[10]. We have also shown an insulin requirement for diet-induced thermogenesis in hyperphagic rats[11] which, with the results reported here, suggests that changes in glucose utilization in the insulin-sensitive VMH may be responsible for the effects of hyperphagia on diet-induced thermogenesis.

The importance of the VMH in BAT thermogenesis may explain the increased metabolic efficiency (reduced diet-induced thermogenesis) of animals with VMH lesions, particularly in young rats where obesity often develops in the absence of hyperphagia[12]. This explanation is supported by the recent observation that bilateral VMH lesions result in atrophy and reduced thermogenic activity of BAT (L. Girardier, personal communication). It is likely that other areas of the hypothalamus influence BAT thermogenesis, particularly those involved in thermoregulation, but their close proximity to the VMH could provide an explanation for the strong interactions observed between thermogenesis, food intake and environmental temperature[13].

Photoperiodicity in the male albino laboratory rat

Edward P. Wallen

Animals inhabiting areas where there are drastic changes in the environment often reproduce only during limited time periods to ensure that young are raised in optimal environmental conditions[1]. The lack of a well defined breeding season in many domesticated animals[2,3], presumably because the selective pressures for seasonal breeding have been minimized, suggests that the neuroendocrine events controlling seasonal cyclicity have been bred out of these animals. Little is known about the underlying neuroendocrine changes which may occur during the evolution of a species from a seasonal to a nonseasonal breeder. Whereas the changing photoperiod is the primary environmental cue which initiates and/or terminates the reproductive season in many animals[4], this is not so in the albino rat *Rattus norvegicus*, a model nonseasonal breeder[5–7]. Nevertheless, daylength can influence various reproductive parameters in laboratory rats [8–17], suggesting that some of the neuroendocrine components that controlled seasonal breeding previously are still extant in this species. To test this hypothesis, we investigated the effect of daylength on the responsiveness of the neuroendocrine–gonadal axis to the negative-feedback effects of testosterone. This paradigm was chosen because of the important role played by photic-induced changes in steroid feedback sensitivity in the control of seasonal reproduction[18–21]. We report here that although daylength has very little effect on neuroendocrine–gonadal function in the intact male laboratory rat, it seems that some component(s) of a photoperiodic system involving the pineal gland has been preserved.

Male inbred Sprague–Dawley albino rats (Gibco, 180–200 g) were housed (four per cage) with food (Purina Rat Chow) and water provided *ad libitum*. Lighting was provided by banks of General Electric cool-white 40-W fluorescent bulbs. The animals were maintained on a light/dark 14:10 h cycle for a 2-week period before starting the experiment. They were then either pinealectomized[22] or sham pinealectomized and implanted subcutaneously with either empty or testosterone-filled Silastic capsules that were 10 or 15 mm long (16 animals per group). Half of the animals in each group remained on LF14:10 while the remaining animals were transferred to LD 6:18. Sixty-three days later the animals were killed by decapitation, blood was collected and the testes removed and weighed. Serum was assayed for luteinizing hormone (LH) and follicle-stimulating hormone (FSH) by methods described previously[23].

0028-0836/81/050402—03$01.00

Consistent with the idea that the male albino laboratory rat is not a photoperiodic species is the observation that testicular weight and serum levels of LH and FSH were similar in untreated animals exposed to either LD 6:18 or 14:10 (Fig. 1, Table 1). On the other hand, in intact rats implanted with 10- or 15-mm long testosterone-filled capsules for 63 days, the testes were significantly ($P < 0.05$) smaller in animals exposed to LD 6:18 compared with those of animals maintained on LD 14:10. The degree of testicular regression observed in the LD 6:18 animals implanted with a 15-mm long testosterone-filled capsule was similar to the maximum regression observed in a previous dose–response study using various sizes of Silastic capsules filled with testosterone[24].

Pinealectomy had no effect on testicular weight in untreated animals exposed to either photoperiod, or in testosterone-treated animals exposed to LD 14:10 (Fig. 1). In contrast, pinealectomy abolished the increased responsiveness to the inhibitory effects of testosterone in animals exposed to short days. Pinealectomized animals maintained on LD 6:18 and implanted with either 10- or 15-mm long testosterone-filled capsules had significantly larger testes ($P < 0.05$) than intact rw on LD 6:18 that were implanted with the same size capsules.

The decrease in testicular weight observed in testosterone-treated rats (Fig. 1) was presumably due to an inhibition of pituitary gonadotropin release[25]. Serum FSH levels were significantly reduced ($P < 0.05$) in all of the testosterone-treated pineal-intact animals when compared with the levels found in animals receiving empty implants. Although serum levels of LH were consistently lower in the pineal-intact rats treated with testosterone than in the untreated control animals, these differences were not statistically significant. However, note that serum LH levels in the intact untreated rats were already near the lower limits of detectability of our assay, and a significant decrease would be difficult to observe.

Surprisingly, no significant effects of either the photoperiod or pinealectomy on serum levels of FSH and LH were observed in testosterone-treated rats (Table 1). This occurred despite the fact that both the photoperiod and pinealectomy did alter the effect of testosterone on reducing testicular size. It is not known how an equal dose of testosterone (that is, 10- or 15-mm testosterone-filled capsules) was able to reduce testis size differentially without also having a differential effect on serum FSH and LH levels. Possibly, a more complete sampling regimen would have yielded differences in gonadotropin levels which were not demonstrable using a single terminal sample. Alternatively, the effect of testosterone may have been via some other hormone which influenced testicular activity in response to the photoperiod and/or pinealectomy. Prolactin is a likely candidate as previous studies indicate that prolactin may be important in the photoperiodic control of testicular activity in rodents[26,27].

Table 1 Measured (mean ±s.e.m.) serum levels of LH and FSH (ng ml^{-1}) in intact and pinealectomized rats

Testosterone capsule size (mm)		LD 14:10		LD 6:18	
		Intact	Px	Intact	Px
0	LH	1.2±0.4	1.2±0.3	1.5±0.4	1.9±0.2
	FSH	336±27	302±17	301±18	345±22
10	LH	0.5±0.2	1.0±0.2	0.6±0.2	0.6±0.1
	FSH	226±20	277±10	220±25	308±37
15	LH	0.6±0.2	0.4±0.1	0.3±0.0	0.9±0.4
	FSH	236±15	289±52	194±15	246±2

The rats were implanted with either empty or testosterone-filled capsules of 10- or 15-mm length. After capsule implantation, the animals were exposed to either LD 14:10 or LD 6:18 for 63 days. LH and FSH values are expressed in terms of nanogram equivalents of NIH-LH-S16 or NIAMMD-Rat-FSH-RP-1.

Px, pinealectomized.

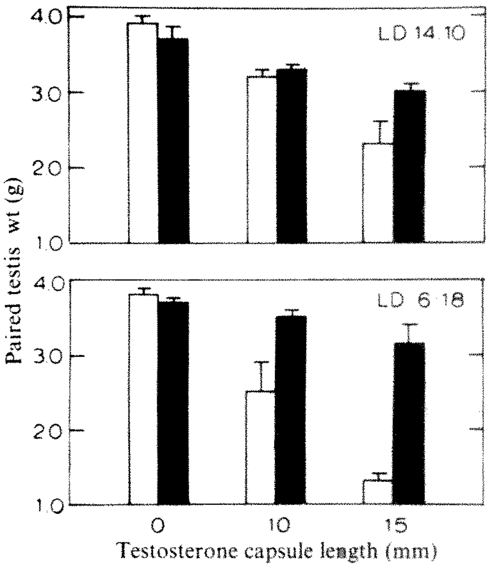

Fig. 1 Mean paired testis weight of rats that were either sham pinealectomized (open bars) or pinealectomized (shaded bars) and implanted with either empty or testosterone-filled Silastic capsules that were 10 or 15 mm long. At the time of capsule implantation the animals were either maintained on LD 14:10 (top panel) or were transferred to LD 6:18 (bottom panel) for 63 days. The vertical line represents the standard error. The testosterone-filled capsules were prepared using Silastic tubing (Dow Corning). Approximately 40 µg of testosterone are released per day per 10 mm of capsule length.

Recent studies on two photoperiodic species, the golden hamster and the sheep, demonstrate the importance of a photic-induced alteration in the responsiveness of the hypothalamic–pituitary axis to the negative-feedback effects of sex steroids in the control of seasonal breeding[18–21,23]—exposure to a nonstimulatory photoperiod renders the animals extremely sensitive to the negative-feedback effects of steroid hormones on pituitary gonadotropin release. Furthermore, in the golden hamster pinealectomy can block the hypersensitivity to testosterone feedback induced by short days[28]. That pinealectomy can block the short day-induced increase in responsiveness to testosterone in both the albino rat and the hamster suggests that the neuroendocrine events associated with photo-induced changes in sensitivity are similar. Indeed, the photoperiod can alter the negative feedback effect of oestrogen on pituitary gonadotropin release in the ovariectomized albino rat[8–10]. However, in the present study, serum levels of LH and FSH were similar in the testosterone-treated pineal-intact rats exposed to LD 14:10 and LD 6:18. Further studies are required to determine how photic-induced changes in sensitivity to steroid hormones in seasonal breeders are related to the change observed in the non-seasonally breeding laboratory rat.

There are conflicting reports regarding the effect of both the photoperiod and pinealectomy on reproductive function in the rat[5–17,29–34]. The present study suggests that such apparent discrepancies may be due to some components of the neuroendocrine system which may have been involved in the photoperiodic control of reproduction at a previous evolutionary time still existing in the rat, and being manifested only in certain experimental conditions. An added complication is that the inbreeding of various strains of laboratory rats may have selected for or against different components of the photoperiodic–neuroendocrine system.

The results reported here on the albino rat are paradoxical. If short days render the animals more sensitive to the inhibitory effects of testosterone, one would expect that testicular regression would occur in untreated rats exposed to short days, as these animals would be more responsive to the testosterone produced by their own testes. One explanation for our results is that the inhibitory effects of short days are blocked or offset by other short day-induced changes which occur in the neuroendocrine system. This hypothesis is particularly attractive because recent evidence demonstrates that at least two mechanisms may be involved in the photoperiodic response of seasonal breeders. In addition to the effects of daylength on steroid-feedback sensitivity, it seems that the photoperiod can also influence pituitary gonadotropin release in the absence of gonadal steroid hormones[35-38]. In rats exposed to short days, there may be neuroendocrine changes which are independent of steroid feedback and which negate the enhanced negative-feedback effects of steroid hormones. Because the photoperiod alters the neuroendocrine–gonadal axis only in certain conditions, the laboratory rat may be useful for the elucidation of the neuroendocrine components involved in the photoperiodic control of reproduction in seasonal breeders.

A human quantitative polymorphism related to Xg blood groups

P. N. Goodfellow

Imperial Cancer Research Fund, Lincoln's Inn Fields,
London WC2A 3PX, UK

P. Tippett

MRC Blood Group Unit, Wolfson House, University College,
London NW1 2HE, UK

A monoclonal antibody, 12E7, raised against lymphocytes from a patient with a T-cell acute lymphocytic leukaemia reacts strongly with cortical thymocytes and, to a lesser extent, with other human cells[1]. The antigen defined by 12E7 is not expressed on mouse or hamster cells; this species specificity allowed us to investigate the genetics of the expression of the 12E7 antigen using human–rodent somatic-cell hybrids[2]. Hybrid cells which contain the human X chromosome as the only human genetic contribution react with 12E7. The X-linkage of the gene, or genes, controlling 12E7 antigen expression and the fact that 12E7 antigen is also expressed on red blood cells led us to investigate the possibility of a relationship with the X-linked Xg blood group system. Although the 12E7 and Xg^a antigens seem to be different antigenic determinants specified by different loci, we report here a sex-limited effect involving the Xg phenotype on the expression of 12E7 antigen.

Expression of the Xg blood group system is controlled by two X-borne alleles, Xg^a and a silent allele *Xg*. The antigenic product, Xg^a, of the dominant Xg^a allele is recognized by alloantisera using the indirect antiglobulin haemagglutination method[3,4]. Experiments to demonstrate Xg^a antigen on tissues other than red blood cells have given conflicting results[5,6]. A quantitative polymorphism of the 12E7 antigen on red blood cells was first detected in a family segregating at the *Xg* locus.

The mother J. B., the father W. B. and daughter H. B. all express the Xg^a antigen—this phenotype is designated Xg(a+). The son M. B. has the alternative Xg(a−) phenotype which lacks the Xg^a antigen, indicating that the mother J. B. is heterozygous Xg^aXg. The Xg(a−) son showed a reduced expression of the 12E7 antigen compared with other family members (Fig. 1). The same quantitative polymorphism of 12E7 antigen expression was also found when red blood cells from random donors were tested (Table 1).

Table 1 Results of tests for 12E7 antigen phenotype in 10 random donors

Donor	c.p.m. × 10^{-3} 12E7	c.p.m. × 10^{-3} W6/34	c.p.m. × 10^{-3} CA2.06	Antiglobulin test score 12E7	12E7 phenotype
1	24.0	31.9	2.0	30	High
2	9.1	32.6	1.1	13	Low
3	28.5	33.5	1.2	30	High
4	23.6	37.2	1.1	30	High
5	37.8	37.1	2.2	28	High
6	35.8	42.5	1.4	28	High
7	9.2	33.8	1.1	13	Low
8	34.1	37.4	1.1	30	High
9	36.6	34.4	1.8	30	High
10	8.6	37.6	1.3	0	Low

The binding assay was carried out as described in Fig. 1 legend. 12E7 was used at a dilution of 1 : 200. W6/34, a monoclonal antibody which reacts with a human red-cell antigen, at 1 : 200 dilution, was the positive control. CA2.06, the negative control, was used as described in Fig. 1 legend. The low phenotype was scored if the counts bound with 12E7 were less than half those bound with W6/34 in the same conditions. Repeated testing of several individuals gave consistent results. For phenotypic scoring of 12E7 by the antiglobulin haemagglutination method, see Table 2 legend.

Although the 12E7 antigen was originally detected by the indirect radioimmunoassay (RIA), it could also be demonstrated by an indirect antiglobulin haemagglutination test with the same pattern of high and reduced expression (Table 1); over 50 people were typed by both techniques and complete concordance between the different methods was achieved. Subsequent tests were carried out using the haemagglutination method.

The relationship between the *Xg* locus and the 12E7 polymorphism was investigated by testing over 300 Europeans for Xg^a and for the level of expression of 12E7 antigen (Table 2). All Xg(a+) individuals show high levels of 12E7 antigen expression but Xg(a−) individuals fall into two categories, showing either high- or low-level 12E7 phenotype. The probability that these results occurred by chance is less than 1 in 10^8, indicating a relationship between the *Xg* locus and the 12E7 polymorphism. The simplest explanation for these results is that the 12E7

0028-0836/81/050404—02$01.00

polymorphism is controlled by a previously undetected variant of the silent *Xg* allele. Thus, the Xg^a allele and one *Xg* allele would lead to a high-level expression of 12E7; a different *Xg* allele would give low-level expression of the 12E7 antigen. Alternatively another polymorphic locus might exist with an allele for low-level expression of the 12E7 antigen in very strong linkage disequilibrium with the *Xg* allele. However, both these explanations fail to explain the sex distribution shown in Table 2*b*. Although Xg(a−) males may be high- or low-level expressors of 12E7, Xg(a−) females always have the low-level 12E7 phenotype ($P < 0.001$).

These data imply sex limitation of 12E7 expression. One hypothesis is that there is a polymorphic 12E7 modifying gene and that the allele for high-level 12E7 expression cannot be expressed in females lacking the Xg^a antigen.

An alternative, and perhaps controversial, hypothesis is that a locus, *Yg*, equivalent to *Xg*, is present on the Y chromosome. Like *Xg*, the *Yg* locus must have two alleles, Yg^a and *Yg*. It is postulated that Xg^a and Yg^a allow high-level expression of the 12E7 antigen, whereas *Xg* and *Yg* do not. Thus all Xg(a+) individuals (Xg^a Xg^a, Xg^a *Xg* females and Xg^a Yg^a, Xg^a *Yg* males) and Xg(a−) Yg(a+) males (*Xg* Yg^a) express high levels of 12E7, whereas Xg(a−) females (*Xg Xg*) and Xg(a−) Yg(a−) males (*Xg Yg*) express a low level of 12E7. It is interesting that the gene frequency of the postulated Yg^a allele (0.68), as calculated from Xg(a−) males who are 12E7 high expressors (Table 2*b*), is very similar to that of the Xg^a allele (0.66) in similar populations[5]. We are now searching for the rare families which can be used to distinguish between these hypotheses and are attempting to investigate the biochemical relationship between the Xg^a and 12E7 antigens.

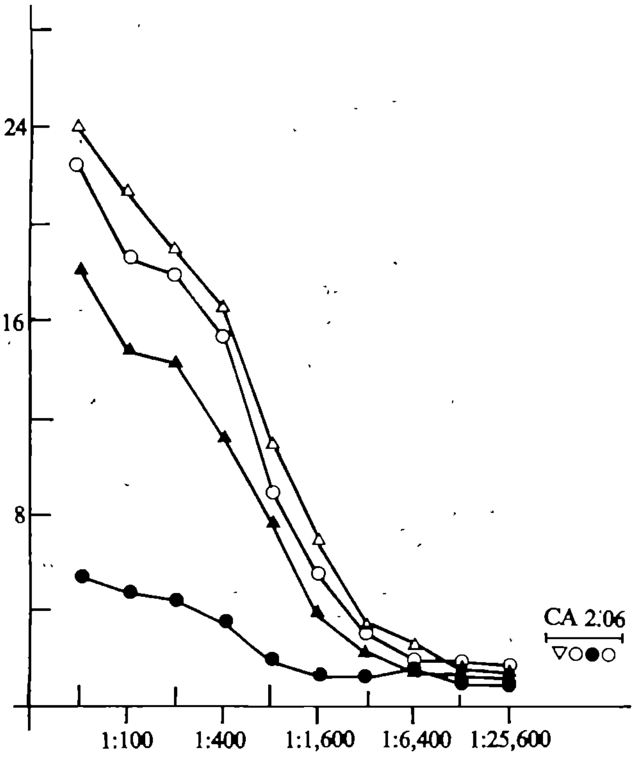

Fig. 1 Binding of 12E7 to red blood cells from a family segregating at the *Xg* locus. 12E7 tests on red cells of: △, father (W.B.); ○, daughter (H.B.); ▲, mother (J.B.); ●, son (M.B.). The indirect RIA was as described elsewhere[2]. Red blood cells carried out (5×10^6) were mixed with 50µl of antibody and incubated overnight at 4 °C The cells were washed and 2×10^5 c.p.m. of ^{125}I-labelled, column-purified, rabbit anti-mouse immunoglobulin added. The mixture was incubated at 4 °C for 1 h. The cells were washed and the bound second antibody quantified in a gamma counter. All dilutions and washes were performed with Dulbecco's phosphate-buffered saline supplemented with 1% bovine serum albumin and 0.1% sodium azide. The 12E7 antibody was prepared by ammonium sulphate precipitation from the cultured hybridoma supernatant[2]. The negative control, CA2.06, a monoclonal anti-human DRw, was used as undiluted culture supernatant[7].

Table 2 Two by two tables comparing Xg^a and 12E7 expression

a		Xg(a+)	Xg(a−)
12E7 expression	High	237	56
	Low	0	42

b		Xg(a−)	
		♂	♀
12E7 expression	High	56	0
	Low	26	16

Phenotypic scoring of 12E7 was carried out 'blind' using either the indirect antiglobulin technique or both indirect RIA and the antiglobulin method. For the latter, washed red blood cells sensitized with 12E7 antibody were tested with rabbit anti-mouse globulin by the capillary method and agglutination was scored at 10, 20 and 30 min. High expression: 25–30; low expression: 0–18. Male Xg(a−) with low expression generally scored more, 0–18, than did female Xg(a−), 0–5.

We thank our colleagues who gave blood for this study; Dr M. Contreras and Mr P. Bowell for providing many blood samples and Drs P. W. Andrews, J. Bodmer, W. F. Bodmer, B. Knowles, R. Sanger, E. Solomon and J. Trowsdale for discussion and guidance. The 12E7 monoclonal antibody was produced and generously donated by Dr R. Levy.

Genetic basis of BCG-induced suppression of delayed hypersensitivity

Denis J. Schrier, John L. Sternick, Elizabeth M. Allen & Vernon L. Moore

Research Service, Wood Veterans' Administration Medical Center, and the Departments of Medicine and Pathology, The Medical College of Wisconsin, Milwaukee, Wisconsin 53193

BCG can either act as an adjuvant to potentiate immunological responses or, in some cases, can induce suppression. The reasons for these differential activities are not clear but may include routes and doses of administration, as well as variable host reactivity to the agent. In this study, we have used killed BCG administered intravenously to produce chronic granulomatous inflammation (CGI) in the lungs and spleen of inbred mice. We report that strains which developed CGI were usually anergic, as evaluated by the development of delayed hypersensitivity (DH) to sheep erythrocytes (SRBC). Studies on the genetics of BCG-induced anergy indicated that it was unigenic, recessive and linked (approximately 28 recombination units) to the immunoglobulin heavy-chain allotype (*Igh*). There was no influence by genes linked to the major histocompatibility complex. The study indicates that anergy associated with CGI is under genetic control, which may explain the variability of anergy in patients with granulomatous diseases. The implication of linkage to the *Igh* complex is not clear, but it may be associated with V_H receptors on T lymphocytes, which in turn act on macrophages to mediate suppression.

We are interested in BCG because it can be used to induce CGI in the lungs of rabbits[1] and in the lungs and spleens of only certain strains of inbred mice[2]. A seemingly paradoxical observation has been that inbred mice which develop CGI in response to BCG are suppressed in their response to mitogens and in the development of DH and a primary antibody response to SRBC[3]. Mice which did not develop CGI were not suppressed in any of these reactivities. Suppression was mediated by cells from inflamed spleens which were adherent to plastic petri plates, lacked Thy 1 and immunoglobulin surface markers, and were removed with carbonyl iron[4]. These traits are characteristic of macrophages.

We examine here the genetic basis of BCG-induced suppression in various inbred mice, in their F_1, F_2 and backcross progeny, and in selected congeneic strains. Data in Table 1 indicate that whereas C57BL/6 (B6) mice (which develop CGI in response to BCG) are markedly suppressed in their ability to develop DH to SRBC, CBA mice (which do not develop CGI to BCG)[2] express DH to SRBC. This is not due to an innate inability of B6 mice to develop DH to SRBC as both strains respond when not treated with BCG (Table 2). Table 1 also indicates that BCG-induced suppression is recessive because BCG-treated (B6 × CBA)F_1 mice were not suppressed. Analysis of F_2 progeny of (B6 × CBA)F_1 mice showed that 26.6% (33/124) were suppressed. Assuming independent segregation, these data suggest that a single gene or gene complex is responsible for suppression. Note also that several of the F_2 progeny of (B6 × CBA)F_1 mice which developed BCG-induced anergy displayed only minimal inflammation. On the other hand, many of the F_2 progeny which were not anergic developed intense inflammation. Although this suggests that genes controlling the development of CGI are different from those which influence anergy, we realise that this is difficult to prove in this system because of the multigenic control of CGI, as contrasted with single gene control of anergy[5]. Because F_1 offspring of either sex from B6 females are not suppressed (data not shown), the control of suppression does not seem to be sex-linked.

To test whether suppression was linked to the *H–2* complex, we performed linkage analysis in F_2 progeny of (B6 × CBA)F_1 parents. The F_2 progeny were typed for either the *H–2*^{b} or *H–2*^{k} allele using anti-*H–2* serum prepared in our laboratory. Anti-*H–2*^{k} serum was produced by injecting B10.BR cells into C57BL/10 mice and anti-*H–2*^{b} serum was produced by injecting C3H.SW cells into C3H mice. The following results were obtained: *H–2*$^{b/b}$, suppressed (10); *H–2*$^{b/b}$ nonsuppressed (18); *H–2*$^{b/k}$ suppressed (11); *H–2*$^{b/k}$, nonsuppressed (40); *H–2*$^{k/k}$, suppressed (4); and *H–2*$^{k/k}$, nonsuppressed (18). These results do not differ significantly from a 6.25 : 18.75 : 12.5 : 37.5 : 6.25 : 18.75 ratio based on independent segregation of a recessive trait ($P > 0.10$). A strain distribution analysis (Table 2) also suggested that genes linked to the *H–2* complex are not involved in suppression. In particular, C57BL/6 (*H–2*^{b}), C57BL/10 (*H–2*^{b}), B10.BR (*H–2*^{k}), and BALB/c.*Igh*^{b} (*H–2*^{d}) all exhibited suppression even though they were different *H–2* types. Table 2 shows also that all strains which were suppressed were *Igh*^{b}, suggesting linkage to the *Igh* allotype. This is further substantiated because BALB/c mice (*Igh*^{a}) were not suppressed, but the congeneic partner, BALB/c.*Igh*^{b}, was. We analysed linkage to the *Igh* complex further by performing linkage analysis on male and female (C57BL/6 × CBA)F_1 × C57BL/6 backcross mice. The backcrosses were typed for either the *Igh*^{b} or *Igh*^{a} allele with the following results: *Igh*$^{b/a}$, nonsuppressed (14); *Igh*$^{b/b}$, suppressed (9); *Igh*$^{b/a}$, suppressed (6); *Igh*$^{b/b}$, nonsuppressed (3). These results differ significantly from a 1 : 1 : 1 : 1 ratio expected on the basis of independent segregation ($P < 0.025$). The estimated recombination frequency is 0.28 ± 0.08.

Table 1 BCG-induced suppression of delayed hypersensitivity to sheep erythrocytes

	Footpad increment (mm)*		
Mouse strain	Positive	Negative	No. suppressed total (%)
C57BL/6		0.16 ± 0.02	8/8 (100)
CBA	0.77 ± 0.06		0/10 (0)
[B6 × CBA]F_1	0.79 ± 0.04		0/22 (0)
[(B6/CBA) × (B6/CBA)]F_2	0.61 ± 0.02	0.17 ± 0.01	33/124 (26.6)†

Mice were injected intravenously with 300 μg of killed BCG in an oil-in-saline emulsion. Four weeks later, B6, but not CBA, mice exhibited intense CGI in their lungs and spleen.

* Increase in 24-h footpad swelling due to specific antigen compared to footpad injected with equal volume of saline. Footpad values >0.31 mm are considered positive; this figure was obtained by calculating two standard deviations from the mean footpad increment of animals developing positive DH responses. DH was produced by injecting mice intravenously with 5×10^5 SRBC 4 weeks after BCG injection. Five days later, animals were challenged in one rear footpad with 10^8 SRBC and in the other hind footpad with an equal volume of saline. Increases in footpad thickness were quantified using a pressure-sensitive caliper (Dyer).

† 33/124 (26.6%) is not different from an expected percentage of 25 ($P > 0.5$) predicted in the F_2 generation for a recessive trait controlled by a single gene.

Table 2 Strain survey of BCG-induced suppression of delayed hypersensitivity to sheep red blood cells

Mouse strain	BCG injected	*H–2*	*Igh*	Footpad increment*

† Negative footpad responses.

In summary, BCG-induced suppression of DH to SRBC is under genetic control. It is recessive, autosomal, due to a single (or closely linked group of) gene, and controlled by genes linked to the *Igh* complex.

Macrophage-mediated suppression is caused by a variety of agents, is usually not immunospecific, and suppresses a variety of immune responses[6–8]. Its overall role in immunoregulation is not understood. In our system, this type of suppression occurs in conjunction with intense CGI in the lungs and spleen. In another study, we have shown that adherent spleen cells from BCG-treated B6 mice produce soluble factors *in vitro* that suppress the production of CGI in the lungs and spleen[9]. Therefore, macrophage-mediated suppression may be important in the control of inflammation. Further studies are needed, however, to test this hypothesis.

The significance of linkage to *Igh* allotypes is not yet clear. In some studies, macrophage-mediated suppression is controlled by T lymphocytes[10,11], and several T cell-related immunological phenomena are linked to the *Igh* allotype[12,13], which may be related to V_H receptors on T cells. Studies are in progress in our laboratory to test these possibilities.

This research was supported by funds from HL22301, HL15389 and the Veterans Administration. We acknowledge the BALB/c.Igh^b mice from Dr Noel Warner, a gift of anti-*Igh* serum by Dr Mel Bosma, and the editorial assistance of Ms Mavis Baurle and Peggy LaSusa.

Chronic immune stimulation is required for Moloney leukaemia virus-induced lymphomas

John C. Lee & James N. Ihle

Biological Carcinogenesis Program, Frederick Cancer Research Center, Frederick, Maryland 21701

C-type viruses are known to be aetiologically related to naturally occurring leukaemia in a variety of species[1], although the mechanisms of transformation are largely unknown. The long latency periods, requirement for an acute viraemia and monoclonality of the tumours[2,3] distinguish leukaemogenesis from neoplasias induced by the acute transforming viruses and suggest an indirect mechanism. Consistent with this is the lack of *in vitro* transforming activity of replication-competent leukaemogenic viruses[4]. We have shown previously that the presence of T cells which proliferate *in vitro* in response to viral antigens is uniquely associated with the conditions leading to leukaemia. Based on these observations we have hypothesized that chronic immune stimulation is required for leukaemogenesis. We now demonstrate that CBA/N mice, when inoculated as newborns with Moloney leukaemia virus (MoLV), develop an acute viraemia but do not develop leukaemia or have detectable T-cell responses against the virus. This supports the hypothesis that chronic immune stimulation is essential for leukaemogenesis.

Previous studies have shown that MoLV can induce leukaemia in a variety of strains of mice[5]. However, as illustratedin Fig. 1, CBA/N mice failed to develop leukaemia after inoculation with a MoLV preparation which rapidly induced leukaemia in BALB/c mice. This result was surprising because the closely related CBA/J strain has been shown to be as susceptible to MoLV as BALB/c mice[5]. We therefore examined the virological and immunological status of MoLV-inoculated CBA/N mice.

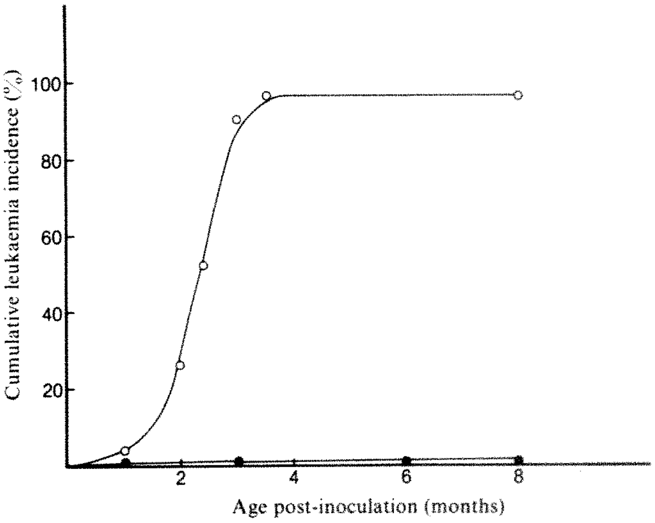

Fig. 1 Cumulative leukaemia incidence in MoLV-inoculated BALB/c or CBA/N mice. Groups of 20 BALB/c (○) or CBA/N (●) mice were inoculated as newborns with MoLV. The mice were reared in specific pathogen-free conditions. Moribund mice were killed and assessed histopathologically for the presence of lymphomas. The lymphomas in BALB/c mice were both of thymic and splenic origin, as previously described[23].

The ability of the virus to establish viraemia is known to be essential for leukaemogenesis[6,7]. To obtain a quantitative measure of virus replication we examined spleen extracts from inoculated mice for the viral proteins gp71, p30 and p12 using competition radioimmunoassays. As shown in Table 1, these proteins were readily detectable in CBA/N mice at 2 or 4 months post-inoculation. For comparison, the range of values obtained with MoLV-inoculated BALB/c or CBA/J mice are also shown. At 2 or 4 months post-inoculation, there were minimal differences in viral protein concentrations among the various strains. One important parameter which is known to be inversely related to leukaemia and viraemia is the presence of antibody against the virus[6]. Therefore, we examined the above mice for the presence of free antibody against MoLV. As shown in Table 1 none of the mice examined had detectable antcodies. These data demonstrate that the absence of leukaemia in CBA/N mice is not due to an inability of MoLV to replicate and establish viraemia.

It is well established that CBA/N mice differ from CBA/J mice in an immune response function and fail to develop immune responses to certain antigens early in life[8]. This deficiency has been shown to be due to a X-linked recessive locus[9]. Because our previous results demonstrated that the presence of T cells which respond *in vitro* by proliferation against viral proteins is correlated with leukaemogenesis[6,10], we compared this cellular immune response of MoLV-inoculated BALB/c, CBA/J and CBA/N mice. Splenic lymphocytes were obtained from individual mice, partially purified by passage through nylon wool columns as previously described[10] and assayed in a blastogenesis assay for proliferation in response to MoLV gp71. The responses of lymphocytes from individual BALB/c, CBA/J and CBA/N mice to various antigen concentrations are shown in Fig. 2. Lymphocytes from normal BALB/c, CBA/J and CBA/N did not respond to MoLV gp71. However, as previously demonstrated[10] and shown in Fig. 2, lymphocytes from preleukaemic BALB/c and CBA/J mice

Table 1 Levels of MoLV proteins and antibody against MoLV in inoculated BALB/c, CBA/J and CBA/N mice

Strain	Age (months)	Protein (ng per mg) gp71	p30	p12	Antibody titre
BALB/c	1	100–500	250–900	3–7	<1:20
BALB/c	2	300–1,400	400–1,100	10–50	<1:20
CBA/N	2	400–800	500–700	5–20	<1:20
BALB/c	3	900–1,700	700–1,500	60–70	<1:20
CBA/N	4	500–850	500–650	15–20	<1:20
CBA/J	4	1,500–1,900	1,000–1,200	30–50	<1:20

BALB/c, CBA/N and CBA/J mice were inoculated with MoLV at birth. At the indicated ages post-inoculation three to five individual mice were killed and used to determine the levels of antibody and viral proteins. The levels of viral proteins were determined using splenic extracts in competition radioimmunoassays for MoLV gp71, p30 and p12 as previously described[21]. The values represent the range of viral protein concentrations observed. The presence or absence of antibody in the serum was determined using ^{3}H-leucine-labelled intact MoLV virions in a radioimmune precipitation assay as previously described[22].

responded *in vitro* to MoLV gp71 with typical antigen concentration dependence. Previous studies[10] have shown this proliferative response to be dependent on a Thy-1.2$^+$, Lyt-1$^+$,2$^-$ T-cell subpopulation. In distinct contrast, however, lymphocytes from viraemic CBA/N mice had no detectable responses against MoLV gp71. Therefore, viraemic CBA/N mice seemed to be unique in lacking T cells specific for MoLV gp71.

We have also demonstrated that preleukaemic BALB/c mice have lymphocytes which respond *in vitro* to the internal viral protein p12 (ref. 10), although less consistently than to MoLV gp71. As shown in Fig. 2, lymphocytes from both preleukaemic BALB/c and CBA/J mice responded to p12 and showed typical antigen titration curves. Normal control BALB/c or CBA/J mice did not respond. The response to p12 in preleukaemic BALB/c and CBA/J mice was also found to depend on a Thy-1.2$^+$, Lyt-1$^+$,2$^-$ T cell (data not shown), whereas the MoLV-inoculated CBA/N mice had no detectable responses to p12.

We next examined individual MoLV-inoculated BALB/c, CBA/J and CBA/N mice at various ages. The results are summarized in Fig. 3, which presents the stimulation indices (SIs) against MoLV gp71 or p12. When lymphocytes from uninoculated BALB/c mice were examined, none had a significant blastogenic response (SI > 2.0) against gp71 or p12. In contrast, the majority of MoLV-inoculated BALB/c mice (86%) responded to gp71, whereas ~41% responded to p12. Interestingly, only one mouse (indicated by the solid circles in Fig. 3) failed to respond to either antigen. Using lymphocytes from individual MoLV-inoculated CBA/J mice, all the mice responded to MoLV gp71 *in vitro*, whereas five of the seven mice responded to MoLV p12. In distinct contrast, however, most of the CBA/N mice did not respond to either gp71 or p12. Only one mouse (indicated by the solid circles) had lymphocytes which responded at low levels to both MoLV gp71 and p12. These data demonstrate that MoLV-inoculated viraemic CBA/N mice are distinct from the other strains and generally lack a T-cell response against the viral proteins.

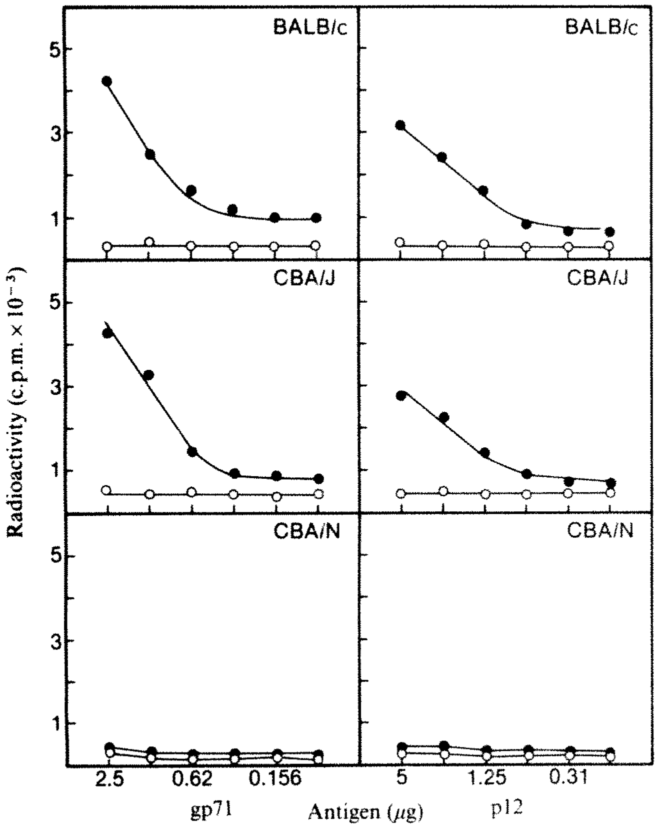

Fig. 2 T-cell proliferative responses of BALB/c, CBA/J and CBA/N mice to MoLV gp71 and p12. Lymphocytes were obtained from either 6-week-old normal mice (○) or mice inoculated as newborns with MoLV (●). An enriched T-cell preparation was obtained by nylon wool column fractionation and assayed in a microblastogenesis assay as previously described[24]. The lymphocytes were stimulated *in vitro* using purified MoLV gp71 (left panels) or p12 (right panels) at the indicated concentrations. The purification techniques have been previously described[24] and the antigens used were homogeneous as assessed by SDS-polyacrylamide gel electrophoresis. After 3 days of incubation the cells were pulse-labelled with ^{3}H-thymidine for 8 h and the incorporated radioactivity determined. Samples were done in triplicate and the individual samples varied less than 10% from the mean.

Our results describe two unique characteristics of the response of CBA/N mice to MoLV, that is, the lack of leukaemia and the lack of T cells which respond to MoLV proteins. The lack of leukaemia in viraemic mice is quite unusual. Gisselbrecht[5] has reported that DBA/2 mice fail to develop leukaemia by 6 months of age after MoLV inoculation at 4 weeks of age. However, we have observed that inoculated newborn DBA/2 mice develop leukaemia with a cumulative incidence of 85% by 8 months after inoculation (unpublished data). Interestingly, of the DBA/2 mice examined in those studies all hj T-cell proliferative responses to MoLV gp71. Therefore, we believe that CBA/N represents the only mouse strain in which MoLV-induced viraemia is not associated with leukaemia.

Although several genetic factors are known to influence MoLV-induced leukaemogenesis[5], most of these factors phenotypically decrease the level of viraemia. Our results clearly demonstrate that there were no significant differences in viraemia between the susceptible BALB/c and CBA/J strains and the resistant CBA/N mice. Another possible reason for the absence of leukaemia is the lack of an appropriate recombinant oncogenic virus. It has been suggested that spontaneous leukaemias in AKR mice require recombination to generate oncogenic MCF viruses[11,12]. In MoLV-inoculated CBA/N mice this seems unlikely for two reasons. First, cloned MoLV is oncogenic in rats and only the parental virus is found in most lymphomas (ref. 2 and D. Steffen, personal communication); therefore, recombination does not seem to be required. Second, the stock of MoLV used in these studies is an uncloned animal passaged stock which contains recombinant viruses similar to those previously described[13]. Nevertheless, the oncogenic potential and host range characteristics of viruses recovered from CBA/N mice are now being evaluated.

Our results demonstrate that viraemic CBA/N mice lack lymphocytes that respond to MoLV proteins whereas such lymphocytes are found in viraemic mice of other strains[6,10]. CBA/N mice are known to differ from CBA/J mice in their ability to respond to certain antigens[8]. However, the immune deficiency of CBA/N mice has only been shown to involve thymus-independent antigens, whereas our data suggest the absence of a T-cell function. One important distinction in our studies, however, is that MoLV was given to newborn mice, whereas other studies have examined the effect of immunizing adult mice. Therefore, the lack of responses may be related to the X-linked immune response gene and is manifested as tolerance. Preliminary genetic experiments support this in that the lack of a response to viral antigens is X linked.

The essential question is whether the absence of a detectable T-cell response against MoLV is responsible for the lack of leukaemia in CBA/N mice. Although the present results suggest this, appropriate genetic crosses will be required to confirm the relationship. If the lack of an immune response is involved, several possible explanations exist. McGrath and Weissman[14] presented evidence that T cells with appropriate virus-specific receptors were required for leukaemogenesis. If these receptors represent the immune specific receptors of T cells, our results demonstrate that CBA/N mice lack this subpopulation of T cells. Second, it is conceivable that an immune response is required to generate appropriate target-cell populations for virus infection and/or transformation. In a somewhat analogous manner we have previously hypothesized that chronic immune stimulation is required for leukaemogenesis. The basic

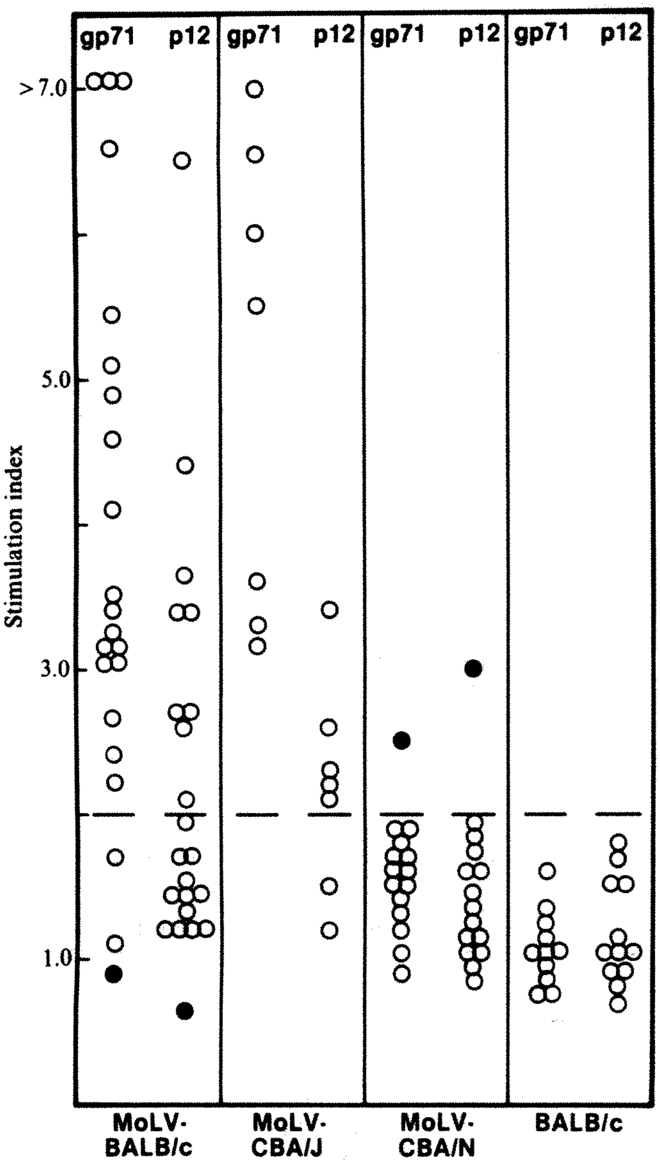

Fig. 3 T-cell proliferative responses of individual MoLV-inoculated or control BALB/c, CBA/N or CBA/J mice. Mice inoculated as newborns with MoLV or normal uninoculated BALB/c mice were used. Individual mice at 1–4 months of age were killed and splenic lymphocytes obtained and assayed in blastogenesis assays as described in Fig. 2 legend. Assays included the responses to MoLV gp71 (2.5 μg per well) or p12 (5 μg per well). All samples were tested in triplicate and the mean c.p.m. incorporated was determined. Individual samples generally varied less than 10% from the mean. The stimulation index presented is the ratio of c.p.m. of ^{3}H-thymidine incorporated in the presence of antigen to that in the absence of antigen. A stimulation index of 2.0 is considered a significant response. The solid circles indicate individual mice which either failed to respond to either antigen (BALB/c) or responded to both antigens (CBA/N), as discussed in the text.

components of this hypothesis are: (1) As a consequence of the establishment of an acute viraemia and expression of viral proteins, antigen reactive Thy 1.2$^+$, Lyt-1$^+$,2$^-$ T cells are continually recruited. (2) In response to antigen these T cells produce a variety of soluble lymphokines which influence the proliferation and differentiation of the immune system. Such factors include macrophage activating factors[15] which in turn cause the production of lymphocyte activating factor (LAF) or interleukin I (ref. 16). In addition, blastogenic factors are produced which promote proliferation of early T cells[17]. Other factors include those related to T-cell growth factors which promote thymocyte differentiation[18] and induction of differentiation of mature T cells[19]. (3) This chronic state of proliferation and differentiation increases the probability of spontaneous events leading to transformation. One likely 'error' commonly found associated with murine leukaemias that may be associated with transformation would be the generation of a trisomy in chromosome 15 (ref. 20). Irrespective of the validity of this interpretation, the results described here should provide important approaches to studying the mechanisms by which C-type viruses induce leukaemia.

Phagocytosis requires repeated triggering of macrophage phagocytic receptors during particle ingestion

Denise R. Shaw & Frank M. Griffin Jr

Departments of Microbiology and Medicine, University of Alabama in Birmingham, Birmingham, Alabama 35294

The phagocytic functions of polymorphonuclear leukocytes and mononuclear phagocytes are crucial elements in host defence against a variety of invading microorganisms. Phagocytosis is a highly selective process, requiring specific interactions between the surface of the particle to be ingested and the plasma membrane of the phagocytic cell. The phagocyte can therefore discriminate between 'ingestible' and 'non-ingestible' particles even when the different particles are located in close proximity on the plasma membrane of the phagocytic cell[1]. Previous work has demonstrated that these specific interactions between particle and phagocyte are required not only for the initiation of phagocytosis—that is, attachment of the particle to the phagocytic cells and generation of a signal to trigger phagocyte pseudopod extension—but also for the subsequent progression of pseudopods over the entire surface of the particle[2,3]. We present evidence here that the continued interactions between phagocyte plasma membrane receptors and particle-bound ligands do not function merely to direct otherwise random phagocyte pseudopod movement, but instead are required for the repeated generation of intracellular phagocytic signals during the entire ingestion process.

All plasma membrane receptors for immunological ligands promote the binding of ligand-coated particles to the phagocytic cell surface; however, only certain receptors are able to generate a phagocytic signal, and this ability depends on the physiological state of the cell. Mouse peritoneal macrophages possess well characterized plasma membrane receptors of both phagocytic signal generating and non-generating classes. Receptors for the Fc portion of immunoglobulin G (IgG) molecules mediate both the attachment and the ingestion of particles coated with IgG (refs 4, 5). Receptors for the third component of complement (C3) mediate the attachment of particles coated with C3, but resident macrophages (R-MΦ) do not ingest the attached C3-coated particles[5-7]; however, inflammatory macrophages, such as those elicited by the intraperitoneal injection of Brewer's thioglycollate medium (TG-MΦ)[8], and resident macrophages treated *in vitro* with certain lymphokine preparations (LT-MΦ)[9] attach and ingest C3-coated particles.

Previous studies have indicated that the density of the immunological ligands on the surface of a particle can determine whether or not the particle will be phagocytosed. For example, particles coated with diminishing quantities of IgG are ingested by macrophages with progressively reduced efficiency; however, particles coated with inadequate amounts of IgG can be converted into particles which are readily ingested by R-MΦ after the addition of C3 ligands to the particle surface[10]. Other work has shown that if the phagocytosis-triggering ligands on an ingestible particle are sequestered on one hemisphere of the particle surface, that particle cannot be ingested[3]. From these previous experimental observations, we considered that there were two possible hypotheses for the role of phagocyte plasma membrane receptors in the process of particle ingestion: (1) Once a phagocytic cell has been triggered by a certain minimum number of phagocytic signals generated by appropriate ligand–plasma membrane receptor interactions, the phagocyte is committed to pseudopod extension of a degree sufficient to result in interiorization of the bound particle. Subsequent ligand–receptor engagement is required only to guide this pseudopod movement towards particle engulfment. Without such direction, fusion of the leading edges of pseudopods around the attached particle would be a random, inefficient process. (2) The engagement of phagocytic signal-generating plasma membrane receptors by the corresponding ligands triggers the phagocytic cell to produce only a limited amount of pseudopod extension. Unless such movement results in additional engagement of signal-generating receptors, particle engulfment will cease. Ligand–receptor interactions which do not generate phagocytic signals may function to facilitate each increment of pseudopod movement over the surface of the particle and thereby increase the efficiency of signal-generating receptor binding to additional ligands on the particle, but they cannot by themselves complete the process of particle engulfment.

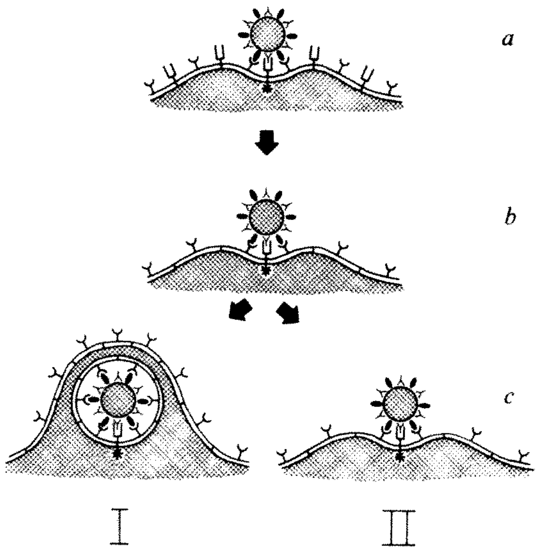

Fig. 1 Schematic representation of the experiment. *a*, IgG + C3-coated erythrocytes were bound to macrophage plasma membranes at 4 °C through the interactions of particle-bound IgG (Y) and C3 (●) ligands with the macrophages' Fc (Ψ) and C3 receptors (Y), respectively. *b*, Fc receptors located on the remainder of the macrophages' surfaces were functionally removed by treatment with anti-macrophage serum at 4 °C. *c*, Macrophages were then incubated at 37 °C for 30 min and examined for erythrocyte ingestion. If the initial phagocytic signal-generating (*) ligand–receptor (IgG–Fc) engagement triggers sufficient pseudopod extension, R-MΦ should complete erythrocyte ingestion through the 'passive' binding of C3 receptors to C3 ligands on the remainder of the erythrocyte surface (result I). However, if repeated phagocytic signal-generating ligand–receptor interactions are required for each increment of pseudopod extension, then IgG + C3-coated erythrocytes should not be ingested by R-MΦ (result II).

To discern which of the two hypotheses best describes the mechanism of phagocytosis, we have performed the experiment schematically shown in Fig. 1. First, macrophages were allowed to attach, through their Fc and C3 receptors, particles coated with both IgG and C3, in conditions which prevented particle

Table 1 Attachment and ingestion of erythrocytes by macrophages

Erythrocytes coated with:	Attachment index ± s.e.m.			Phagocytic index ± s.e.m.		
	R–MΦ	TG-MΦ	LT-MΦ	R-MΦ	TG-MΦ	LT-MΦ
			Control MΦ

2. C3	1,200 ± 100 (3)	940 ± 28 (2)	840 ± 140 (3)	9.8 ± 6.8 (3)	490 ± 180 (2)	350 ± 85 (3)
3. IgG	510 ± 139 (4)	1,100 ± 290 (4)	1,100 ± 200 (3)	300 ± 59 (5)	700 ± 230 (4)	670 ± 96 (4)
4. IgG + C3	710 ± 280 (4)	970 ± 160 (4)	2,000 ± 310 (3)	440 ± 110 (5)	610 ± 140 (4)	1,000 ± 54 (4)
			MΦ treated with anti-macrophage serum			
5. IgG	520 ± 100 (7)	960 ± 250 (4)	1,200 ± 280 (4)	13 ± 4.2 (8)	29 ± 9.5 (4)	53 ± 6.5 (8)
6. IgG + C3	750 ± 130 (7)	900 ± 320 (5)	1,700 ± 170 (4)	19 ± 9.5 (8)	460 ± 48 (5)	310 ± 24 (8)

Macrophages from non-treated mice (R-MΦ) or from thioglycollate-injected mice (TG-MΦ) were cultured for 48 h before the assay. Some macrophages from non-treated mice were cultured in medium containing the previously described lymphokine (LT-MΦ) which enhances macrophage C3 receptor function[9]. After attachment of erythrocytes to macrophages, some cultures were treated with anti-macrophage serum at a concentration that reduced Fc receptor-mediated phagocytosis by 90% but was not toxic to macrophages. Results are expressed as attachment or phagocytic indices, calculated by multiplying the percentage of macrophages attaching or ingesting one or more erythrocytes by the mean number of erythrocytes attached or ingested per macrophage. Numbers in parentheses indicate the number of determinations, each determination being made on 100 macrophages. The macrophage cultures were relatively homogeneous, and attachment and phagocytic indices are representative of the population as a whole. Thus, small indices (<60) were obtained only when less than 20% of macrophages attached or ingested a few erythrocytes each, whereas large indices (>300) were never the result of a minority of macrophages attaching or ingesting large numbers of erythrocytes but were obtained only when greater than 65% of the population participated in the function assessed.

ingestion (Fig. 1*a*). Non-engaged macrophage Fc receptors were specifically blocked without affecting the preformed receptor interactions (Fig. 1*b*). Cultures were then restored to conditions permissive for ingestion (Fig. 1*c*). The protocol used was intended to provide an initial phagocytosis trigger in the form of the engagement of macrophage Fc receptors by particle-bound IgG. However, completion of particle ingestion, if it occurred, would have to proceed through macrophage C3 receptor binding to particle-bound C3, interactions which alone are unable to promote ingestion by R-MΦ.

Procedures for obtaining monolayer cultures of R-, TG- and LT-MΦ and for preparing sheep erythrocytes (particles) coated with IgG, C3 or IgG + C3 have been described in detail elsewhere[1-3,7-9]. Erythrocytes were incubated with macrophage cultures at 4 °C for 30 min, conditions which allow the attachment but not the ingestion of ligand-coated particles[11]. Cultures were then treated for 60 min at 4 °C with the IgG fraction of a rabbit anti-mouse macrophage serum which has previously been shown to block specifically macrophage Fc receptor function without affecting macrophage C3 receptors[8,12]. Cultures were then transferred to 37 °C and an atmosphere of 95% air–5% CO_2, conditions which are permissive both for phagocytic signal transmission by IgG–Fc receptor bonds previously formed at 4 °C (ref. 3) and for particle ingestion[2,3]. After incubation for 30 min, cultures were prepared for phase contrast microscopy and scored for erythrocyte phagocytosis as previously described[1].

Control experiments (Table 1, lines 1–5) confirmed that non-coated erythrocytes were neither bound nor ingested by any macrophage preparation (line 1), that C3-coated erythrocytes were attached but not ingested by R-MΦ and were ingested by TG- and LT-MΦ (line 2), that erythrocytes coated with IgG (line 3) and those coated with IgG + C3 (line 4) were attached and ingested by all three types of macrophages, and that treatment with anti-macrophage serum did not affect the previously established attachment of IgG-coated erythrocytes, but did efficiently block the subsequent ingestion of these erythrocytes by all macrophage preparations (compare lines 3 and 5).

As expected, TG- and LT-MΦ were able to ingest IgG + C3-coated erythrocytes even after treatment with anti-macrophage serum (line 6, columns 5, 6). The phagocytic indices were nearly identical to those obtained when untreated TG- and LT-MΦ were incubated with erythrocytes coated with C3 alone (line 2), in agreement with previous observations that anti-macrophage serum treatment completely blocks macrophage Fc receptors but does not impair macrophage C3 receptor function[8,12]. In contrast, R-MΦ treated with anti-macrophage serum were unable to ingest IgG + C3-coated erythrocytes (line 6, column 4).

The inability of R-MΦ to ingest IgG + C3-coated erythrocytes supports hypothesis (2). These erythrocytes presented sufficient C3 ligands so that, even after macrophage Fc receptors had been blocked, they could be ingested by TG- and LT-MΦ, macrophages for which C3 receptor engagement is capable of generating phagocytic signals. However, in similar conditions, R-MΦ were unable to ingest these IgG + C3-coated particles, even though the initial interaction of particle with macrophage could occur by phagocytic signal-generating ligand–receptor (IgG–Fc) engagements and even though the R-MΦ could efficiently attach particles through their C3 receptors.

Nonjunctional acetylcholine receptor channel open time decreases during development of *Xenopus* muscle

R.W. Kullberg

Biology Department, University of Alaska, Anchorage, Anchorage, Alaska 99504

The Salk Institute, PO Box 85800, San Diego, California 92138

The mean channel open time of junctional acetylcholine receptors (AChRs) decreases during development of mammalian skeletal neuromuscular junctions[1-3]. The junctional AChRs of newborn rats have long mean channel open times of about 4.5 ms and in this respect are similar to nonjunctional AChRs of adult denervated muscle[3-5]. Mature neuromuscular junctions have channels with shorter mean open times of about 1 ms, whereas junctions at intermediate stages seem to have a mixture of channels with short and long open times[1-3]. These observations, taken together with findings on receptor distribution during development[6,14], suggest that the establishment of nerve–muscle contact induces an aggregation of embryonic AChRs with long mean channel open times at the point of contact and that these embryonic junctional receptors are then replaced, modified or subjected to local membrane changes leading to a discrete reduction in channel open time. However, the fate of those embryonic nonjunctional receptors which are not aggregated at the newly formed neuromuscular junction is unknown. Are they an unchanging population, or do the changes in kinetic behaviour which occur at the junctional regions also take place at other regions of the muscle membrane? The kinetics of nonjunctional receptors in mammalian skeletal muscle have not been studied during development. We have now, however, examined this question in amphibian myotomal muscle, where nonjunctional receptors are present in substantial numbers throughout development, making it possible to measure the mean open time of both classes of AChR channel. We observed a shortening of mean channel open time of junctional AChRs, from about 3 ms to 1 ms, and an identical change in mean channel open time of AChRs at nonjunctional regions of membrane.

The experiments were performed on myotomal muscles of *Xenopus laevis* embryos and tadpoles. Procedures of dissection and staging have been described previously[7]. The muscle cells extend the length of a myotome and insert at myocommata where the neuromuscular junctions are located. Focal synaptic potentials may be recorded with an extracellular pipette positioned at the myocommata[8], and staining with fluorescent-labelled α-bungarotoxin reveals extensive receptor accumulations at the ends of the muscles[9]. Muscle cells ranged in length from 100 μm in the earliest stages studied to 200 μm in the latest stages.

Recordings of ACh-induced extracellular noise were obtained from muscles using the method developed by Schuetze, Frank and Fischbach[10]. An extracellular pipette (3–7 μm o.d.) filled with bathing solution (see Fig. 1 legend) containing either 25 or 50 μM ACh was pressed against the muscle to record agonist-induced noise. Recordings were

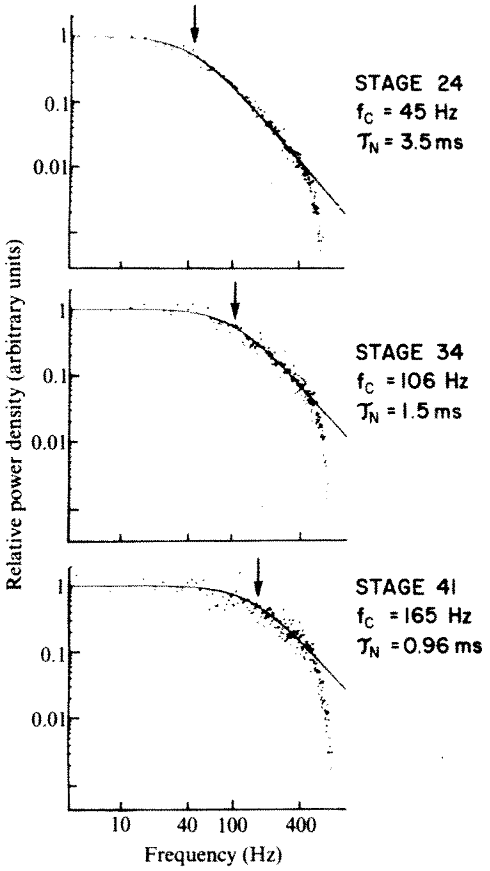

Fig. 1 Sample spectra for fluctuations recorded from nonjunctional regions of *Xenopus* myotomal muscle cells at three different developmental stages. The spectra are plotted logarithmically and the power is expressed in arbitrary units. Data were bandpass filtered at 0.5–500 Hz and digitized at 0.49-ms intervals. Spectra were computed with a fast Fourier-transform routine using a Digital PDP 11/34 computer. The spectra shown have had background spectra subtracted (this correction resulted in a change of less than 10% in the power at frequencies less than approximately twice the half-power frequency). The background spectra were obtained from records in which the pipette was not pressed against a cell. Single lorentzian curves are shown, fitted to the data by eye. A lorentzian curve is described by the equation $S(f) = S_0/[1+(f/f_c)^2]$, where S_0 is the zero frequency power, f_c is the half-power frequency and f is frequency. The recording solution contained 111 mM NaCl, 3 mM KCl, 1.8 mM $CaCl_2$ and 8 mM HEPES-NaOH buffer (*p*H 7.4). Records were made at room temperature (20–23 °C).

classified as 'nonjunctional' when the electrode tip was placed at the middle of the myotome, where no synapses are located, and 'junctional' when positioned at the myocommata. In the latter case, the occurrence of infrequent, miniature endplate currents (m.e.p.c.s) in some recordings confirmed the close proximity of the electrode tip to junctional regions. To avoid possible differences in myotomal development along the length of the tadpole, only the anterior myotomes were included in this study. Sealing of the ACh-containing pipette against the muscle membrane (sealing resistance 0.5–5 MΩ) was accompanied by an increase in voltage fluctuations and a mean negative voltage shift. This signal resulted from the activity of ACh-activated channels, as it was abolished by (+) tubocurarine (3×10^{-5}M) and was not observed when the electrode was either lacking ACh or pressed against epidermis.

Estimates of mean channel open time were obtained from spectral analysis of ACh-induced noise. Power density spectra were computed and fitted by single lorentzian curves (Fig. 1) which describe the theoretical spectra produced by randomly opening ACh-activated channels[11]. In conditions of low ACh concentration, the half-power frequency (f_c) of a spectrum of fluctuations recorded from receptors on adult amphibian muscle is determined only by the channel-closing rate constant and provides an estimate (τ_n) of the mean channel open time according to the equation $\tau_n = 1/(2\pi f_c)$ (ref. 11). At high concentrations of ACh, τ_n will underestimate the true mean channel open time, because the half-power frequency is then determined by both channel opening and closing rates[11,12]. To minimize the error in our estimate of mean channel open time, we have used the lowest possible ACh concentration which gave consistently satisfactory recordings. Because of dilution, the ACh concentration at the tip of the recording pipette was less than 25–50 μM. In most cases, a pipette was used until dilution rendered the ACh concentration so low that no further response could be recorded.

Spectral analysis of both junctional and nonjunctional AChR channel fluctuations was performed at developmental stages between 2 and 58 h after initial nerve contact. The power in the fluctuations extended to higher frequencies at later stages, yielding estimates of mean channel open times of the AChRs that are shorter in later developmental stages (Fig. 1). Values of τ_n were determined from spectra recorded at 101 sites (39 embryos). The values of τ_n measured at junctional regions decreased from 3.0±0.7 ms (mean ±s.d., $n = 8$) at stage 24 to 1.1±0.3 ms ($n = 7$) at stages 38–42. These values were not significantly different from the corresponding values for the nonjunctional AChRs, 2.7±0.9 ms ($n = 8$) at stage 24 and 1.2±0.3 ms ($n = 9$) at stages 38–42 (Fig. 2).

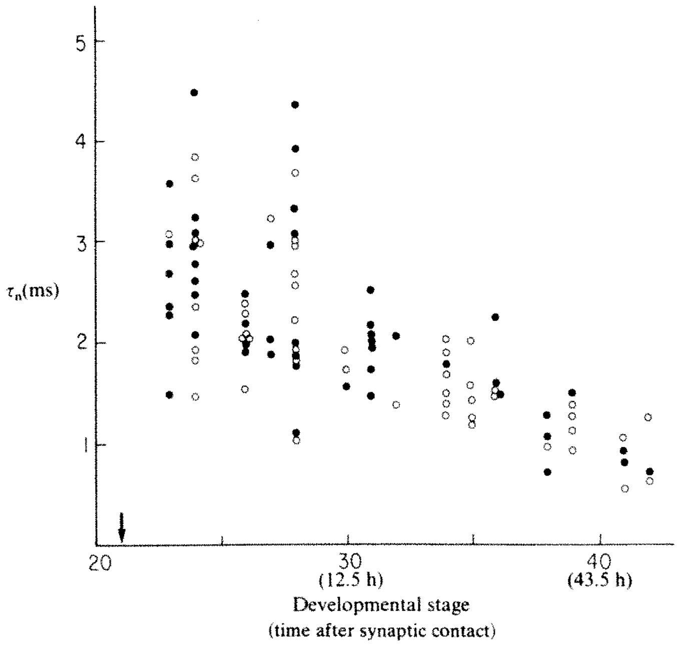

Fig. 2 The calculated τ_n for junctional (filled circles) and nonjunctional (open circles) AChRs are plotted as a function of developmental stage. The abscissa is also marked in terms of hours of development after the first signs of synaptic transmission[7,15]. The arrow indicates the time when the first synaptic activity may be recorded. Each point gives τ_n for a single recording site.

Developmental changes in junctional AChR channel kinetics were also examined by analysis of focally recorded synaptic currents (focal m.e.p.c.s). In conditions where the transient rise and fall of cleft concentration of transmitter is rapid relative to channel closing kinetics, the decay time constant of synaptic currents provides an independent estimate (τ_m) of the mean

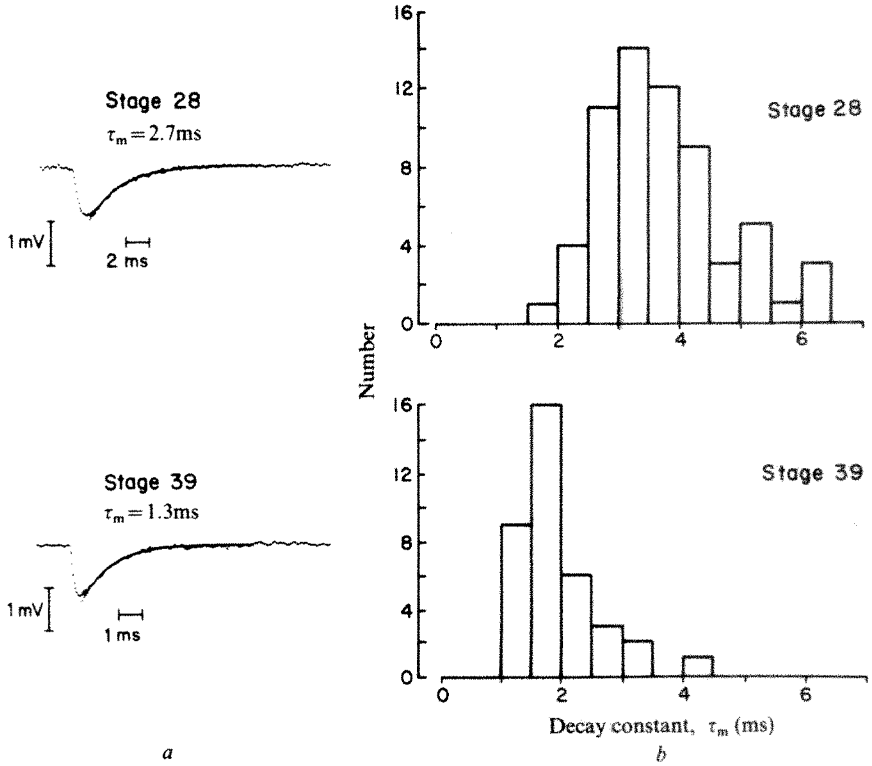

Fig. 3 *a*, Focal m.e.p.c.s recorded at stages 28 and 39. Recordings were made by positioning the tip of a Ringer-filled extracellular pipette at the myocommata. Focal m.e.p.c.s were bandpass filtered (0.5–2 kHz) and sampled on-line by computer. The individual m.e.p.c. decays were then fitted by the best least-squares exponential curve. These curves are shown superimposed on the m.e.p.c. decay phases. *b*, Histograms of decay constants of focal m.e.p.c.s at stages 28 and 39. Each histogram is based on a sample of focal m.e.p.c.s recorded at a single site.

channel open time[11,13]. In developing rat neuromuscular junctions, there is a fairly good correspondence between the time constant of m.e.p.c. decay and spectral estimates of mean channel open time[1–3]. We recorded samples of focal m.e.p.c.s at selected stages of development, and the decay phases were fitted by single exponential curves (Fig. 3*a*). At any single recording site, there was a wide scatter of estimated decay constants, many of which were longer than the spectral estimates of mean channel open time at the same stage (Fig. 3*b*). However, the shorter decay constants, as illustrated by the m.e.p.c.s in Fig. 3*a*, were similar to spectral estimates of the mean channel open time at each stage. We never observed focal m.e.p.c.s which had briefer time constants than the fastest spectral estimates of mean channel open time at the same stage. These facts suggest that in the developing myotomal neuromuscular junction there is a fraction of ACh release sites where the decay of synaptic current is limited by channel kinetics and not by the rate of disappearance of transmitter.

We were unable to obtain measurements of τ_n in animals beyond stage 42 using the focal noise technique, possibly because of a decrease in nonjunctional receptor density and an increase in connective tissue at the myocommata, which made the receptors less accessible to the ACh-containing electrode. We were, however, able to estimate τ_m from focal m.e.p.c.s. In stage 50 muscle, τ_m was 0.7 ± 0.1 (mean ± s.d., $n = 181$ focal m.e.p.c.s; 6 recording sites); this indicates that receptor kinetics continue to accelerate beyond our stage 42 noise measurements.

The acceleration of junctional AChR channel kinetics observed at the mammalian neuromuscular junction results from a discrete shift to shorter mean channel open times[1–3]. If this mechanism explained the shift in τ_n seen for *Xenopus* AChRs, the spectra at intermediate stages should be fitted by the sum of two lorentzian functions corresponding to the two populations of receptors. The values for τ_n would be expected to correspond, as in the case of rat muscle, to the slowest and fastest estimated values of mean channel open time at early and late stages. However, of 69 spectra recorded from intermediate stages (26–39), 50 spectra were satisfactorily fitted by eye with single lorentzian curves, as in Fig. 1, stage 34. The remaining spectra seemed to be fitted better with double lorentzian curves composed of slow and fast components. Further examination of high resolution spectra will be necessary to determine whether the changes in channel kinetics occur gradually or discretely.

The importance of the present study is the finding that a modification of AChR channel kinetics occurs in both junctional and nonjunctional AChRs in developing *Xenopus* myotomal muscle. The process of change in AChR channel kinetics does not seem to depend on the proximity of receptors to the site of nerve contact with muscle, but affects receptors over the entire surface membrane. The development of the mammalian skeletal neuromuscular junction is similar to that of the myotomal synapse in that nonjunctional receptors are present in significant numbers (150 μm^{-2})[14] during the period of transition from slow to fast kinetics of junctional receptors. Given the present observations of *Xenopus* embryonic receptors, it would be interesting to see if similar changes in the kinetics of mammalian embryonic nonjunctional receptors occur during neuromuscular junction development.

Interferon action—sequence specificity of the ppp(A2′p)$_n$A-dependent ribonuclease

Daniel H. Wreschner*, John W. McCauley*, John J. Skehel & Ian M. Kerr*

National Institute for Medical Research, Mill Hill,
London NW7 1AA, UK

The oligonucleotides pppA2′p5′A2′p5′A and related oligomers (2-5A) are synthesized by an enzyme that is widely distributed in a variety of cells, the activity of which varies with interferon treatment, growth and hormone status[1,2]. Because significant amounts of 2-5A have recently been detected in interferon-treated cells[3], it has been suggested that the oligonucleotides may be involved in interferon action and in the control of cell metabolism. In both intact cells[4,5] and cell-free systems[6–11] 2-5A has been shown to activate a ribonuclease. We report here investigations of the sequence specificities of the 2-5A-dependent ribonucleases in extracts of rabbit reticulocytes, mouse ascites tumour cells and human lymphoblastoid cells in conditions of partial digestion using terminally labelled RNA substrates. The enzymes cleaved on the 3′-side of UN sequences to yield UpNp terminated products. Cleavage was observed predominantly at UA and UU sequences.

Partial nuclease digestions in the presence and absence of tetramer 2-5A were done using rabbit reticulocyte lysates[12] with the 3′-terminally labelled small RNA of the La Crosse virus genome[13] and influenza virus genome RNAs 7 and 8 as substrates[14]. The products were compared by electrophoresis in polyacrylamide gels, with those obtained by specific limited chemical degradations of the RNAs[15]. For La Crosse virus sRNA, in the presence of 2-5A, specific cleavages were observed at UN sequences where UA and UU were preferred (Fig. 1*a*). In this experiment cleavage was obtained at nucleotides 32, 30, 29 and 34, the first of which is at a UA and the others at UU sequences. The precise nature of the products of digestion is not defined by these results and will be described below. Analysis of larger oligonucleotide products of digestion indicated cleavage at residues 54, 58, 69, 100 and 149, in all cases at UA sequences (Fig. 1*b*, Table 1*a*). Additional cleavages at nucleotides 59, 66, 73, 123 and 124 were at UU sequences and in the case of nucleotide 72, at a UG. These data are summarized in Table 1. Denaturation of the RNA by boiling before addition to the lysate did not alter the pattern of cleavage (Fig. 1*b*). In addition, identical results were obtained when 2-5A tetramer, pentamer or oligomers obtained from interferon-treated, virus-infected cells[3] were used for activation (data not shown).

The same specificity was observed using influenza virus RNAs 7 and 8 as substrates (Fig. 1*c*, *d*; Table 1). With RNA 7 the major sites of degradation were at nucleotides 17, 36 and 64 (Fig. 1*c*), all at UA sequences. Less extensive cleavage also occurred at nucleotides 23 and 49 (UU sequences), and 53 and 57 (UA sequences). For RNA 8 distinct cleavages were obtained at residues 19, 20, 21, 25 and 26. The major site of cleavage at

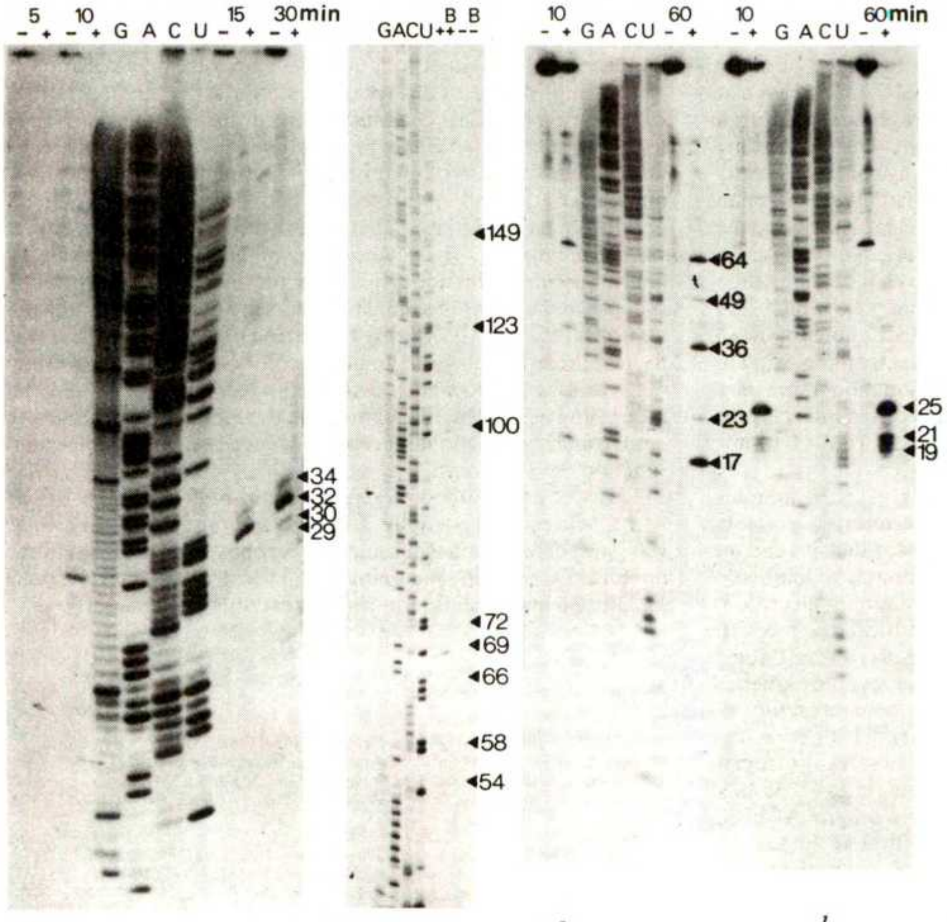

Fig. 1 Comparative electrophoretic analysis of the products of 2-5A-activated RNase activity and those obtained by limited chemical degradation. Virus RNAs were labelled at their 3′-termini with cytidine 3′5′-[5-^{32}P]biphosphate and T$_4$ RNA ligase[21] and purified by polyacrylamide gel electrophoresis[13,16]. Assays were performed using rabbit reticulocyte lysates in protein synthetic conditions[12] but in the absence of creatine phosphokinase. Nuclease digestions in the presence (+) or absence (−) of tetramer 2-5A (100 nM) were at 30 °C for up to 60 min. Reactions were terminated by cooling to 0 °C, glycerol was added to 20% w/v and aliquots (10 µl) were applied to polyacrylamide gels containing 7 M urea, 100 mM Tris-borate *p*H 8.3, and 2.5 mM EDTA. 3′-Labelled RNAs specifically degraded as described by Peattie[15] were applied to adjacent lanes, labelled GACU. *a*, Autoradiogram of a 20% polyacrylamide gel (40×40×0.05 cm) containing the products of cleavage of La Crosse sRNA after incubation for 5, 10, 15 and 30 min. *b*, Autoradiogram of a 12% polyacrylamide gel (100×20×0.05 cm) containing the digestion products of La Crosse sRNA after 10 min incubation. In the samples labelled B the RNA substrate was incubated in a boiling water bath for 1 min immediately before addition to the digestion mixtures. *c*, *d*, Autoradiograms of 12% polyacrylamide gels (40×40×0.05 cm) containing the digestion products of X31 influenza virus RNAs 7 (*c*) and 8 (*d*) after incubation for 10 and 60 min. The numbers indicate the positions of cleavage of the RNA molecules by the 2-5A-dependent nuclease.

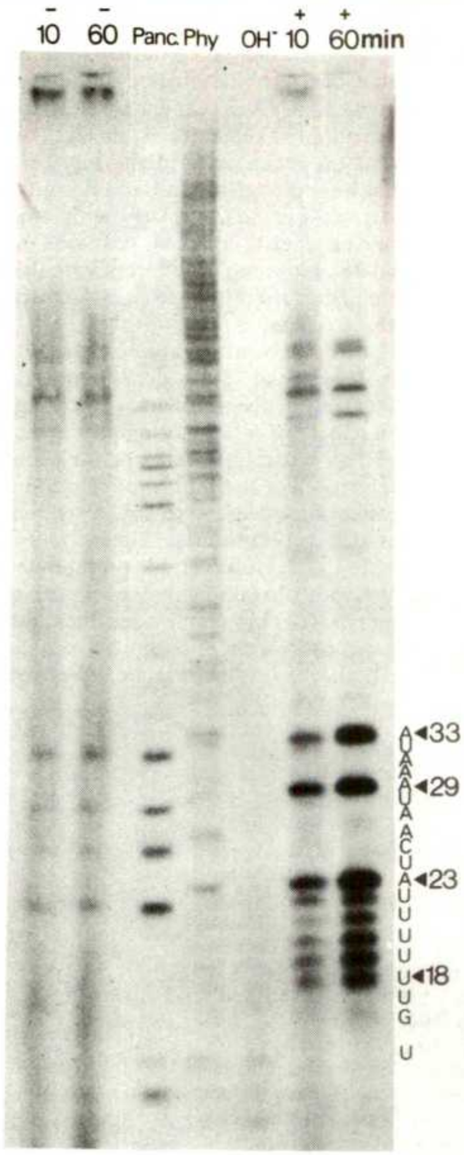

Fig. 2 Analysis of the products of digestion of 5′-labelled influenza virus RNA 8 by the 2-5A-activated RNase from rabbit reticulocytes. X31 influenza virus RNAs were labelled at their 5′-termini using polynucleotide kinase and [γ-^{32}P]ATP and separated as described elsewhere[16]. RNA 8 was incubated in the reticulocyte lysate in the presence (+) and absence (−) of 2-5A for 10 and 60 min as described in Fig. 1 legend. The products of digestion were separated on a 12% polyacrylamide gel (40 × 40 × 0.05 cm) in parallel with the products of partial alkaline hydrolysis (OH⁻) and partial digestions with pancreatic ribonuclease (Panc) and *Physarum polycephalum* nuclease M (Phy) as described elsewhere[13,22,23]. The relevant nucleotide sequence of RNA 8 is indicated.

position 25 was at a UA sequence, the other sites at UU sequences (Figs 1*d*, 3*b*; Table 1*c*).

With 3′-terminally labelled 18S ribosomal RNA from rabbit reticulocytes, cleavage was exclusively observed at UA and UU sequences (data not shown).

To define further the sites of cleavage by the 2-5A-activated RNase, the products obtained using 5′-terminally labelled influenza virus RNA 8 were examined. As shown in Fig. 2 and detailed in Table 1*d*, the products of partial digestion in the presence of 2-5A have identical electrophoretic mobilities to the oligonucleotides terminating at residues 18, 19, 20–23, 29 and 33 which were obtained after partial digestion with *Physarum* or pancreatic nuclease, or partial alkaline hydrolysis, all of which terminate in 3′ phosphates[16]. This indicates that all the products obtained from the reticulocyte lysate were phosphorylated at their 3′ termini and also that their 3′-terminal sequences were UpNp. These conclusions are consistent with the data presented in Fig. 1, where the electrophoretic mobilities of the 2-5A-activated nuclease digestion products were less than those of the oligonucleotides derived from chemical degradation, which contain 5′-terminal phosphates and from which the modified bases have been eliminated.

2-5A activates a ribonuclease and inhibits protein synthesis in a variety of cell-free systems[6–11]. To determine whether or not these enzymes have a common specificity, cell extracts were

prepared from mouse Krebs ascites tumour cells and human lymphoblastoid (Daudi) cells and their enzyme activities compared with that of a rabbit reticulocyte lysate. Using 3'-labelled influenza virus RNA 7, similar patterns of cleavage were obtained with all three cell extracts: the 2-5A-dependent cleavages seen using the reticulocyte lysate (Fig. 1*c*) at nucleotides 17, 36 and 64 were also clearly observed using the mouse and human cell extracts (Fig. 3*a*). Similarly, with influenza virus RNA 8 (Fig. 3*b*), cleavages at identical positions (nucleotides 19, 20, 21, 25 and 26), although to different extents at nucleotide 25, were obtained in the presence of 2-5A using extracts from cells of all three types.

We conclude from these results that in extracts from cells of several different types, the 2-5A-dependent ribonuclease specifically cleaves at UpN sequences yielding 3'-phosphorylated oligonucleotides which terminate in the sequence UpNp. With the RNA substrates examined the sequences UA and UU were preferred. For the rabbit reticulocyte lysates the most susceptible sites of cleavage were at UA sequences, particularly sequences rich in U (residues 32 and 25 in Fig. 1*a*, *d*; bold figures in Table 1*a*, *c*). However, the preference for sites in U-rich regions was not obvious with the enzymes from the mouse and human cells. This emphasizes that although the 2-5A-dependent nucleases from different sources show similar specificities (Fig. 3), they may not be identical. Furthermore, the reticulocyte enzyme is known to be unusual in that it requires the tetramer (rather than the trimer) or higher oligomers of 2-5A for full activity[3].

Crude extracts were used in these experiments; thus it is possible that more than one nuclease is involved in any given extract. However, studies in progress on the purification of the nuclease and its specific interaction with 2-5A provide results against this.

Cleavage was not obtained at all UA and UU sequences. The reason for this is not known, but it is likely that the specificity is also influenced by the secondary structure of the substrate. In the parts of La Crosse sRNA and influenza RNA 7 examined, the only UA sequences at which cleavage was not observed were in regions of the molecule which may be double stranded[13,16]. However, the specificity of the nuclease reported does not simply reflect an unusual structure for the viral RNAs because the same specificity for UpN sequences was also observed with ribosomal RNA. Limited cleavages of rRNA have been observed in interferon-treated, SV40 virus-infected cells[17] and in cells into which 2-5A has been deliberately introduced[18]. Because specific rRNA cleavages can inactivate ribosome function (for example, those produced by colicin E3 in prokaryotes[19] or by reticulocyte RNase M[20]) it will be of considerable interest to determine whether rRNA cleavages are a common feature of interferon treatment and virus infection and whether

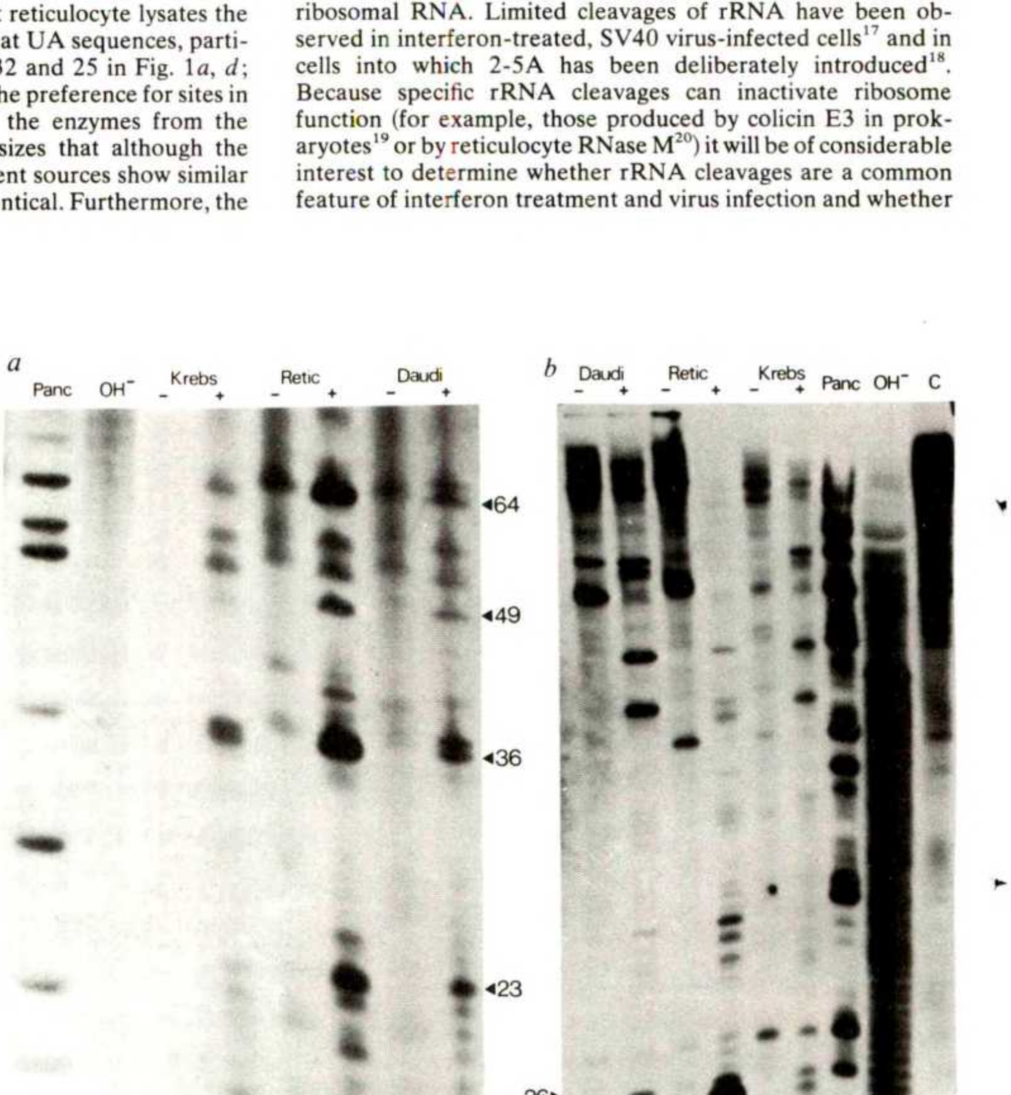

Fig. 3 Comparison of the specificities of the 2-5A-dependent ribonucleases prepared from rabbit reticulocytes, human Daudi lymphoblastoid and mouse Krebs tumour cells using 3'-labelled X31 influenza virus RNAs 7 and 8. 3'-Labelled influenza virus RNA 7(*a*) or RNA 8(*b*) were incubated for 60 min at 30 °C in a rabbit reticulocyte lysate (Retic), human Daudi lymphoblastoid extract (Daudi) or a mouse Krebs cell extract (Krebs) in the presence (+) or absence (−) of 100 nM tetramer 2-5A. Aliquots (10 μl) were diluted to 200 μl with 100 mM Tris *p*H 8.0, 100 mM NaCl, 1 mM EDTA and extracted twice with phenol/chloroform (1:1). The oligonucleotides were ethanol precipitated, redissolved in 7 M urea, 10 mM Tris *p*H 7.4 and applied to the polyacrylamide gel. The figure shows an autoradiogram of a 12% polyacrylamide gel (40×40×0.05 cm) containing the products of partial digestion with pancreatic RNase and partial alkaline hydrolysis, prepared as described in Fig. 2 legend. The numbers indicate the positions of cleavage by the 2-5A-dependent ribonucleases. Extracts of reticulocytes, Krebs and Daudi cells were prepared as described elsewhere[12,24], except that dialysis was omitted and the Duadi cells were homogenized in 40 mM KCl, 10 mM HEPES *p*H 7.6, 2.5 mM $MgCl_2$, 0.5 mM ATP and 2.5% glycerol. The Daudi and Krebs extracts were further centrifuged at 100,000*g* for 4 h to obtain the supernatant (S100) fraction. Incubations (50 μl) contained 20 μl of lysate (±20 μM haemin) or S100, and 1 mM ATP, 0.2 mM GTP, 10 mM creatine phosphate, 2 mM glucose, 75 mM KCl, 2 mM Mg acetate, 10 mM Tris-HCl buffer *p*H 7.6, a mixture of 19 amino acids (excluding cysteine), labelled RNA (50,000 c.p.m.) and tetramer 2-5A.

these or other nucleolytic cleavages in such cells show the same specificity as that reported here.

Since submission of this manuscript P. Lengyel and his colleagues (personal communication) have observed that of the four different ribohomopolymers poly(A), (U), (G) or (C), only poly(U) is cleaved by the 2-5A-dependent nuclease.

D. H. W. was the recipient of an EMBO fellowship. We thank Jack Obijeski for La Crosse virus RNA, Helen Donis-Keller for the *Physarum* RNase and Debora Peattie for communicating the chemical sequencing procedures.

Removal of O^6-methylguanine from DNA of normal and xeroderma pigmentosum-derived lymphoblastoid lines

Robert Sklar & Bernard Strauss*

Department of Microbiology, The University of Chicago, 920 East 58th Street, Chicago, Illinois 60637

The ability to excise (repair) UV-induced pyrimidine dimers in *Escherichia coli* is not related to its ability to remove *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG)-induced O^6-methylguanine (O^6-MeG) from DNA[1]. It was therefore surprising that certain xeroderma pigmentosum cell lines, deficient in dimer excision, were also unable to remove O^6-MeG[1–3]. We find that removal of O^6-MeG occurs rapidly with a half life of less than 1 h. Two cell types can be distinguished: mex$^+$, which remove O^6-MeG residues produced by incubation with 0.5 μg ml^{-1} MNNG, and mex$^-$ cells, which are unable to remove the adduct. Xeroderma pigmentosum-derived lymphoblastoid lines of complementation groups A, C or D may be either mex$^+$ or mex$^-$. The biochemical mechanism for the removal of O^6-MeG in human cells is distinct from the excision of adducts produced by compounds such as *N*-acetoxy-*N*-2-acetylaminofluorene (AAAF) or by UV irradiation but it is not clear whether the distinction between mex$^+$ and mex$^-$ lines is genetic or epigenetic.

Treatment of cells or DNA with MNNG produces a variety of adducts in the DNA[4,5]. Of these, O^6-MeG is particularly important because it seems to lead to increased mutagenesis in prokaryotes and has been implicated as a potentially carcinogenic lesion[6–8]. Similar importance has been ascribed to the O^6-ethylguanine adducts produced by certain ethylating agents.

Cells have evolved systems for dealing with the O^6-alkylguanine lesion although the detailed biochemistry of the reaction remains to be determined[9,10]. The removal systems are unequally distributed in mammalian tissues: liver is efficient in removing O^6-alkylguanine compared with brain tissue which is inefficient[11]. It has also been observed that simian virus 40 (SV40)-transformed fibroblasts from patients with xeroderma pigmentosum are deficient in the ability to remove O^6-alkylguanine[2,3] and this observation has been extended to lymphoblastoid cells derived from an individual with xeroderma pigmentosum[1]. To determine whether the inability to remove O^6-MeG was genetically associated with the xeroderma characteristic, we decided to survey a variety of lymphoblastoid lines, including xeroderma heterozygotes, and determine whether they could remove the O^6-methyl adduct.

We first determined the kinetics of O^6-MeG and 3-methyladenine (3-MeA) removal from the DNA of Raji human

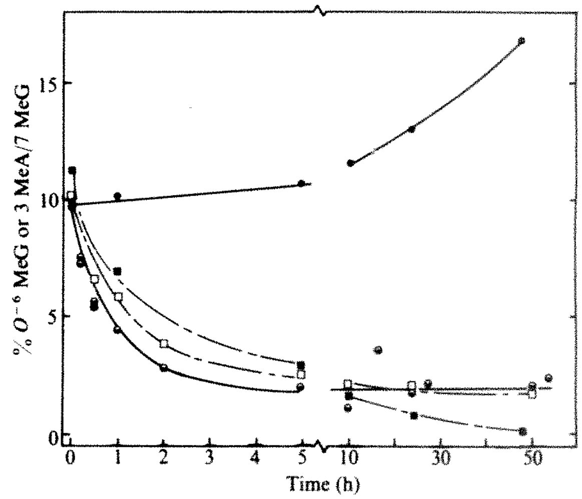

Fig. 1 Kinetics of O^6-MeG and 3-MeA removal in Raji and H2BT. Two litres of cells (~8 × 10^5 cells ml^{-1}) grown in spinner cultures were centrifuged and resuspended in 90 ml (Raji) or 60 ml (H2BT) of prewarmed SSC (0.15 M NaCl + 0.015 M sodium citrate) at 37 °C. Aliquots (10 ml) were treated for 2 min at 37 °C with 0.5 μg ml^{-1} ^{3}H-MNNG (112 mCi mmol^{-1}, Radiochemicals, Amersham) and 1 ml *N*-acetyl-L-cysteine (100 mM, *p*H 7.2) (ref. 12). Immediately after treatment a 0-time aliquot was lysed with 1 ml 2% SDS in SSC and frozen; later samples were centrifuged and resuspended in 100 ml RPMI 1640 plus 10% fetal calf serum and 4 mM L-glutamine in a 75 cm^2 Falcon flask and incubated with mild agitation for the time indicated. Cells were then centrifuged, resuspended in SSC and lysed with SDS as above. Cell lysates (10 ml) were treated for 1 h with 0.5 ml of 20 mg ml^{-1} heat-treated RNase (Worthington Biochemical) and for 4 h with 1.5 ml of 20 mg ml^{-1} heat-treated pronase (Calbiochem-Behring). Digested lysates were extracted three times with redistilled phenol saturated with SSC and neutralized with 0.2 volumes of 1 M Tris base. DNA was precipitated by adding 0.1 volume of 2.5 M sodium acetate and 2 volumes of 2-ethoxyethanol, washed twice with ice-cold 100% ethanol and dried. The DNA was dissolved in 100 μl of 0.05 M ammonium formate with 0.02% sodium azide, *p*H 7.5, and hydrolysed at 70 °C for 20 min after adding 0.2 volumes of 1 M HCl and a 50 μl mixture of 3-MeA (2 mg ml^{-1}, Cyclo Chemical), 7-MeG (5 mg ml^{-1}, Sigma), and O^6-MeG (5 mg ml^{-1}) (O^6-MeG, obtained from Dr D. Ludlum, was hydrolysed to yield the free base). The hydrolysate was spotted over 6 cm of a 0.5-mm cellulose MN300 thin-layer chromatography plate pre-chromatographed with solvent (Anal-tech) and developed in 2-propanol : 28% NH_4OH : H_2O (7 : 2 : 1) (ref. 11). UV absorbing bands corresponding to the above markers and guanine were removed from the plate with a razor blade and placed in scintillation vials, then 2 ml of 0.05 M ammonium formate, 0.02% sodium azide with 0.1 volume of 1 M HCl were added. Aquasol was added to the radioactive bands and the vials were vortexed and counted after several hours of equilibration. The guanine band was centrifuged twice in a microcentrifuge to remove the cellulose and diluted for absorbancy reading at 260 nm. The amount of DNA (in μg) was determined by multiplying the total guanine absorbancy by 164, a number determined from the absorbancy of a known amount of guanine and the molar ratio of guanine in DNA. Squares represent ratio of 3-MeA to 7-MeG × 100; circles, ratio of O^6-MeG to 7-MeG × 100; completely filled symbols, line H2BT; open squares and half-filled circles, lymphoma line Raji.

lymphoma cells because this line is known to remove methylation products from DNA[1]. Exponentially growing cells were treated with a pulse of MNNG and at intervals portions of the culture were collected and the alkylation products analysed. Figure 1 shows that O^6-MeG was rapidly removed from the DNA with a half life of less than 1 h at 37 °C, and that at the concentration of MNNG used (0.5 μg ml^{-1}) the ratios of O^6-MeG and 3-MeA to 7-methylguanine (7-MeG) declined at about the same rate. Experiments at higher MNNG concentrations indicate that the capacity for O^6-MeG removal is much more limited than for 3-MeA. The results in Fig. 1 are expressed as a ratio of radioactivity in O^6-MeG to 7-MeG and because 7-MeG is gradually lost from the DNA[1], the inability to remove the O^6-MeG adduct from the DNA results in an increase in this ratio with time of incubation in strain H2BT.

The result that the H2BT line, derived from a spherocytosis patient and heterozygous for thymidine kinase[13], was deficient in O^6-MeG removal was unexpected, as was the discovery that other non-xeroderma lines were also deficient (Table 1). In a series of control experiments in the Raji line at different MNNG doses we found that the 0-time value for the O^6-MeG/7-MeG ratio was 10.4% and the 0-time 3-MeA/7-MeG ratio was 10.1%. All the lines which remove O^6-MeG have O^6-MeG/7-MeG ratios which are consistent with the data obtained with

500 ml of cells (~8×10^5 ml^{-1}) grown in spinner culture were collected by centrifugation and resuspended in 20 ml SSC. Aliquots (10 ml) were treated with 0.5 μg ml^{-1} ^{3}H-MNNG (112 mCi mmol^{-1}), resuspended in RPMI 1640 as described in Fig. 1. legend and incubated for the indicated time. The cells were then collected and lysed and the DNA purified as described in Fig. 1 legend. The Burkitt's lymphoma lines were obtained from P. Gerber (Raji) and G. Klein (Daudi and HR-1). H2BT supplied by W. Thilly; L 33-6-1 from J. Littlefield.

Table 2 Excision repair in mex$^+$ and in a mex$^-$ lymphoblastoid line

			Repair synthesis (c.p.m. μg^{-1}) induced by:										
			AAAF (μg ml^{-1})		AAAF/ control	MMS (μg ml^{-1})			MMS/ control	MNNG (μg ml^{-1})			MNNG/ control
Strain	Origin	Control	12.5	25	(25 μg)	110		220	(440 μg)	1	2.5	5	(5 μg)
D 70-1-2	JAGR father (mex$^+$)	13.2		128	(9.7)								
D 70-2-2	JAGR mother (mex$^+$)	11.1		138	(12.4)								
D 70-3-1	JAGR proband (mex$^+$)	16.6		22	(1.3)								
D 70-3-2	JAGR proband (mex$^+$) (2nd culture)	12.9		22	(1.7)								
D 70-4-1	JAGR brother	28.2		170	(6.0)								
D 70-5-2	JAGR sister	18.3		136	(7.4)								
D 70-1-2	JAGR father (mex$^+$)	79.0	476	733	(9.3)	192	294	285	(3.6)	129	272	424	(5.4)
GM 621	Normal male (mex$^-$)	37.0	286	398	(10.8)	162	220	179	(4.8)	88	169	243	(6.6)

DNA excision repair was measured by the BND cellulose method[16]. Rapidly growing cells were diluted to 4×10^5 ml^{-1}, grown overnight, concentrated to about 10^6 ml^{-1}, and 2 ml of suspension used for determination. Repair synthesis was measured in the presence of 2 mM hydroxyurea and 10^{-6} M fluorodeoxyuridine along with 5 μCi ml^{-1} ^{3}H-thymidine (15 Ci mmol^{-1}). Results were not corrected for pool size and the ratio of drug-induced counts to the background is given as an indication of the relative repair capacity. Determinations of repair induced by MMS, AAAF and MNNG were done separately from the tests of the JAGR family, which were carried out by Mr Dino Vallera.

Raji (Fig. 1). Of 26 lymphoma and lymphoblastoid lines classified for their ability to remove O^6-MeG, we found 19 removers and 7 non-removers. We call the non-removers mex$^-$ (methyl excision minus) for convenience but the terminology has no genetic significance.

Mex$^+$ strains include three Burkitt's lymphoma lines, lines derived from xeroderma patients of complementation groups A, C and D, and representatives of tx xeroderma families of unknown complementation group. All xeroderma lines were tested in this laboratory for repair synthesis induced by AAAF and found to be repair negative compared with controls including the xeroderma heterozygotes. As the lymphoblastoid cultures are continuous lines, this result indicates that transformation does not affect repair deficiency. The seven mex$^-$ lines we have identified include a line derived from an infectious mononucleosis patient, a spherocytosis patient, a xeroderma heterozygote and a normal male and female culture.

The dose of MNNG used in these experiments (0.5 μg ml^{-1}) reduced the survival of mex$^+$ Raji cells to ~20%, as determined in a cloning experiment. Inability to remove O^6-MeG adducts after treatment at 0.5 μg ml^{-1} may indicate sensitivity of MNNG at lower concentrations for mex$^-$ strains. Most lymphoblastoid lines cannot be efficiently cloned in soft agar but their growth can be followed by cell counts in liquid medium[14]. We have observed (Fig. 2) that mex$^-$ cells are more sensitive to growth inhibition at low MNNG doses than are removal-competent strains (mex$^+$). The greater sensitivity of mex$^-$ strains was not found when treated with the carcinogen AAAF whose adducts are removed by UV-like (nucleotide) excision[15]. The mex$^-$ strain GM 892 was also more sensitive to growth inhibition by 3 or 5 μg ml^{-1} *N*-ethyl-*N'*-nitro-*N*-nitrosoguanidine (ENNG) than the mex$^+$ D70-1-2, and ENNG pretreatment (2.5 μg ml^{-1}) 2 h before MNNG challenge eliminated the capacity of the mex$^+$ Raji line to remove O^6-MeG, suggesting that the mex system is involved in the metabolism of ethyl adducts.

Both mex$^+$ and mex$^-$ strains respond to treatment with methyl methanesulphonate (MMS), MNNG or AAAF with increased DNA excision-repair synthesis (Table 2) and estimation of the relative activities by comparison of the ratio of repair synthesis with the controls (Table 2) indicates that the mex$^+$ D70-1-2 and mex$^-$ GM 621 give an almost equivalent repair synthesis response. Inability to respond to AAAF by increased repair synthesis is not related to the ability to remove O^6-MeG in lymphoblastoid cells (Tables 1 and 2).

The result that mex$^-$ strains respond to treatment with MNNG by increased repair synthesis seems to indicate that MNNG produces a variety of lesions, some of which (for example, 3-MeA) are removed, producing apurinic sites which can be repaired by an intact AP (apurinic/apyrimidinic) repair system, and either that O^6-MeG removal is a minor reaction which does not show up in the repair measurements at the high MNNG dose used, or that removal of the O^6-methyl group is not accompanied by base removal as suggested by *in vitro* studies[9,10].

We do not know the genetic basis for the mex$^-$ characteristic. There could be a major mex polymorphism in human populations and this hypothesis could account for a mex$^+$ xeroderma line and a mex$^-$ heterozygous line from the same family (Table 1). Alternatively, some epigenetic process might occur in cultured cells resulting in a mex$^+$ to mex$^-$ conversion. Such processes are known to occur in normal development because different organs of the same animal (for example, brain and liver) can have a different mex characteristic[11]. If the process is epigenetic, it is possible that functions other than the ability to remove O^6-MeG would be simultaneously affected.

Our mex$^+$ and mex$^-$ strains have properties like those studied by Day *et al*[17,18] who reported strains which differ in their ability to reactivate MNNG-treated adenovirus. We have found that a pair of Day's mer$^-$ and mer$^+$ are mex$^-$ and mex$^+$ respectively and this observation has been confirmed (Day, personal communication). Separation of the mex characteristic from xeroderma phenotype also agrees with the finding that only a SV40-transformed xeroderma cell line was hypersensitive to sister chromatid induction by the alkylating agent, ethyl methanesulphonate[19].

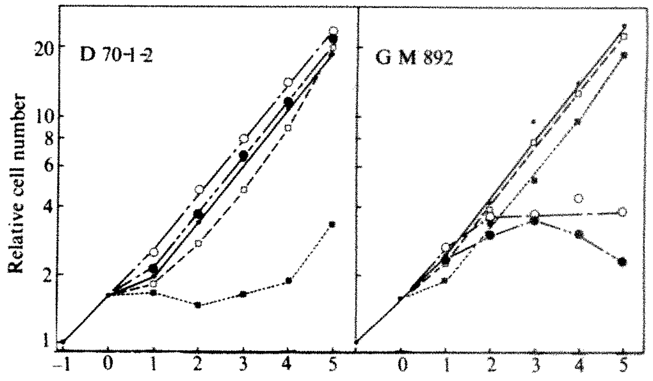

Fig. 2 Effect of MNNG and AAAF on the growth of the mex$^+$ (D70-1-2) and mex$^-$ (GM 892) lymphoblastoid lines. Cultures were maintained in a rapidly growing state by daily dilution to 4×10^5 ml^{-1} in RPMI 1640+16% fetal calf serum. At day '0', the cells were diluted to 4×10^5 ml^{-1} and treated with AAAF or MNNG for 1 h at 37 °C. The cells were then collected by centrifugation, resuspended in medium at 4×10^5 ml^{-1} and incubated at 37 °C. Cultures were counted daily using a Coulter counter and the population density was adjusted to 4×10^5 ml^{-1}. The daily increase in population size was used to calculate a relative cell number assuming no dilution. AAAF was dissolved in dimethyl sulphoxide, which was added in equal amounts to all cultures. Small •, control; large ○, MNNG (0.1 μg ml^{-1}); large ●, MNNG (0.2 μg ml^{-1}); □, AAAF (4 μg ml^{-1}); ■, AAAF (8 μg ml^{-1}).

We thank Dr Earl Henderson for supplying mex$^+$ strains. This work was supported by NCI contract NO1-CP-85669, and by grants from the NCI (CA 14599) and the Department of Energy (EY75 S-02 2040). R.S. was a trainee on a NCI-sponsored training grant in environmental biology (CA 09273).

Assembly units of clathrin coats

Ernst Ungewickell & Daniel Branton

The Biological Laboratories, 16 Divinity Avenue,
Harvard University, Cambridge, Massachusetts 02138

Clathrin, a polypeptide of molecular weight (MW) 180,000, is the main constituent of the polygonal network that forms the coat of coated pits and vesicles[1]; these vesicles play a part in intracellular transport between membranous organelles[2,3]. This function involves specific recognition of target membranes as well as fusion and fission events that must be coordinated with the assembly, partial disassembly or reorganization of the clathrin coats. To understand these interactions on a molecular level, information about the structure of clathrin and the interactions of clathrin with itself and other proteins is required. Here we show that purified clathrin coats dissociate reversibly into triskelions, structures composed of three usually bent, rather flexible legs radiating from a centre. We have determined the molecular weight of these triskelions and conclude that they contain trimers of clathrin together with about three light molecular weight polypeptide chains.

Coated vesicles were isolated from fresh calf brains according to the procedure of Keen *et al.*[4] and the clathrin coats were dissociated in 2 M urea[5]. Two successive gel filtrations separated clathrin from polypeptides with apparent molecular weights of ~90,000–125,000 and 50,000–60,000, but failed to remove two light chains with apparent molecular weights of ~36,000 and 33,000 (Fig. 1). Experiments in which this column-purified clathrin was reacted with the cleavable cross-linking reagent 3,3′-dithiobis-propionimidate confirmed Pearse's[6] suggestion that these two light chains are bound to clathrin (results not shown). From the relative intensities of the Coomassie Brilliant Blue staining, we estimated that there is approximately one light chain per clathrin polypeptide. This ratio did not vary significantly between preparations although we did observe that the clathrin light chains are very sensitive to proteolysis.

It has been reported that antibodies to two polypeptides in the 30,000–40,000 MW range (probably the light chains) cross-react with brain tropomyosin[7]. We compared the electrophoretic mobilities of brain tropomyosin and clathrin light chains in SDS-polyacrylamide gels and in SDS-polyacrylamide gels containing urea. Tropomyosins from skeletal muscle and calf brain show anomalously low electrophoretic mobility in urea/SDS-polyacrylamide gels[8]. In these conditions brain tropomyosin with an apparent molecular weight of 30,000 in SDS

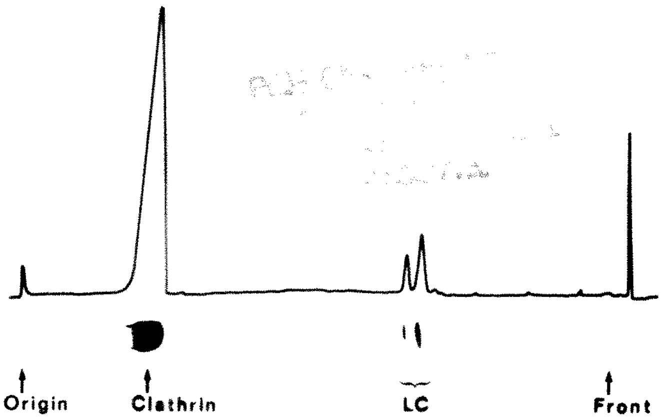

Fig. 1 Polyacrylamide gel electrophoresis of purified dissociate clathrin coats. Coated vesicles were prepared according to the procedure of Keen *et al.*[4] except that all solutions contained 0.005% phenylmethylsulphonylfluoride (PMSF). To dissociate the coats, purified coated vesicles were dialysed overnight at 4 °C against 500 volumes of 30 mM Tris-HCl, 20 mM NaCl, 1 mM EDTA, 0.2 mM dithiothreitol (DTT), 2 M urea, 0.02% NaN_3 and 0.005% PMSF, *p*H 7.5. Vesicles were removed by centrifugation at 100,000*g* for 1 h. The supernatant, which contained large amounts of protein in addition to clathrin, was chromotographed at 4 °C on a Sepharose 4B-Cl gel filtration column (90×2.5 cm), which was equilibrated with dialysis buffer. Clathrin eluted together with two low-MW polypeptides (light chains) and small amounts of polypeptides with apparent molecular weights of ~100,000 and 55,000 (molecular weights were estimated from the relative mobilities of polypeptides in SDS-polyacrylamide gels) which were completely removed by a second gel filtration in triethanolamine. The clathrin-containing fractions from the first column were concentrated by precipitation with 50% ammonium sulphate and immediately dissolved in 50 mM triethanolamine, 20 mM NaCl, 1 mM EDTA, 0.2 mM DTT and 0.02% NaN_3, *p*H 8.3. After dialysis against the same buffer, the protein was chromatographed in the same medium at 4 °C on a Sephadex 4B-Cl gel filtration column (100×1.5 cm). The polypeptide composition of the final pooled clathrin-containing fractions was analysed in SDS-polyacrylamide gradient gels (6–15%) using the discontinuous buffer system of Laemmli[9]. The gel was scanned with a Joyce Loebl microdensitometer. LC, clathrin light chains.

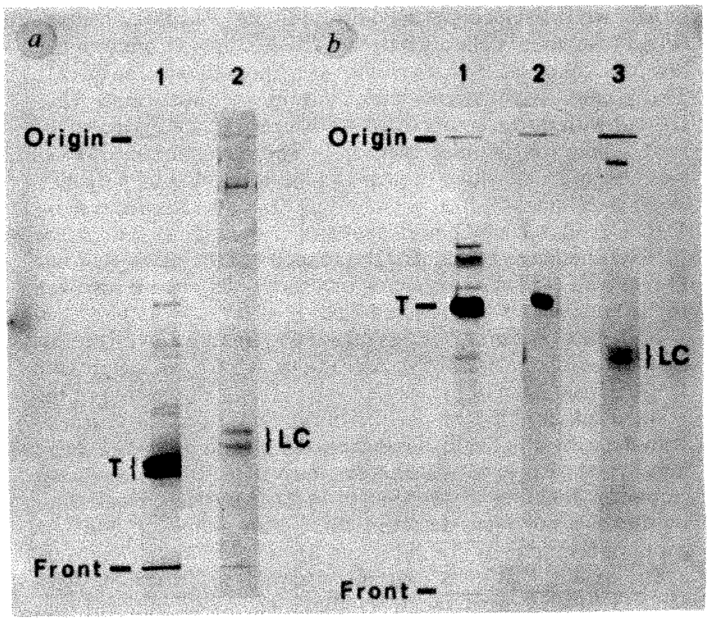

Fig. 2 Comparison between the electrophoretic behaviour of brain tropomyosin and clathrin light chains in SDS- and urea/SDS-polyacrylamide gels. *a*, 10% SDS-polyacrylamide gel[8]: lane 1, brain tropomyosin (T); lane 2, clathrin light chains (LC). *b*, urea/SDS-polyacrylamide gel: lane 1, brain tropomyosin; lane 2, skeletal muscle actin; lane 3, clathrin light chains.

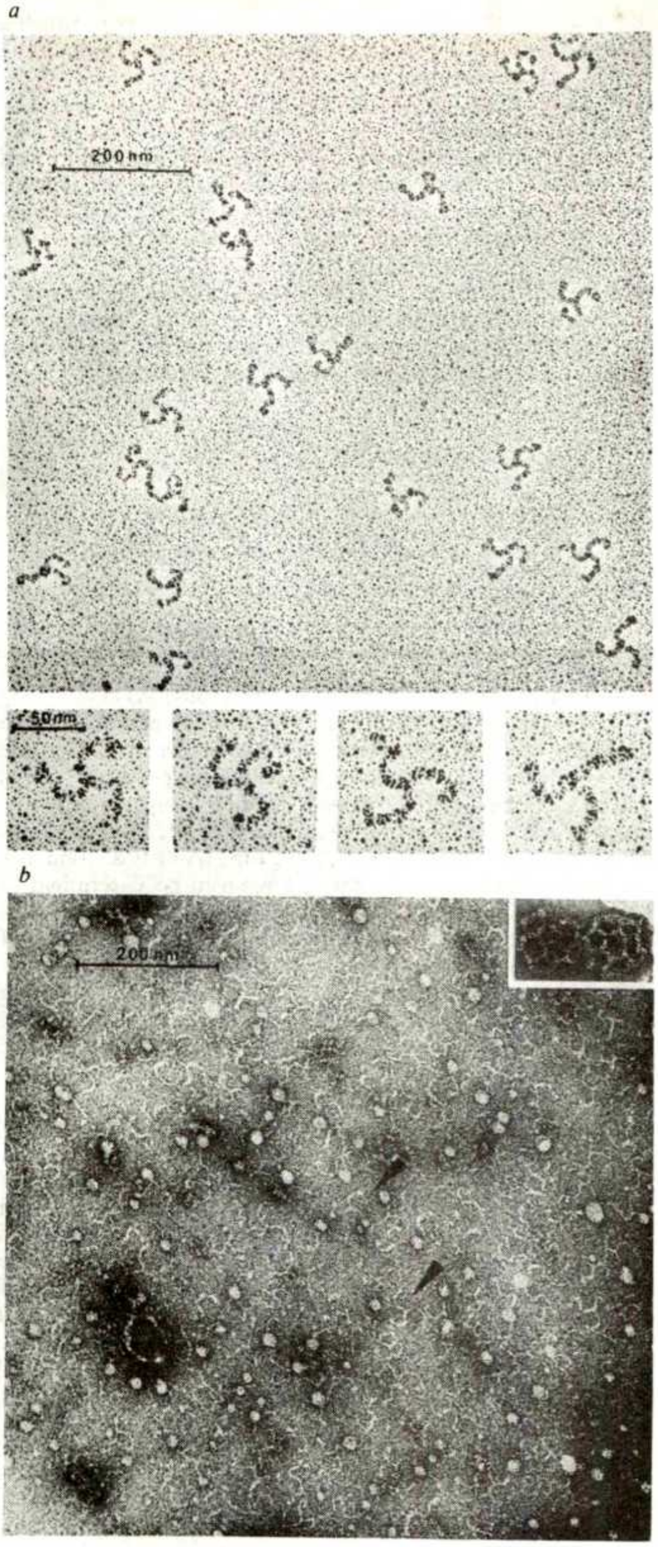

Fig. 3 Electron micrographs of 8.4 *s* clathrin triskelions, after *a*, rotary shadowing and *b*, negative staining with uranyl acetate. For rotary shadowing, dissociated clathrin coats (20 μg ml^{-1}) in 50 mM triethanolamine, *p*H 8.3, were mixed at room temperature with two volumes of glycerol and sprayed onto freshly cleaved mica. The molecules were then dried at room temperature under vacuum in a Balzers freeze-etch device, rotary-shadowed at an angle of 4.5° with Pt/C and coated from above with pure carbon (for details of method see ref. 11). For negative staining dissociated clathrin coats in 0.3 mM Tris-HCl, *pH* 8.0 (20 μg ml^{-1}) were applied to Formvar- and carbon-coated grids and negatively stained with 1% uranyl acetate. Arrows in *b* mark structures which resemble those seen in *a*. Inset in *b* shows coats reassembled from purified triskelions after dialysis against buffer A. All specimens were examined in a Philips EM 301 electron microscope at 80 kV. *a*, ×90,000 and 180,000; *b*, ×90,000.

gels has almost the same electrophoretic mobility as actin (43,000 MW) (ref. 8 and Fig. 2). In contrast, the clathrin light chains which ran with apparent molecular weights of 36,000 and 33,000 in SDS did not show a low electrophoretic mobility in SDS gels containing urea (Fig. 2). From this observation and from results of one-dimensional peptide maps (not shown) we conclude that the light chains and brain tropomyosin are not closely related proteins.

Analytical ultracentrifugation showed that the purified clathrin–light chain complex had a sedimentation coefficient, $s_{20,w}$, of 8.4 in 50 mM triethanolamine, 20 mM sodium chloride, 1 mM EDTA at *p*H 8.3. On dialysis against 0.1 M 2-(*N*-morpholino)-ethanesulphonic acid, 0.5 mM magnesium chloride, 0.2 mM EGTA and 0.002% sodium azide, *p*H 6.5 (buffer A), the 8.4 *s* material formed typical coats or baskets with relatively uniform diameters of ~800 Å (Fig. 3*b* inset). In several reassembly experiments, 75–93% of the total protein was recovered in the pelleted baskets after centrifugation at 100,000*g* for 1 h. The polypeptide composition of the pellets was identical to that of the starting material.

After rotary shadowing or negative staining, the 8.4 *s* material appeared as triskelions with a mean leg length of 445 Å ± 23 (s.d.). The legs in most of the molecules showed a preferred direction of curvature. When the curvature was sharp, it was located ~190 Å from the centre point where the three legs join. At higher magnification each leg seems to be composed of two strands which are twisted around each other and which seem to form a hairpin loop at the end.

The molecular weight of triskelions was determined by electron microscopy[12] and sedimentation equilibrium. For electron microscopy we mixed triskelions at a known weight concentration (determined by colorimetric micro-Kjeldahl analysis[13] using a nitrogen factor of 6.33 (ref. 14)) with myosin (at a known weight concentration), and counted the ratio of triskelions to myosin molecules in electron micrographs of droplets that had been dried and rotary shadowed. The estimated molecular weight was 627,000 ± 55,000 (s.d.; total number of particles counted was ~2,000). For sedimentation equilibrium the high-speed Yphantis method was used[15]. An apparent molecular weight of 630,000 was calculated from the plot in Fig. 4.

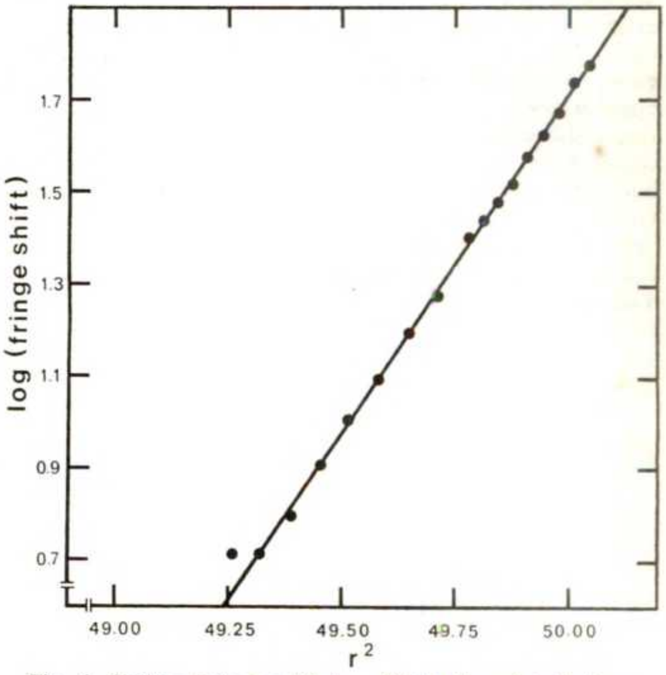

Fig. 4 Sedimentation equilibrium distribution of triskelions. Sedimentation equilibria were performed by the high speed method[15], with the use of the Rayleigh interference optical system in a Spinco model E ultracentrifuge at 9,341 r.p.m. and 9.1 °C. The protein concentration was 0.5 mg ml^{-1}, and the partial specific volume calculated from the amino acid composition was 0.75 cm^3 g^{-1} (ref. 14).

Assuming a 180,000 MW for a single clathrin polypeptide[1], the most straightforward interpretation of our data is that triskelions comprise three clathrin monomers and probably three light chains. We do not know whether a single triskelion contains both the 36,000 and 33,000 MW light chains. Because triskelions are stable molecular structures observed in various conditions, it is probable that other investigators studying the properties of dissociated clathrin coats have been dealing with triskelions (for example, the 8.8 *s* preparation of Puszkin and coworkers[16,17]).

According to Crowther *et al.*[18], a clathrin coat which is constructed of 8 hexagons and 12 pentagons (36 vertices) contains approximately 100 clathrin monomers. This suggests that each vertex in the coat is the centre of a triskelion. A triskelion leg is long enough to span two edges of the polygons that make up the coat[10,18] but other arrangements in which a portion of each leg could extend out of the coat towards the contained vesicle cannot be excluded.

We thank F. Marty, A. Verkleij, D. Caspar, S. Lehrer and D. Siegel for encouragement and discussions, W. Gratzer for help with the hydrodynamic measurements (which were performed at the MRC Cell Biophysics Unit in London), and Ken Giedd for technical assistance. E.U. was supported by a Training Grant from the Deutsche Forschungsgemeinschaft; the research was supported by NIH grant GM 20396.

Note added in proof: T. Kirchhausen and S. C. Harrison (Harvard) have recently shown by cross-linking experiments that the 8 *s* species contains three heavy chains, each in close contact with a light chain (manuscript submitted for publication).

Disulphide bonds of haemagglutinin of Asian influenza virus

Michael Waterfield & Geoffrey Scrace

Imperial Cancer Research Fund Laboratories, Lincoln's Inn Fields,
London WC2A 3PX, UK

John Skehel

National Institute for Medical Research, Mill Hill,
London NW7 1AA, UK

The complete amino acid sequences of the haemagglutinins (HAs) of one strain of each of the Hav1 and H2 subtypes and of three strains of the H3 subtype of influenza virus have been established[1–3]. A large external fragment (BHA) of HA can be released from virus particles using the protease bromelain[4] that cleaves the protein close to its carboxyl terminus, which is inserted in the virus membrane (see Fig 1). Here we show that a single disulphide bond joins the two component polypeptide chains BHA_1 and BHA_2 and establish the location of five intrachain disulphides. These disulphide bonds have been located in the three-dimensional structure of HA which is known to 3 Å resolution[5,6].

Sequence analysis of HA of infectious A/Japan/305/57(H2N1) shows that the subunit contains 546 amino acids, 16 of which are half-cystine residues[3]. Analyses of BHA_1 and BHA_2 calculated as 324 and 170 residues respectively[7] reveal 9.1 and 2.9 half-cystine residues in these polypeptides. The precise location of the bromelain cleavage site(s) is unknown because the enzyme does not cleave the HA of this strain at a single site. However, cleavage is known to be C-terminal to half-cystine 473 in BHA_2 (ref. 8). Established sequence data suggest that four of the 16 half-cystines are in the C terminus of HA_2, which is removed by bromelain treatment. Alkylation of half-cystine residues of BHA in 6 M guanidine hydrochloride using ^{14}C-iodoacetamide failed to reveal any free sulphydryl groups, thus all the 12 half-cystines in BHA must exist in disulphide bonds.

To locate the half-cystines linked by disulphide bonds, fragments containing cystine residues were purified. BHA was first cleaved with cyanogen bromide and fragments fractionated by size using gel permeation HPLC (Fig. 1). Amino acid analyses of performic acid-oxidized aliquots showed that peaks A, B, C and D contained cysteic acid. SDS polyacrylamide gel analysis showed that peak A contained a mixture of partial cleavage products. Aliquots of material in the incompletely resolved peaks B and C were fully reduced with dithiothreitol and component polypeptides analysed by gel permeation HPLC

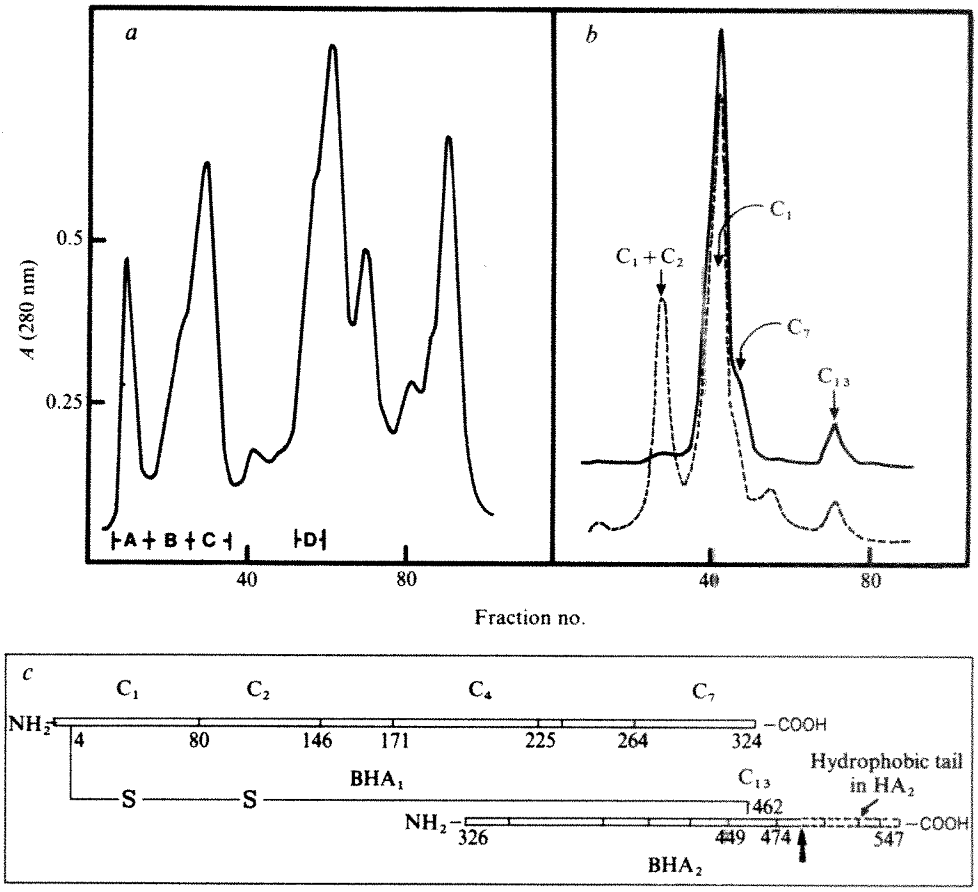

Fig. 1 Fractionation of the CNBr fragments of BHA by gel permeation HPLC. *a*, Separation of peptides from intact BHA. *b*, Separation of peptides released from peak B (——) and peak C (– – –) after full reduction and alkylation. BHA (100 nmol) was prepared from virus grown in the allantoic cavity of eggs[12], cleaved with CNBr in 70% formic acid for 24 h and directly injected in 4 aliquots onto two Waters I–125 columns run in series using a Waters M6000A pump and M450 detector (Milford). Columns were run in 6 M urea containing 0.2 M formic acid at 0.5 ml min^{-1} and monitored for absorbance at 280 nm; 0.5-ml fractions were collected and combined to give peaks A, B, C and D (*a*). Material in peaks B and C was deslated by dialysis or by absorption to Sep-Pak cartridges[13], fully reduced and alkylated in 6 M guanidine at *p*H 8.5 (ref. 12) and directly re-injected onto the gel permeation columns (*b*). Fractions corresponding to absorbance peaks were pooled, urea removed, and amino acid compositions and amino-terminal sequences determined using methods described elsewhere[7–9,12]. CNBr peptides C_1, C_2, C_7 and C_{13} were identified. *c*, Line drawing of the location of sites of CNBr cleavage of HA and the numbering of the half-cystines in fragments referred to in the text. The arrow indicates the approximate site of cleavage by bromelain. For the sake of clarity the original nomenclature[7] has been changed. Thus, here the partial cleavage product (C_1+C_2), and peptides C_1, C_2, C_4, C_7 and C_{13} correspond to BHA_1-C_1, BHA_1-C_2, BHA_1-C_4, BHA_1-C_3 and BHA_2-C_4, respectively, in Waterfield *et al.*[7].

(Fig. 1*b*). Appropriate fractions were pooled and the amino acid composition and amino-terminal sequence determined. Previous studies on the cyanogen bromide (CNBr) cleavage products of BHA_1 (refs 7, 8) and BHA_2 (ref. 9), knowledge of the complete amino acid sequence[3] and amino-terminal sequence analysis using methods described elsewhere[7,9] allowed us to establish the identity of the disulphide-linked fragments. Figure 1*c* shows the location of CNBr cleavages. Previous studies have shown that a partial CNBr cleavage occurs between residues 80 and 81 at a Met–Glu bond. This partial cleavage results in formation of a fragment containing C_1 joined to C_2. Peak B contained the partial cleavage fragment (C_1+C_2), fragment C_1 (which results from complete cleavage), the C-terminal fragment C_7 of BHA_1 and fragment C_{13} of BHA_2. Complete cleavage had occurred in the material eluted in peak C. After full reduction and re-chromatography, peak C was shown to contain peptides C_1 and C_7 of BHA_1 and C_{13} of BHA_2 (Fig. 1*b*). Peak D was found to contain a mixture of fragments C_2 and C_4 of BHA_1. Fragment C_4 is known to contain no half-cystine residues.

These results suggested that peptide C_2 of BHA_1 contained an intrachain disulphide bond and C_1 and C_7 of BHA_1 were linked to C_{13} in BHA_2.

CNBr fragment B was digested with *Staphylococcus aureus* V8 protease and the whole digest fractionated by reverse-phase HPLC on a C8 column (Fig. 2*a*). Fractions corresponding to optical density peaks were pooled, aliquots oxidized with performic acid and amino acid analyses carried out to locate half-cystine-containing peptides. A second portion of the V8 digest was further digested with trypsin and chromatographed and analysed in identical conditions (Fig. 2*b*). The amino acid compositions of pooled fractions containing half-cystine are given in Table 1 and the peptides can be located in Fig. 3 by the residue numbers of the half-cystine residues.

Two V8 peptides (A and B) which eluted at the end of the reverse-phase column run were identified by amino acid composition, using the single letter code of Dayhoff[10], as

(A) LGDCSIAGWLLGNPECDRLLSVPE
55 67

301
CPKYVKSE
|
(B) TKCQTPLGAINTTLPFHNVHPLTIGE
277

Further digestion with trypsin allowed identification of a tryptic cleavage fragment (C) which was derived from the V8 peptide (A). The V8 peptide (B) was recovered as peptide (D) after tryptic cleavage:

(C) LGDCSIAGWLLGNPECDR
55 67

301
CPK
|
(D) TKCQTPLGAINTTLPFHNVHPLTIGE
277

It was also possible to identify the following peptide (E)

4
(E) DQICIGYHANNSTE
|
LGNGCFEFYHK
462

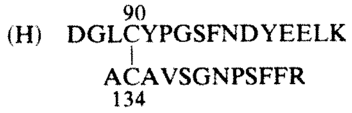
Re-chromatography of the digest using a flow rate of 0.5 ml min^{-1} allowed resolution of the peptides eluted early and made it possible to identify (F) and (G):

469
(F) CDDE
|
CM
473

42
(G) LCK
|
GTLENCE
273

These peptides allowed assignment of the single interchain bond which joins half-cystines 4 of BHA_1 and 462 of BHA_2 and also the assignment of intrachain disulphides between half-cystine residues 42 and 273, 55 and 67, 277 and 301 of BHA_1 and between 469 and 473 in BHA_2.

Assignment of the intrachain disulphide bond in CNBr peptide C_2 of BHA_1 was made by fractionation of a tryptic digest of a mixture of C_2 and C_4 which had been purified as peak D by gel permeation HPLC. The elution profile is shown in Fig. 2*c* and the composition of peptide (H), recovered in peak H, is given in Table 1. This compositional analysis confirmed the location of a disulphide bond between half-cystines 90 and 134:



$$\text{(H)}\ \begin{array}{l}\text{DGL}\overset{90}{\text{C}}\text{YPGSFNDYEELK}\\ \quad\ \ |\\ \text{A}\underset{134}{\text{C}}\text{AVSGNPSFFR}\end{array}$$

The peptides isolated from BHA allow the assignment of disulphide bonds which link the twelve half-cystine residues of BHA. The results are summarized in Fig. 3. A similar study of the disulphide bonds of the haemagglutinin from Hong Kong virus A/Memphis/102/72 (H3N2) has been reported by Dopheide and Ward[11] who present evidence that half-cystine 139 of HA_1 is linked to half-cystine 472 in HA_2 in the H3 strain and suggest that residue 97 may be linked to residue 476. Our results show that half-cystine residues homologous to those at positions 139, 97, 472 and 476 are arranged differently in the H2 virus HA. Because the position of half-cystine residues is highly conserved in haemagglutinins of viruses of both subtypes[3] it is unlikely that the disulphide bonds differ. Analyses of the three-dimensional structure of the BHA fragment from an H3 virus (X-31) indicates a single interchain bond[5] and it is likely that methodological difficulties remain to be resolved in the analysis of the disulphide-linked thermolytic peptides isolated by Dopheide and Ward[11]. In agreement with their results, we assign an interchain bond between half-cystine residues 14 of HA_1 and 465 in HA_2 in the H3 strain, which are homologous with residues 4 of BHA_1 and 462 in BHA_2 in the H2 strain. Our results also agree with those of Dopheide and Ward[11] in the placement of intrachain disulphides between half-cystines at residues 52 and 277, 64 and 76, and 281 and 305 in HA_1 of the H3 strain, which are homologous to disulphides in HA_1 of the H2 strain which link residues 42 and 273, 55 and 67 and 277 and 301.

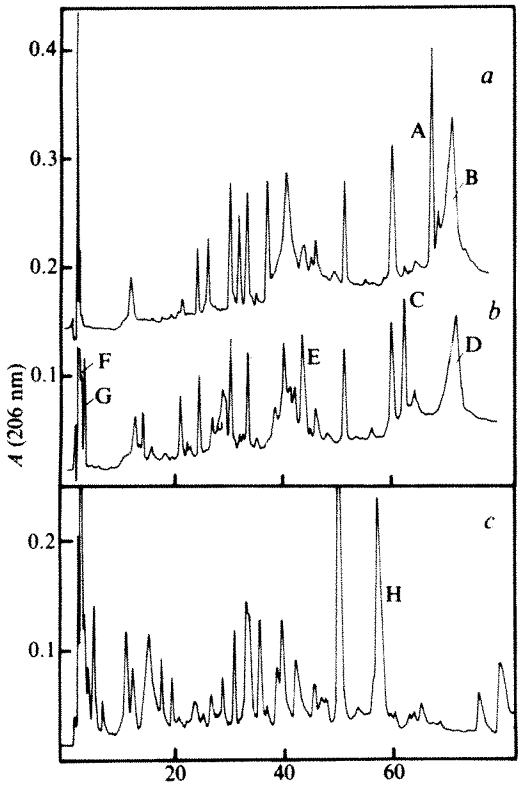


Fig. 2 Separation of enzymatic digests of disulphide-containing CNBr fragments by reverse-phase HPLC. Fragment C (purified as described in Fig. 1 legend) was digested with *S. aureus* V8 protease (70 nmol, enzyme/substrate 1:18) in 0.1 M ammonium bicarbonate buffer for 18 h and directly injected onto a Dupont Zorbax C8 column which was eluted with a gradient of acetonitrile in 10 mM ammonium acetate buffer, *p*H 6.5 (ref. 13). *a*, Column effluent was monitored for absorbance at 280 and 206 nm using two Uvicord S monitors (LKB Instruments) equipped with HPLC flow cells. Fractions (0.75 ml) were collected, peaks pooled by optical density and aliquots oxidized with performic acid and the amino acid composition determined. *b*, An aliquot of the V8 digest was further digested with trypsin (enzyme substrate 2% by weight) and analysed by the same methods. Material from pool D (see Fig. 1) was digested with 2% trypsin (by weight) and analysed by chromatography on Zarbox C8 as described for pool C. *c*, Separation of tryptic peptides. Peptides with disulphide bonds are indicated by letters referred to in the text.

Fig. 3 The disulphide bonds of the bromelain-released fragments of the haemagglutinin of A/Japan 305/57 (H2N1). * Indicates the attachment site for carbohydrate side chains.

The results presented here establish disulphide bonds for the region of HA which is external to the membrane of the virus. A further four half-cystine residues are located near the C terminus of the HA of A/Japan 305/57(H2N1)—two of these are conserved in the HAs of all strains examined (543 and 546)[3]. These half-cystines may be located inside the virus particle, below the lipid bilayer because N-terminal to these residues there is a 26–30-residue hydrophobic sequence that would be expected to cross the lipid bilayer. The remaining two half-cystines of this HA, which are not conserved in other strains, may simply serve as hydrophobic or uncharged amino acides. Whether these four half-cystines are disulphide bonded remains to be established. The contribution of the disulphide bonds to the three-dimensional structure of the HA is described by Wilson *et al.*[6].

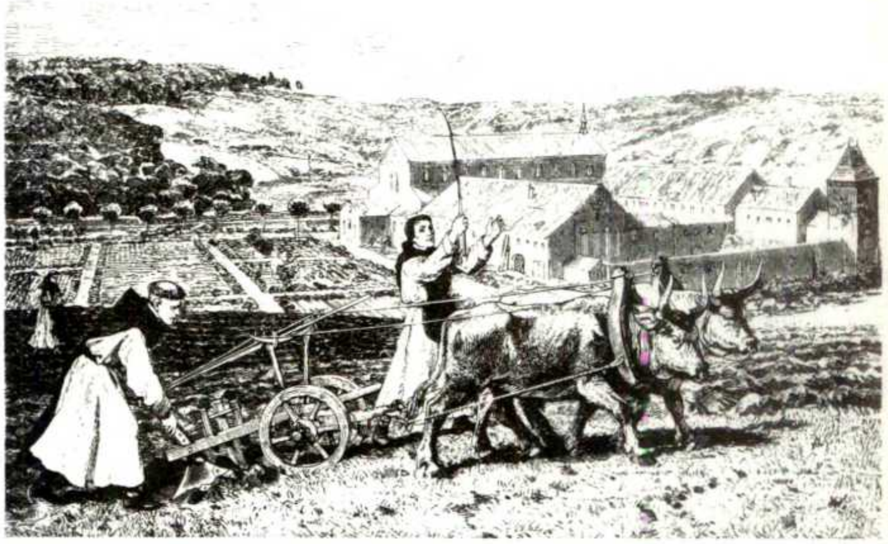
BOOK REVIEWS

Swimming against the tide

Eric Ashby

The Politics of Self-Sufficiency. By Michael Allaby and Peter Bunyard. Pp.242. (Oxford University Press: 1980.) Hbk £7.95, $24.95; pbk £3.95.



Self-sufficiency in the Middle Ages — how viable today?

IF YOU see someone swimming against the tide, watch him. He may sink without trace; he may bring ashore a new idea. It is in this spirit that I commend this duet by Michael Allaby and Peter Bunyard. A duet? Yes, for in each chapter first one author, then the other, has his say. The two authors agree in principle that self-sufficiency in a Good Thing. They do not agree about the way in which self-sufficiency might be achieved nor about the part it might play in Western industrial society.

On the first page the authors define what they are writing about. It is not the self-sufficiency of pioneers colonizing a hostile environment, often by a ruthless exploitation of nature; it is self-sufficiency as an alternative "lifestyle": the community which grows its own food (preferably without artificial manures), generates its own energy (or some of it) from sunlight and the burning of timber, disposes of its own wastes, imports such things as it cannot make in exchange for its own surplus, by barter, not money. There are already little communities of this kind in Britain, and the Israeli kibbutz and Chinese commune are viable versions of a similar idea. Indeed, if one is looking for historical precedents for self-sufficiency, the mediaeval monastery is surely an impressive example.

The self-sufficient community, like the monastic community, can be sustained as a minority way of life in an industrial pluralistic democracy. It is when enthusiasts for self-sufficiency urge us to make it a majority way of life that doubts arise. All sorts of awkward questions have to be answered. Is it, in any case, a "better" lifestyle? Could such a lifestyle be sustained by the minorities who enjoy it if they were not embedded in a conventional capitalist society which can come to their rescue when they need to travel, to listen to music, to get medical attention, to type and publish books such as this one, to replace tools? And, since this is a book about the politics of self-sufficiency, under what kind of political system could self-sufficiency ever become a majority lifestyle?

The virtue of the book is that it does examine these questions honestly. It considers the prospects for a mass-movement toward self-sufficiency. The prophets have to step warily between the ideologies of anarchy on one side and fascism on the other. Except for hermits, self-sufficiency implies co-operation, and "the moment a group of people act collectively they cease to act anarchically". So the self-sufficient society would have to submit itself to some sort of government. If it is to be a government which rejects an economic system based on motives of profit, then "the economy itself would be changed from a market to a command type. The injunction to industrialists would no longer be the simple 'Be profitable!' but the much more complex 'Make this, but not that'." The only known patterns of government capable of behaving this way are far-left or far-right dictatorships. The authors don't relish either of these. They seek a middle way: some communal ownership of property; some concession to the fact (which they freely admit) that an atavistic retreat to a bucolic past is simply not on; some compromise with the harsh reality of the human condition, which is that greed, selfishness and love of comfort are majority attitudes, and that beneficence, self-denial and austerity are likely to remain minority attitudes. They adduce plenty of evidence that small communities can — and some do — drastically reduce their reliance upon the products of industrial society, and consume much less per capita than the average consumption of the limited resources of nature. They make the point clearly that they do not consider self-sufficiency to be a middle class élitist indulgence or a highbrow name for drop-outs. Self-sufficiency is a deep — they call it a "spiritual" — protest against a way of life which is carrying us out on a tidal current to God knows what dangers.

Anyone who seriously contemplates self-sufficiency in political terms had better stand at Waterloo Station in the rush hour and ask himself exactly how any political movement is going to lead this surge of commuters into such a different lifestyle, and ensure that they are adequately fed, sheltered and kept warm in (say) the idyllic conditions of rural Devon and Cornwall. (And, incidentally, ask himself what would happen to Devon and Cornwall if such a miracle occurred.) But this would be a slick and insensitive way to end this review: for there is one important conclusion to be drawn from this book, though it may not be a conclusion the authors approve. It is that little self-sufficient communities such as Allaby and Bunyard describe have an important part to play in contemporary Britain. Like monasteries in the Dark Ages, they affirm that there is another, and perhaps a better, way to live than the way most people live and that it is not out of reach. They are not composed of cranks. They are men and women who believe in swimming against the tide. They may sink without trace. But, like monasteries in the Dark Ages, they may carry the seeds for a new kind of civilization, one able to transform the taint of unemployment into the boon of leisure for those without work, and the drudgery of attending an assembly line for the satisfaction of manual labour for those who have work. □

Health risk: just a guessing game?

T. A. Connors

Ethylene Dichloride: A Potential Health Risk? 5th Banbury Report. Edited by B. Ames, P. Infante and R. Reitz. Pp.350. (Cold Spring Harbor Laboratory: 1980.) $45, $54 outside USA.

"WELL, *is* ethylene dichloride a health risk?" is the question that comes to mind after reading this book. The comment does not imply any specific criticism of the report but rather sums up our present knowledge of the toxicology of a wide variety of chemicals to which human beings are exposed. We suspect from animal and other laboratory tests that many chemicals may be a risk to human health as carcinogens, teratogens, mutagens and so on, but we do not have reliable methods to determine whether there is an actual risk in any situation or what the degree of that risk may be.

Ethylene dichloride is a very important chemical indeed, the US production in 1977 amounting to 11,000 million pounds in weight. It is used mainly as an intermediate, so most high-level exposure is in the chemical industry, but significant amounts are also used in the textile and food industries and in agriculture, for example. The possibility that ethylene dichloride might be carcinogenic was first suggested when it was shown to be mutagenic in bacteria. In a large international study, tests of this type have been shown — at least for certain classes of chemical — to correlate reasonably well with animal carcinogenicity tests which in turn have given positive results for most human carcinogens identified by epidemiological or case control studies. This Banbury Report summarizes what is known of the toxicology of ethylene dichloride and one learns that it can be metabolized *in vivo* to an alkylating agent which can react with DNA and initiate the events that many people think can lead to cancer. One also learns that other short-term tests, using *Drosophila* and yeast, for example, have given positive results and that the chemical, like many of its congeners, is carcinogenic in rats and mice. However not all of the data are unequivocal. In a well-controlled study, Maltoni and his colleagues could find no evidence for the carcinogenicity of ethylene dichloride in rats and they question the validity of earlier studies from a number of aspects including "the professionality of the team carrying on treatment, control of animals and autopsies". Furthermore, no teratogenicity or major reproductive toxicity was found either in animals or in exposed workers, nor was there any evidence of an increased incidence of cancer in workers exposed to ethylene dichloride for 20 years or more.

All in all the book is a wonderful miniature of the multidisciplinary field of toxicology and the problems that arise in interpreting data from different types of test, in choosing between conflicting results and in attempting to assess the risk to human beings. Although scientists, as in this report, are to be commended for attempting to measure carcinogenic potency and to quantify risk, the equation contains so many unknowns that the assessed level of risk must be seen to be based on a working hypothesis with many assumptions rather than as the result of an extrapolation based on scientifically reliable methods. It follows then that in making the decision to restrict a chemical, to replace it with "safer" alternatives or to ban it altogether, economic and social argument must be considered as well as the scientific aspects. There is concern that a number of chemicals which have been used for many years and considered to be safe because there was no acute toxicity associated with exposure, may nevertheless be highly dangerous in the long term. The Banbury Report, with contributions from industrialists, government scientists and university researchers, shows how widespread this concern is, but until animal experiments can be related to human situations the debate on the dangers of chemicals will continue.

However, there has already been one welcome outcome. Workers are nowadays exposed to less dirty, dusty and smelly conditions than even a few years ago, while urban environments are certainly more wholesome than they once were. Whatever the effects may be on the cancer incidence only time will tell; but for those people who believe that quality of life is at least as important as quantity of life then there is already a vast improvement. □

Catastrophes for starters

Colin Upstill

An Introduction to Catastrophe Theory. By P.T. Saunders. Pp.144. (Cambridge University Press: 1980.) Hbk £9.50, $27.50; pbk £3.25, $8.95.

ALL previous introductions to catastrophe theory have been either popularizations, devoid of any serious mathematics and often riddled with falsehoods, or works of considerable mathematical sophistication. This book succeeds in filling the gap between these extremes. It divides naturally into two parts. The first is an exposition of the theory, which deals with the singularities of smooth real valued functions, using only a limited mathematical vocabulary yet not glossing over anything of importance: structural stability, equivalence, the splitting lemma, determinism and universal unfoldings are all explained as clearly as one could wish. The second half of the book gives the flavour of applications of the theory by way of a selection of examples from the physical, social and biological sciences, all of which are to be found discussed in much greater detail elsewhere in the literature. The author is careful not to exaggerate the status of catastrophe theoretic models in the social and biological sciences, and concludes with a lucid discussion of the explanatory powers of the theory and some cautionary words on appropriate standards of judgement of applications in different disciplines.

My enthusiasm is not unqualified, however. Central to catastrophe theory are the geometries of the catastrophes themselves, so it is inexcusable that their illustration in this book leaves something to be desired. Most of the relevant figures are slavishly and uncritically copied, with due acknowledgement, from the book by Bröcker and Lander (*Differentiable Germs and Catastrophes*; Cambridge University Press, 1975); some include labelling in a nomenclature incompatible with that used in Saunders's text, others include construction lines which are here irrelevant and unexplained, or fail to display the nature of the singularity at the origin of control space. Where the drawings are original, similar lack of care is evident. At the hyperbolic umbilic singularity, the rib (cusped edge) and the fold touch parabolically, yet here they are depicted as intersecting straight lines; the sketch of the lips event is quite dreadful.

The text does not suffer from any such sloppiness, but there are some omissions which are surprising in such a recent publication. Most notable is the absence of any reference to the work of the Russian mathematician V.I. Arnol'd, who is responsible for the enormous extension of Thom's classification to catastrophes of codimension >4, and for a rational system of symbols to label the catastrophes, which Saunders eschews — the Thomist "pet names" are fine if one is only considering a few low-dimensional catastrophes, but things get out of hand as the dimensionality and number of catastrophes in the list increases. Explanations of the role of higher dimensional catastrophes as organizing centres and of the importance of compact catastrophes in applications would not come amiss; neither would some discussion of (or at least references to) recent vociferous criticisms of some applications of catastrophe theory in the social and biological sciences.

In a rapidly expanding subject it is inevitable that any book will be out of date as soon as it is published. However, much of this book could have been written four years ago. Whilst there is no claim to define the "state of the art", it is an uneven treatment, to say the least, that for some applications covers material from one or two expository works of several years ago, but for others refers to a quantity of very specialized material of recent date. One is forced to conclude that the author has made no great effort to acquaint himself with recent work outside his own particular interests, which is a pity, because as a result he has written a good book when he could have written a superb one.

Colin Upstill is a Research Fellow at the H.H. Wills Physics Laboratory, University of Bristol.

Potpourri of nuclear structure theory

J. M. Irvine

Nuclear Spectroscopy. Lecture Notes in Physics, 119. Edited by G. F. Bertsch and D. Kurath. Pp.250. (Springer-Verlag: 1980.) DM33, $19.50.

THE Gull Lake workshop on nuclear spectroscopy, held in the summer of 1979, reviewed most of the basic topics in theoretical nuclear structure physics. This book is a record of the deliberations of the participants.

The opening chapter by Gerry Brown takes us through the familiar analysis of the meson exchange nature of nuclear forces, linking it to the quark structure of the nucleon in the "little bag model" of Brown and Rho. The Brueckner–Bethe and Landau–Migdal theories of effective interactions are developed and the predictions for the bulk properties of nuclear matter presented. In other interesting papers, Dieter Kurath presents an introduction to the nuclear shell-model which is novel in that it includes a short discussion of the current shell-model computer codes, and George Bertsch discusses nuclear vibrations — both in the random phase approximation and Landau formalisms — and presents an up-to-date account of the new giant resonances. Amand Faessler gives a unified account of deformed and transitional nuclei. Concentrating first on high spin states in deformed nuclei, he discusses the "backbending" phenomena and the nature of Yrast traps, and goes on to give an account of the breakdown of pairing due to the Coriolis force in transitional nuclei. Franco Iachello describes the use of group theory in the analysis of nuclear spectroscopy with a natural emphasis on the successes of the interacting boson approximation.

The use of statistical analysis in describing complex spectroscopies has been advocated for a long time. At last there are signs that it is being put to use in nuclear physics and it is appropriate that the field should here be reviewed by J. B. French. Finally, there is an interesting appendix by Bertsch, Zamick and Mekjian which highlights some of the unsolved theoretical puzzles which abound in nuclear structure physics.

I found this an exceptionally readable account of current topics in nuclear theory. The level of presentation of the material is remarkably uniform for a multi-author volume. I am sure that students and research workers in the field will find this a useful addition to their bookshelves. □

J. M. Irvine is Reader in Theoretical Physics at The University of Manchester.

Various vectors and plant diseases

G. D. Heathcote

Vectors of Plant Pathogens. Edited by Kerry F. Harris and Karl Maramorosch. Pp.467. (Academic: 1980.) £27, $48.

THIS book succeeds admirably in what it sets out to do, providing much detailed, up-to-date information on the interrelationships of many plant pathogens, their plant hosts and various vectors. It is third in a series of four volumes being published on this general topic. The earlier volumes were concerned with aphids and leaf-hoppers, and, although the first chapter of this volume is devoted to pathogen–vector relationships within these groups of insects, most of the current book is concerned with other, generally less well-known vectors. These range from mealybugs, to fungi and to nematodes where, although the relationships may be equally close and complex, they can be non-obligate and accidental, as with dipterous flies and many bacterial plant pathogens.

The book clearly points out the wide gaps in our knowledge and understanding of this subject. Many chapters end with questions for the reader or indicate need for further study. One contribution is even devoted to the search for the vector of a disease (lethal yellowing of coconut palm) where the very nature of the pathogen is still uncertain, although the reader may assume it to be a mycoplasma-like organism (MLO); a cixiid bug appears to be the most likely candidate as the vector.

The 13 chapters are written by different specialists, or groups of specialists who were clearly given a free hand and who have very different styles of writing. This variation in style adds to the interest but perhaps the editors might have tied the volume together a little more closely.

This thought-provoking book contains many references and will be of value and interest to researchers as well as to students and teachers. For example, how many of us have considered the possibility of a link between the use of mustard gas in the First World War and the recent spread of Dutch elm disease? The book suggests one. □

G. D. Heathcote is at Broom's Barn Experimental Station, Higham, Bury St Edmunds, Suffolk, and works on transmission of viruses by aphids.

Seabird synthesis

J.B. Nelson

Behavior of Marine Animals. Vol.4, Marine Birds. Edited by J. Burger, B.L. Olla and H.E. Winn. Pp.515. (Plenum: 1980.) £28.35, $54.

STUDENTS of seabirds will warmly welcome this fine and wide-ranging compilation of data, ideas and references. Many important aspects of breeding biology such as choice of habitat, mate-selection, various factors and strategies relating to breeding success and the nature of communication behaviour are excellently reviewed. These articles form the core of the book but three others (seabirds at sea, the distribution of gulls in North America and, somewhat oddly placed, chemoreception in seabirds) stand outside this major theme.

Systematic use of headings and subheadings produces welcome internal consistency within the volume but, in view of inevitable omissions in such a wide-ranging and essentially review work (references average 148 per article, excluding that by Southern), space could have been saved by editorial restrictions on the text authors devote to their own research. As it is, several contributors suddenly abandon the review style and launch into detailed and specialized exposition. Undoubtedly, though, seabird workers will warmly welcome this work as evidence that their research, despite its heterogeneous and incomplete nature, nevertheless engenders valuable syntheses. Seabird studies, as one might expect after two highly productive decades, are moving away from general data gathering and towards more detailed investigations of specific problems. These contributions point the way to many such areas. Perhaps the chief merit of the book lies in its discussion of the relevance of this mass of work to well-recognized problems, and in the clarification of these problems, rather than in the formulation of new concepts. Old terms, hitherto loosely and confusingly employed — for instance synchrony, colony, fledging, starvation period, display, social stimulation and the Darling effect — are carefully dissected. Again, nowhere else in all the seabird literature can one find a properly detailed discussion of the effect of age on breeding success. As an example of "properly detailed" there is Burger's Table II, which gives information individually for 86 species under 10 subject headings.

Yet there are fundamental concepts, affecting most of these subjects, which receive no critical attention. I would have welcomed a thorough review of the concept of direct, density-dependent competition which I am convinced often does not operate among seabirds. Within the constraints of this volume, no single contributor could have tackled the subject of the regulation of seabird populations, but there are reliable and reviewable field data which bear directly on the validity of density-dependent regulation in seabirds.

Among the many ideas canvassed, I liked Hunt's emphasis on the need to distinguish a lifetime's reproductive output from that of any one year, an important but rather inaccessible statistic when considering the reproductive strategies so beloved of today's theoreticians. Ryder's excellent summary of age-effects brings out the intriguing phenomenon of reduced success in old individuals. In related vein, Montevecchi and Porter indicate the minimum detail which must be obtained on time and energy budgets before one can begin to theorize about optimal use of resources. They emphasize, as does Gochfield, what I too have suggested, that for many seabirds, especially males, the costliest part of the reproductive cycle is not chick-rearing but the pre-laying stage when sites are established (or re-established) and courtship performed. Beer, bristling with ideas, emphasizes the importance of context on the form and function of display — a minefield of potential ambiguity. His article should be required reading for behaviourists, to steer them away from beguilingly simplistic approaches. But even he founders in the complexities inherent in the notion of "intention" in animals.

Gochfield must speak for many in his plea for adequate presentation of data (and he gives an excellent account of methods) to allow others to re-work them. Highly processed results may satisfy statisticians but are useless, except in a take-it or leave-it form, to the Indians.

Bridge-building is an important function of review articles and Brown diligently and perceptively connects the many scattered observations on birds at sea with some oceanographic data. Even so, the key words remain "broad outline" in his statement that "we now know in broad outline the pelagic distribution of the common seabirds in summer at least, in almost all the world's oceans". Many of his valuable references will be new to most ornithologists.

Throughout the book, and rightly so, functional interpretations are stressed, for it is essential to generate testable ideas about the adaptive significance of the intricate web of behaviour by means of which animals cope with environmental demands. ☐

J.B. Nelson is Reader in Zoology at the University of Aberdeen, and the author of Seabirds: Their Biology and Ecology, *published earlier this year by Hamlyn.*

The second of the six core volumes of the *Handbook of Applicable Mathematics* has been published by John Wiley (for review see *Nature* **288**, 37). Volume II, *Probability*, edited by Emlyn Lloyd, is available as a single volume at £32.50, $85. Subscription price for the core volumes is £27.50, $75.

Mass spectrometry for biochemists

Howard R. Morris

Biochemical Applications of Mass Spectrometry: First Supplementary Volume. Edited by George R. Waller and Otis C. Dermer. Pp.1,279. (Wiley-Interscience: 1980.) £79.80, $187.50.

THIS is the first supplementary volume of a previous work of the same title, and is a compendium of contributions by well-known authors in specialist fields. The chapters have been written at a level suitable for postgraduate students, and in general they provide useful background reading for the "layman", whether he be a newcomer to research in one of these fields, or a biochemist or biologist seeking a solution to a particular problem.

The editors predict in the preface that certain sections are unlikely to be comprehensive in content, and this is indeed so in a number of cases. For example, in the section on instrumentation there is, inexcusably, no reference to one of the most significant and highly relevant developments in the area of biochemical mass spectrometry, the high-field magnet. The new range of commercial instruments based upon this concept (giving high sensitivity operation up to m/e 1800 — "extended" — or m/e 3000 — "high-field") is of special interest and importance to the biochemist, since he is often dealing with small amounts of high-molecular-weight polar compounds.

A considerable portion of this large book is taken up with matters which are not *per se* biochemical mass spectrometry, such as basic principles, and a listing of the equipment in several different spectrometry laboratories. The choice of these laboratories would appear to be somewhat arbitrary, since a number of them are not noted for major contributions in the field of biochemistry. The validity of detailed descriptions of mass spectrometric data systems is in any event debatable for the intended audience. Similarly, in the section on interpretation of mass spectra, a series of methods and computerized techniques is given which, as far as one can tell, have not yet been applied to the solution of biochemical problems, and would therefore more properly have appeared in a subsequent volume.

In contrast, the section covering applications makes very worthwhile reading, since this is the real meat of biochemical mass spectrometry. The chapter on antibiotics is excellent, and that on proteins is commendably comprehensive, despite a few inevitable inaccuracies in the interpretation of some of the details of the work covered. Unfortunately, not all of the authors are so thorough; for example the section on tetrapyrroles is notable for its superficial coverage. Finally, the descriptions of some interesting new applications make enjoyable reading, in particular the extension of mass spectrometric techniques into the study of volatiles emitted by human beings; one might predict a rapid growth of interest in this area since the information provided would appear to be highly relevant to the physiological status of the body in both health and disease.

As a whole, *Biochemical Applications of Mass Spectrometry* is a useful and often stimulating reference work, providing the biochemical student or researcher with a basic background from which to make a more detailed exploration of the literature. ☐

Howard R. Morris is Professor of Biological Chemistry in the Department of Biochemistry at Imperial College, University of London.

Two views of the causes of cancers

What is the cause of cancer? This question has for the past half-century engaged physicians, biologists and laymen. It is, of course misstated. There is no one kind of cancer and no single cause. Readers of *Nature* will, however, have been struck by the contrast between the two substantial articles on the subject published in the past few weeks. Three weeks ago (*Nature* **289**, 127–130; 1981), Epstein and Swartz, under the title "Fallacies of lifestyle cancer theories", set out to demolish the earlier arguments of Peto (*Nature* **284**, 297; 1980), who had himself complained about Epstein's book *The Politics of Cancer.* The issue in dispute is the relative weight to be given to voluntary and involuntary sources of chemical pollution in the causation of human cancer, but there are also subsidiary disputes about questions such as the proper interpretation of the epidemiological data. Is there now an epidemic of cancer, or is it merely that more people are dying of cancer because there are fewer competing (or masking) causes of death? The second article, by Cairns (*Nature* **289**, 353–357), tackled almost the same question in a very different way. His objective was not to demonstrate causes but to point out the weaknesses of the mechanisms suggested in recent years as plausible explanations of how some kinds of cancers are caused. The truth, says Cairns, cannot be as simple as we would like to think. And much of what is said about the origin of cancer must be wrong.

How can these very different points of view and styles of argument be reconciled? Does it matter if they are not? And how should people, not simply specialists, approach the question of what causes cancer? Cairns's argument deserves the most careful reading, chiefly because it shows how intricate the question is. The biology of cancer is not fully explained by the now familiar model in which (the story goes) damage to a DNA strand in the chromosome of some somatic cell can, if the damage is appropriately placed, give rise to a clone of cancerous cells. The model has the virtue that it accommodates very different carcinogens — particle radiation and chemical carcinogens, for example. Fast particles can obviously damage DNA molecules physically. The metabolites of at least some chemical carcinogens include materials likely to react with DNA, with consequences that are plausibly similar. So such events may be first causes, in Hume's sense, of some kinds of cancer.

The model is useful, and should not be discarded. But it is also incomplete. It does not, for example, account for the length of the induction period for most kinds of cancer. If damage at a single point along a DNA strand can be a sufficient cause of cancer, why does not the cell thus affected instantly become the founding member of a cancerous clone of cells? And why is it that (as Cairns points out) such chromosomes of cancerous cells as can be seen are most often grossly abnormal in ways indicative of drastic rearrangement, not of a defect at a single point? The simple model of cancer causation can be elaborated to accommodate uncomfortable observations such as these. Conceivably, the induction period and the eventual appearance of gross chromosome abnormalities are both consequences of the need that a potentially cancerous clone of cells should evolve into a form no longer subject to the unknown restraints that normally inhibit competition between tissues within the same organism. Damaging a single point along the length of a DNA molecule may still be a sufficient cause of cancer. The chances are, however, that it is not. How else is it possible to account for the well-founded evidence that people differ genetically in their susceptibility to some kinds of cancer? And what, in any case, is to be made of Cairns's argument about the inherited disease xeroderma pigmentosum? The underlying trouble is a defect of the normal biochemical mechanism for repairing damaged DNA molecules. The observation that people afflicted with this genetic disease are prone to skin cancer and melanoma is consistent with the simple model. Ultraviolet light is a well known cause of damage to DNA molecules. But why are not the same people also more susceptible to other kinds of cancer caused by other carcinogenic agents? Cairns asks the question. Nobody knows the answer.

The implication of Cairns's arguments is clear and also depressingly familiar. The phenomenon of human cancer is a problem in biology which is not yet understood. It will be time enough to talk about causes when mechanisms have been worked out. That will require not merely more of the molecular biology and cell biology now supported by the cancer research agencies but also a better understanding of the processes of differentiation, the physiology of homeostasis and even of some long-standing issues in old-fashioned biology. The prospect is nevertheless far from hopeless and, as in other fields, there is no reason why the development of better means of treating cancer should wait on a full understanding of the mechanisms. But, for the time being, the causes of cancer in Cairns's sense are obscure.

How then can Epstein and Swartz pretend such confidence about the causes of cancer? Their starting point is that a cancer requires exposure to some carcinogenic agent, perhaps a chemical in the environment or some component of tobacco smoke. Their methods are epidemiological but not necessarily suspect on that account. Statistical analysis can establish relationships between causes and effects. Epidemiology has, for example, demonstrated the occupational hazards of vinyl chloride monomer. It is also now to be taken as a fact that people who smoke cigarettes are more likely than others to develop lung cancer. The habit of smoking cigarettes is thus in some sense a cause of lung cancer. The link is clear enough for individuals prudently not to smoke cigarettes and for governments to encourage abstention. Yet the habit of smoking is not a first cause of lung cancer. That distinction no doubt lies with a group of chemicals not yet conclusively demonstrated. The mechanism by which lung cancer develops is not known, with the result that there is even room for argument about the influence of unknown genetic factors in the development of the disease. Such difficulties do not of course vitiate the epidemiological approach to cancer. On the contrary, there is undoubtedly great benefit to be won, both in the recognition of specific hazards and in the wider understanding of the natural history of cancer. Prudent practitioners are, however, careful not to make too much of the associations they find between effects and their supposed causes.

Epstein and Swartz appear to be more than a little cavalier in their regard for that simple rule. The trouble seems to start from *The Politics of Cancer,* whose purpose was to argue that governments (but especially the United States government) should do more to regulate occupational and environmental carcinogens, and which has set the tone for much of the discussion that has followed. The purpose, of course, is entirely legitimate. It is the method that is suspect. Epstein, writing for a general audience, has assembled an impressive list of case studies of chemicals whose use has been implicated in cancer, accurately or otherwise. The more gentle among his readers have no doubt by now been persuaded that there is no hope of avoiding cancer while they continue to live in advanced societies such as America's. Some of them, perhaps for other reasons, will no doubt have

0028-0836/81/060431-02$01.00

embraced the conclusion that the chemical industry, by the scale of its recently increased manufacture of organic chemicals, has become the chief hazard. Yet many of the items in Epstein's indictment are, to say the least, disputable — the carcinogenicity of saccharin, for example, as Peto quite properly pointed out nearly a year ago. Epstein's comment on this point (*Nature* **289**, 115; 1981) implicitly confirms that view. The nature of his conclusion, and the clarity with which it is stated, seem entirely at odds with the simple rule that epidemiologists should acknowledge the possibility that their statistical association may be wrong. Self-doubt is not merely seemly but persuasive.

But is not an appearance of self-doubt inappropriate in a book whose purpose is polemical? One objective of *The Politics of Cancer* is after all to persuade governments to change their ways. Epstein, who appears from his bibliography to be a frequent witness before congressional committees, does not lack opportunities for putting his point of view. On this occasion, however, the result may have been so to scare such a large number of readers of the book that they in turn will put pressure on their congressmen, forcing a change of policy towards the chemical industry and its products born not of reason but of fright. There can be no circumstances in which it is permissible for professional scientists to hazard the reputations of their subjects in such a cause. The overstatement of a plausible case is not permissible. To conduct scientific arguments in immoderate language is bad for the public reputation of science. This is why Cairns's way of looking at the problem, with all its inconclusiveness, is so much to be welcomed.

University empire confronts a crisis

What on earth is to be done about the University of London, which is not so much a university as a relic of a university empire? It is a huge and ungovernable federation of more than forty titularly autonomous institutions, more than half of them concerned with medical education. There are eight non-medical colleges providing a general undergraduate curriculum and a further ten with more specialized interests, some only at the graduate level. The schools differ greatly in size, strength and reputation. Some, such as the London School of Economics and Imperial College, are international centres of scholarship — and Imperial College is financed separately from the rest of the university on the grounds of its national importance. Others, not always through their own fault, are at the other end of the spectrum of academic excellence. In 1979–80, there were 30,000 undergraduates and 10,000 graduate students, 18 per cent of them from overseas. London's financial prospects are thus bleaker than those of other British universities because its proportion of overseas students is greater; it stands to be hit harder by the government's insistence that overseas students must now be charged full economic fees (see *Nature*, 29 January). The university has long since abandoned its role as a provider of school-leaving examinations for most of the British Commonwealth and has even, more recently, given up the invidious role of providing other British institutions of higher education with certificates of good housekeeping. Now, like the British Empire before it, the university is faced with the prospect of collapse or, at least, of rapid contraction.

How is the problem being tackled? London's first step was predictable — setting up a committee. There is the obligatory outside chairman (Sir Peter Swinnerton-Dyer, vice-chancellor of the University of Cambridge) and marching orders to suggest how resources should be redistributed so as to keep the university in being ("academic excellence" etc.) at less cost ("having regard to the need to make financial economies" etc.). The committee, which is concerned only with the non-medical parts of the university, has sought to avoid the ructions that greeted the report of the Flowers committee on medical teaching last year by publishing last week an interim discussion document. The result is a collection of figures for the costs of teaching students in different subjects in the various colleges, a solemn warning that the years ahead will see income fall by 15 per cent and student numbers by 10 per cent, and hardly a hint of the recipe for reorganization the committee has promised by the end of the year. The document is thus not so much an interim report as an incitement of the lobbying and horse-dealing that will occupy the University of London for months to come.

That something, almost anything, must be done is crystal clear. For decades, the university has been almost as much concerned with attempts to reform itself as with the teaching of students. The practical difficulty is that change is usually unacceptable to the institutions most affected, which within the federal structure of the university have the final say. The Swinnerton-Dyer committee will succeed where others have failed only if it can persuade the constituent institutions of the university to bury their separate interests for the sake of the university to which they belong. The weakness of the interim document is that it seems designed to frighten the separate colleges into compliance with some unknown grand design by the threat of penury. The document thus urges that the university and its colleges should urgently consider how to manage redundancies among academic and other members of staff: tenure is plainly no longer sacred. It makes little of the threat, uppermost in the minds of many colleges in the past few months, that some of them may be closed or merged with others; there is merely a statement that the university can distribute as it thinks fit the funds it receives from the University Grants Committee (subject only to what the senate and the court of the university have to say). The strongest hint of what is to come is that university teachers might with advantage teach in more than one college. These possibilities, sensible enough, do not amount to a recipe for a stronger university. And they smack more of the stick than the carrot.

For the sake of the university, the Swinnerton-Dyer committee must find a more positive case to put a year from now. Although the interim document is full mostly of figures, it does acknowledge that in the end academic considerations will be paramount. What should these be? The committee must first count its blessings, which are various but not always obvious. The larger general colleges are comparable in size as well as quality with independent universities elsewhere in Britain. Some of the smaller colleges have a claim on public attention (and funds) for their tradition of educating less highly qualified entrants. Birkbeck College is the only institution of its kind in Britain with the objective of providing part-time students with an undergraduate education. Five of the independent schools (architecture, agriculture, education, pharmacy and veterinary science) are predominantly vocational; their place within the university calls for a frank but sympathetic appraisal. Should they all continue and, if so, should they continue to be supported from central funds as if their students were ordinary students? The risk is that the committee will be mesmerized by the reputations of the outstanding schools, letting the others go hang.

Problems of organization are also likely to obtrude. What kind of university should London become? The paradox in the past decade is that all parts of it have become more independent of the centre, which suits the larger schools well enough but makes it harder for the others to enjoy a sense of being part of a university. Nobody wants to see a revival of the dominance of bureaucracy, but the question must arise whether it is not the proper function of a university such as that in London to be a nursery for new kinds of university institutions — and whether the time has not arrived when places such as Imperial College should be encouraged to go their own way, to become autonomous in name as well as in fact. As things are, the equitable allocation of resources is unmanageable. How can the giants be denied? And how then can the pygmies enjoy a sense of partnership in a common enterprise — not that of being mere pygmies?

0028-0836/81/060432-01$01.00

Cutback on West German development

Money now in short supply in Bonn

The West German research ministry is being forced by economic problems to reassess priorities. Last week, the Bundestag began a discussion of the proposals put forward by the new science minister, Andreas von Bulow, whose plan for 1981 will increase the budget by only 5.2 per cent, now less than the rate of inflation. This new small increase has come as a shock to West German planners who are unused to having their budget cut.

The increase is less than had been forecast in the three-year forward plan published a year ago, which promised an increase of 10 per cent (in money terms) for 1981. The new research budget is not, however, out of line with revisions of other government expenditures, consequences of the worsening economy.

The research ministry, which controls the lion's share of funds for German research, is planning to save money by cancelling some new projects. Mr von Bulow says that he does not want to delay projects already under way. Expensive demonstration projects are likely to suffer most, but the government hopes that some of their cost can be taken over by the utilities (in nuclear power and coal), by industry, the Länder or local government. University research may do better because of the commitment to keeping university researchers in employment. The aim is to keep the proportion of the budget spent on basic research at just over 30 per cent.

Three particular projects are affected. A demonstation track for testing an advanced passenger train and a new tokamak device for fusion experiments at the Institute for Plasma Physics in Garching have already been abandoned. The cancellation of the demonstration track is expected to save DM30–40 million this year and DM 250 million by the end of 1983. The fusion device, known as Zephyr, would have cost an estimated DM500 million to build at 1980 prices. Its cancellation has removed a major project from the work of the plasma physics institute and has led the ministry to ask the institute to become more involved in the Joint European Torus (JET) under construction in Britian.

A decision has yet to be reached on the fate of the third project, a coal liquefaction plant being built in Virginia, United States. Germany and Japan are each expected to contribute 25 per cent of its cost and the Bundestag is having to assess the repercussions of cancellation.

Research fields likely to receive more than a 5.2 per cent increase include coal, radioactive waste disposal, microelectronics, biotechnology and polar research. The likely losers include transport, building, space research and the large nuclear research centres. University building is also to be reduced and savings will be made at the Deutsches Electronen-Synchrotron (DESY) by reducing the operating time of PETRA, the electron-positron machine. In all fields, the aim is to cut spending on development in favour of research.

The universities will nevertheless be affected to some extent. The ministry helps to support some specific university projects even though most of the money comes from Länder and from the Deutsches Forchungsgemeinschaft, the chief source of funds for university research. The Länder, which support the basic infrastructure including staff salaries, are also cutting increases in their budgets, but they are limited by their commitment to keep tenured staff in employment. The Forschungsgemeinschaft's budget is intended to increase from DM780 million in 1980 to DM830 million in 1981, an increase of 6.4 per cent.

In a revision of the forward plan to 1983, savings of DM2,000 million on the entire federal government research budget are planned for the next three years. The Bundestag's deliberations on the research budget will last for another few months, but a radical departure from the proposals is unlikely.

Judy Redfearn

Polish students sit in at universities

Poland now also has its student sit-ins. At the University of Lodz, 6,000 students drawn from the university, the technical university and the medical school have so far been involved in a sit-in which began in mid-January. The academic work of these establishments is virtually paralysed. The students' demand is for university autonomy and a less rigid curriculum.

Lodz is not unique. At the end of November, there was a sit-in lasting several days at the University of Warsaw, while in January some 200 final-year students of the Wroclaw agricultural academy held a sit-in over issues such as the system of examinations and credits. In particular, they demanded that the present system of rigid lectures and examinations in "socio-political sciences" should be replaced by informal seminars.

The issue of "socio-political" teaching is one of the fifty-odd grievances of the Lodz protesters. The range of their complaints is considerable and, as the Minister of Science, Higher Education and Technology, Janusz Gorski, said after talks with the university senate last week, many of them are impractical. A maximum of 3 months military service for students, for example, would be meaningless. The most striking feature of the Lodz protest, however, is not the range of demands but the range of participants; the action is backed not only by the new Independent Students' Association and the Solidarity chapters of the academic staff, but also by the university party committee and the "old" organizations — the Association of Polish Socialist Students and the Union of Polish Teachers.

The Lodz protest is a symptom of discontent that runs throughout all Polish academic life. Implementation of the Gdansk Accords, signed at the end of the summer, is slow, and delays in drafting new bills on academic autonomy and the reduction of censorship to the minimum needs of national security have evoked much anxiety that the terms of the accords may remain paper pledges only.

Thus the censorship bill, promised for 30 November, which is to take academic publishing out of the censors' control, has not yet appeared, even though the extended deadline of 15 January has been passed. Two draft bills have in fact been produced — one by the Minister of Justice, Jerzy Bafia, and one by a "public drafting committee", headed by Warsaw philosopher Dr Klemens Szaniawski. The problem of reconciling the two has become bogged down in the question of accountability. Minister Bafia would like the Office of Press, Publications and Performances (the censorship) to remain, as now, accountable to the Council of Ministers (the Cabinet). Dr Szaniawski's committee, however, wants it to be answerable to the Sejm (Parliament). Many of the proposals for "social renewal" put forward in recent months have called for the Sejm to play a more active role in the political life of the country.

In the absence of legislation, some universities have been quietly making their own reforms. Some rectors have made available to their students the university holdings of "restricted" texts.

Anomalies inevitably abound. Thus last week the Procurator General's office warned that issuing uncensored publications still carries a potentially heavy gaol sentence. Yet a few days previously, the censors had passed an issue of the Catholic weekly *Tygodnik Powszechny* which described lectures given in Gdansk by the clandestine "Society for Academic Courses" (Flying University) — lectures which, in pamphlet form, are regularly published by the underground press.

Censorship is only one of the burning academic issues. Dr Aleksander Gieysztor, the newly elected president of the Polish Academy of Sciences, sees the

0028-0836/81/060433-02$01.00

democratization of academic life as a two-stage process. The first, minor, stage, he observed recently, is "already under way" —"the introduction of regulations leading to "autonomy, democratization and better information". The second, and more important stage, is to reform the "overdeveloped" administration, and to ensure that scientific committees truly represent the interests of their members.

Cutbacks in the scientific bureaucracy will be greatly welcomed in the natural and technical sciences where the hierarchical classification of research projects, introduced in the early 1970s, means not only that virtually all research has to be orientated to some need of the national economy but also that there should be a vast bureaucracy to deal with funds and administration.

Given less paper-shuffling and a certain latitude in undirected research, few academics would overlook the needs of the economy. On the contrary, Solidarity has already set up its own "All-Poland Coordinating Committee for Science" and the Solidarity chapters in the various universities have put forward their own proposals for what should be done.

Some proposals are ambitious, such as that drawn up two weeks ago by the Jagellonian University of Krakow which calls for action on censorship, visas for academic travel, health service reform, pollution and the amelioration of the social conditions leading to alcoholism. Others are more specific, such as the defence issued by the Maria Curie-Sklodowska University of Lublin of the claim of Poland's 3.5 million peasant farmers to the right to form a trade union. **Vera Rich**

Telecommunications suit

Pact postponed

For lack of an assistant attorney-general, the Reagan Administration has had to postpone the settlement of its anti-trust suit against AT&T, the telephone company. Details of the settlement, which were to have been made public last Friday, will not now become known until 2 March, the date set by the trial judge, Howard H. Greene, for the submission of a settlement between the telephone company and the US Department of Justice.

The suit was begun in November 1974, and the trial opened on 16 January with formal statements by the two parties, followed by a recess. The further postponement is at the request of the Department of Justice, which explained in a letter to the court that it could not proceed until the Administration had appointed an assistant attorney-general with responsibility for anti-trust affairs.

The settlement, the essence of which has already been agreed, will have an important influence not merely on the future shape of the telecommunications industry in the United States but also on the future role of the Bell Laboratories within it. The terms of the settlement are almost certain to include AT&T's separation of its ownership and management of the United States telecommunications network from its manufacturing subsidiary, Western Electric.

In a letter to the court supporting the request for a further postponement of the settlement, AT&T said last week that it had already bound itself to certain undisclosed conditions. There is increasing speculation that, when published on 2 March, these will be found to embody the reorganization of the corporation announced in August last year, involving separate management and accounting for the operating and manufacturing arms of the business. The future of Bell Labs, undecided then, is still in the air.

There is a sense in which the anti-trust suit by the Department of Justice has been overtaken by events, especially by the ruling of the Federal Communications Commission (see *Nature,* 11 September 1980) that companies wishing to supply terminal equipment cannot also manage the common carrier networks that connect them. This decision of what is known as the "Second Computer Inquiry" seems to have been the spur for the reorganization announced by AT&T last summer. Separately from the anti-trust suit against it, AT&T is applying to the courts to have the deadline for the reorganization decreed by the commission (1 March 1982) extended on the grounds that it cannot bring about the "biggest corporate reorganization in history" by then.

European Community

Squeezing grants

Brussels

Haggling among member states is likely to force down the increase in the budget proposed by the European Community for its scientific and technical training programme. Last Thursday, the member states' permanent representatives to the Community met for the second time and finally decided to allocate to it 8.8 million EUA (European Units of Account) or £4.5 million, which is 3 million EUA less than the original modest proposal. A final decision has still to be taken by the Council of Ministers, but this is expected within the next two weeks. Depending on how the European Community chooses to allocate grants, there will probably be the equivalent of about 340 scholarships.

While the United Kingdom was in favour of keeping the programme at its previous size of 4.5 million EUA, the French were insistent that it should be reduced. Such was their concern that the French felt unable to give their consent without calling Paris for permission. Other member countries were more worried about the number and size of the individual grants. Ireland was in favour of smaller grants for more researchers while the Danes preferred the idea of devoting larger sums to contract researchers of a high quality.

The four-year programme is intended to give students and junior lecturers a chance to study in another part of the Community. This can be either in one of the joint research centres (Geel, Ispra, Karlsruhe or Petten) or in research institutions in another member state with whom the Commission has concluded research contracts. Those wishing to study at home will be forced to accept a cut in their grant of 25 per cent. About 320 grants were allocated in the last programme but since the new programme must include grants to Greek researchers, there will be no increase in the number available in the rest of the Community.

Normally, grants are awarded for up to a year, but they may be extended to two years for those undertaking major research projects. Part of the aim of the programme, however, is to promote contracts between those responsible for the implementation of research programmes and the relevant education and training establishments. Details can be had from the Directorate-General for Research, Science and Education, Rue de la Loi, Brussels 1049.

Last week's meeting also decided on the budget for the next four-year research programme on the environment. The Commission's initial proposal of 51 million EUA was reduced to 42 million EUA. The programme includes the continuation of a major effort in the field of climatology and other areas covered are the treatment of sewerage sludge, air pollution and organic micropollutants in water. Here again, France was keen to see the budget cut, in this case to 35 million EUA. The Greek delegate spoke for seismological studies, which won agreement in principle. Formal research programmes are at present being examined in the Council of Ministers. **Jasper Becker**

UN energy conference

Prospects improve

Washington

Prospects are looking up for the forthcoming United Nations Conference on New and Renewable Sources of Energy, due to take place in Nairobi, Kenya, in August.

Last summer, the second meeting of the conference's preparatory committee found the secretariat's efforts so far behind schedule that postponement was seriously considered. In addition, the Kenyan government began to develop cold feet about the costs of staging a major international conference, the first since the 1979 Vienna meeting on science and technology for development, and to mutter about withdrawing its invitation.

But neither threat has materialized. And when a group meets in New York at the end of this month to process the reports of eight

0028-0836/81/060434-02$01.00

technical panels on the prospects for different energy sources, it is expected to be in a spirit of optimism that few thought possible six months ago.

One reason is the recent appointment of a new secretary general for the conference, Mr Enrique Iglesias, a Uruguayan who is also executive secretary of the Economic Commission for Latin America. Mr Iglesias, thought to be a candidate for Mr Kurt Waldheim's job as Secretary General of the United Nations, succeeds Mr Mohamed H. Gherab, who has recently been charged with accepting loans from subordinate officials.

A second reason for guarded optimism about the energy conference is that at present the UN secretariat seems to be successfully treading the delicate line between the technical and the political.

It has now been generally accepted that, given a lack of time and resources, the conference can only achieve a limited "state of the art" review of new and renewable energy sources (including solar, geothermal, wind, tidal, biomass, oil shale and hydropower energy). The main focus is therefore likely to be on the institutional mechanisms that can accelerate research and development on these various energy sources — and the obstacles that stand in the way of their implementation.

It is unlikely, however, that any new institution will emerge from the Nairobi conference. Proposals are more likely to be along the lines of a scheme being worked on by the World Bank to form an international network of energy research centres, with a clearly defined set of global priorities distributed in a way that minimizes duplication of research efforts.

Parallel initiatives are also under way inside the United Nations Development Programme (UNDP), which last summer set up a new energy account. UNDP has already received $3.5 million from the World Bank to carry out a survey of the energy needs of 60 developing countries, as part of the ambitious scheme announced by bank president Robert McNamara last year for a programme of energy loans and investment to total about $25,000 million by 1985.

The main concern of the UN conference organizers is devize a set of policy proposals that will be sufficiently specific to meet the recommendations of the technical panels, but sufficiently broad to generate the necessary political support.

One idea under discussion, for example, is a coordinated effort to replant trees that have been cut down for fuel. The World Bank has already proposed raising $1,000 million towards such a scheme, on the basis that a comparable sum would be found by the individual countries concerned.

Inevitably, there will be points of conflict, some of which have already come to the surface. Little attention, for example, will be given to the environmental efforts of different energy sources, a problem at present of greater concern to the developed than the developing world. Similarly, the United Nations General Assembly has explicitly stated that the conference will not consider conservation technologies, even though many in the developed countries feel that a reduction in demand is one of the likeliest ways of tackling the energy problem.

There is also dispute about the role of the oil-producing nations. These hold many of the important cards, both in terms of their ability to affect energy prices and in having the cash surpluses available to which access would be needed for any major investment schemes. Their attitude towards the conference remains ambiguous, although Mr McNamara has made it clear that the success of his proposals depends largely on their support.

Given the actual and potential disagreements on each of these topics, therefore, the success of the Nairobi conference still hangs in the balance. But some see light at the end of the tunnel, and argue that although time is getting short, elements such as the World Bank and UNDP initiatives, existing trends in foreign aid budgets and the completion of the technical reports are sufficient to allow a successful outcome. **David Dickson**

Ariane space launcher

Still in trouble

The problems of Ariane, Europe's hope for a space launcher, are not over yet. The third test flight, delayed after a failure in a first stage engine on the second test flight last summer, is now unlikely to get off the ground until well after June, the date to which the European Space Agency is still clinging. The difficulty is that no precise explanation of what went wrong with the second flight has yet emerged, and correcting the fault still seems to be a matter of trial and error.

A new schedule for the Ariane programme will not be released until one of two modified fuel injection systems identified as the cause of the fault has been chosen after tests expected to last 4–8 weeks.

The second test flight failed after high amplitude oscillations at 2,300 and 2,700 Hz developed in one of the first stage engines. Tests last October with modified fuel injectors of improved tolerance seemed to solve the problem at 2,300 Hz, but the 2,700 Hz oscillation remained.

Oscillations at these frequencies had not shown up in early tests of the Ariane engines and injectors. But tests up to the middle of last month indicate that the injectors used in early Ariane development differ from new ones, suggesting that they have been modified during assembly, preparation or testing. Nobody has been able to discover precisely how the injectors were modified, but the space agency says it is now trying to increase the margin of error acceptable in the injector design.

The latest line of attack is to test two modified injectors in the hope that one of them will be free from oscillation problems. Officials are hopeful that one system can be chosen within the next couple of months and work can begin on preparing the third test flight. Even if there are no more setbacks, however, a launch in June seems optimistic.

Meanwhile, the French space agency, whose idea it was that Europe should build its own space launcher, is now planning to propose another multi-million dollar venture to the European Space Agency. France wants to be in on the "industrialization" of space in the 1990s and hopes to suggest a remote controlled space laboratory, along the lines of the Russian Salyut space station.

The plan is to build a laboratory for materials processing under micro-gravity that would be placed in geosynchronous orbit by Ariane. The laboratory would be serviced by an expendable vehicle that would deliver supplies and bring processed materials back to earth. A third spacecraft, also in orbit, would be capable of building large structures and experiments for use by the laboratory. The proposal is still only a feasibility study, and will not be put to the space agency before the end of the year. Before then, the French plan to sound out other European nations; preliminary discussions with Germany have already taken place. **Judy Redfearn**

UK research councils

Getting off lightly

Next year's allocation of the "science vote" of the UK Department of Education and Science is being accepted thankfully by the UK research councils. The thinking may be that if Prime Minister Margaret Thatcher's government can make £200 million cuts in the Conservatives' defence budget, the councils are lucky not to suffer even more.

The Science Research Council, for example, gets £174 million for 1981–82 (at October 1979 prices). Converted to average prices for the current year (say October 1980) this works out at £198 million, compared with current spending for 1980–81 of £204 million — a 3 per cent decrease in real terms. In its annual report for 1979–80, published last November, the council expected "a modest increase" in the next two years; yet a spokesman said this week that the council was "pleased" that the government was treating science and engineering so well.

The Science Research Council's nominal spending on science within the United Kingdom is at present £150.5 million (for 1980–81), and on international subscriptions a nominal £44.5 million. But the latter was calculated at 1979 exchanges rates, since when the pound has strengthened sufficiently to reduce the subscriptions bill by some £9 million to

0028-0836/81/060435-02$01.00

around £36 million. The council has been allowed to use some of this saving to offset its overexpenditure on domestic grants this year (see *Nature* 13 November). Next year, the Science Research Council projects a nominal expenditure of £158.5 million on UK-based science, with £39.5 million on subscriptions (at the same October 1980 domestic prices and exchange rates). Since the pound is unlikely to strengthen further, at least to the degree it strengthened in 1979–80, and the grants to which the council committed itself in 1980 will be continuing, 1981–82 seems set to be a difficult year for SRC.

Among other councils, the Agricultural Research Council has registered a 3 per cent rise from £29.5 million to £30.5 million, and the Natural Environment Research Council remains virtually static at £39.4 million. The Medical Research Council gets £73.2 million, including £13.9 million contract research money recently transferred from the control of the Departments of Health and Social Security. The Social Science Research Council will receive £16.1 million, the British Museum (Natural History) £6.5 million, and the Royal Society £3.3 million. These figures will be adjusted in October this year to account for the inflation rate.

Robert Walgate

Canadian research

Aiming high

Washington

Canada's Liberal Government brought its election promises a step nearer reality last month when it committed itself to increasing the proportion of the country's gross national product spent on research and development from 0.9 per cent to 1.5 per cent by 1985. The commitment is ambitious. Even though the federal government expects a large part of the burden to be carried by the private sector encouraged by tax incentives and other inducements, its own contribution will have to rise from $1,000 million to $2,600 million in the next five years — in real terms a growth of 8 per cent a year, allowing for inflation.

Much will also depend on the attitude of the provinces, which through their support of universities contribute about 20 per cent of the nation's effort in research and development. Relationships between the federal and provincial capitals have been cool recently, but officials in Ottawa hope that the need to spur the competitiveness of Canadian industry is one area in which it may be possible to reach agreement.

It will be some time before the broad commitments, announced in Toronto by the Minister of State for Science and Technology, Mr John Roberts, are translated into specific budgets for the various research agencies. And the scientific community is therefore reserving judgement until it sees the colour of the government's money. But for now, the minister's announcement can be taken as a sign of good faith, since if nothing else it provides a broad framework within which sectoral policies can be worked out.

Spending on research and development has become something of a political football in Canada in recent years, to the surprise of foreign observers who frequently point out that — as the United Kingdom discovered the early 1970s — research spending can be a misleading indicator of industrial strength. Nevertheless, the Canadian public has been convinced that one of the reasons for the country's dependence on foreign investment capital, particularly from the United States, has been its relative lack of an indigenous technological capability. And both the Liberal and Conservative parties have competed with bids to raise research spending to correct the situation.

During last year's election campaign, the Liberals had promised yet again to reach the 1.5 per cent figure, but with no specific target date. Now they have fixed on 1985, and determined that by this time 50 per cent of the nation's research and development spending (equivalent to 0.75 per cent of its gross national product) will come from industry, with a third from the federal government and the rest from the provinces and universities.

Reaching these targets will require a considerable shift in responsibility from the public to the private sector. Industry is being asked to increase its share of the budget from 40 to 50 per cent, while the federal government's contribution would fall in relative terms from 40 to 33 per cent, even though the actual amount of money would increase.

To meet these targets, industry would have to increase its spending by 27 per cent a year — a goal which has already been viewed with a certain amount of scepticism, since the government will have to devise an appropriate set of indirect mechanisms to encourage such growth. Officials in Ottawa are now carrying out a quantitative analysis of the effects of previous policy measures, such as tax breaks on research investment and industrial training grants. One official admitted last week that the studies have so far not been too productive; but there is optimism that some fine tuning can be achieved.

Canada's efforts in this direction bear a close resemblance to the recent domestic policy review of industrial innovation carried out two years ago in the United States under President Carter.

One significant difference, however, is that the Canadian government supports a strongly sectoral approach, identifying areas of high technology — such as nuclear energy, telecommunications or space technology — where it feels that Canadian industry has a particular role to play on international markets.

Although there were structural elements in the policy recommendations put forward by President Carter eighteen months ago, these were overshadowed by broader proposals aimed at encouraging the general climate for innovation. And with the election of President Reagan, even schemes such as the joint government/industry sponsored Cooperative Automotive Research Project, a pet project of the former president's science adviser, Dr Frank Press, are under threat from free marketeers.

In Canada, the sectoral approach has been strongly supported by groups such as the Science Council, whose chairman, Dr Claude Fortier, wrote in the council's recent annual report that government action is urgently needed along sectoral lines to stimulate innovation and productivity.

This concern is reflected in the government's new proposals. Of the new money which it is proposing to make available for the support of research and development, one half will go to support work in the private sector in clearly defined categories, one third to the government's own mission-oriented laboratories and the rest to universities and other research institutes.

But how much Mr Roberts' announcement indicates a genuine commitment by the Canadian government, already facing a growing budget deficit to increased funding, and how much is merely a political exercise, has become a subject of intense debate.

David Dickson

Environmental cadmium

Europe to ban?

Brussels

Moves to restrict the use of cadmium are gathering momentum in Europe. In Brussels, the European Commission's directive laying down limits for the discharge of cadmium into the aquatic environment is close to being adopted, before it goes to the Council of Ministers, while in Germany, the Home Office Minister has caused a furore in industrial circles by announcing that a new report on cadmium may lead to tough restrictions on its use.

This closely follows news of a Swedish ban due to come into force in July 1983, which has caused much unease among European producers of plastics, stabilizers and pigments, many of which contain cadmium compounds. As a result of research carried out by the Danish National Agency of Environmental Protection, the EEC Council of Environment Ministers has concluded that present environmental levels of cadmium are potentially harmful, the cadmium accumulating in the lungs, bone tissue, and particularly in the kidneys. Cadmium accumulates slowly in man, reaching dangerous levels at around the age of 50. Heavy smokers are thought to be most at risk.

German research has revealed dangerously high cadmium levels in beef, veal,

0028-0836/81/060436-02$01.00

fish, cereals and potatoes, as well as in some types of mushrooms and mussels. Both Danish and German reasearchers thought that the cadmium in foodstuffs came mainly from sewerage works through the use of the end product as fertilizer.

The European Commission has previously made strenuous efforts to dissuade the Swedes from making a sweeping ban on cadmium's industrial uses. The Swedish government is phasing out "unnecessary" uses of cadmium, but there are not as yet suitable substitutes for cadmium in its many industrial applications.

According to German Home Minister Gerhardt Baum, industry will either have to restrict its use or be faced with a legally enforced ban. The Commission's proposals, if they are finally adopted, will become national law in any case, but as they stand they only serve to protect the aquatic environment, falling short of the restrictions likely in Sweden and Germany.

Two other draft directives on discharge of chemicals into the aquatic environment are already with the council, one on mercury and the other on the "drins" (dieldrin, aldrin and endrin). Other directives are to follow but so far none have been adopted, because member states have failed to agree on limiting values and suitable environmental quality objectives.

The new directive on cadmiun will add to the confusion, particularly as it is in two stages, to come into effect in 1983 and 1986, in recognition that the technology for removing cadmiun from effluents has still to be developed. One major problem yet to be solved is how to remove cadmium from the wastes created during the manufacture of phosphoric acids from phosphate ore. So until a viable technique is developed, the restrictions will not apply to this industry.

Jasper Becker

Soviet psychology

IQ rehabilitated?

An article in the November/December issue of the Soviet Academy of Sciences publication *Psychological Journal* could pave the way for a controversial about-face by Soviet authorities on the issue of intelligence testing.

Stalin made IQ tests illegal in the Soviet Union in 1936. Before that, over-enthusiastic and under-qualified Russian educational psychologists, working with Western tests not standardized on the local population, had designated massive numbers of rural schoolchildren educationally subnormal — to the dismay and outrage of their parents and teachers.

The article in *Psychological Journal*, under the title "The evolution of cognitive processes and abilities", is likely to be especially influential because its author is Friedhard Klix, president of the International Union of Psychological Sciences and director of the psychology section of the Humboldt University, East Berlin. The text formed the presidential address to the opening of the Eastern bloc's 22nd International Psychology Conference in Leipzig in July 1980.

The article stresses the need to treat human intelligence as a subject for study in exactly the same way as other biological phenomena. This is in itself a heresy, since Marxist-Leninist theoreticians have always stressed the need to avoid what they called "reductionism", particularly in relation to aspects of behaviour such as intelligence.

Klix places human intelligence firmly in a biological context and subject therefore to the laws of evolutionary genetics; thereby he accepts an indisputable element of heritability. He refers scathingly to the choice (carefully backdated in his example) that has always faced man in attempting to predict and control his own environment — that is, between adherence to a "cult" and the (scientific) alternative of methodical observation. The unspoken inference is that scientists must be allowed to work unhampered by the dogma of political theory.

Klix later refers (under cover of a paragraph concerned with Sumerian mathematical innovation) to recent experiments in his own university department aimed at pinpointing differences in performance between mathematically gifted children and "normals". The Soviet "ukaz" against objective testing, and in particular the prevention of the development of quantitative norms agains which children with learning difficulties or exceptional gifts can be measured, is well known to Klix's audience.

Western observers feel that the demands of the Soviet-styled "scientific and technological revolution" may show that this prohibition works against rather than in favour of the very children whom it was intended to protect — selection for special education in one of the schools for gifted children at present depends on performance in one of the so-called "Olympiads". These events are held all over the country, but regularly return an embarrassing over-representation of urban males. The use of tests capable of revealing intelligence potential, uncrystallized by access to sophisticated teaching methods or the enriched cultural opportunities of the city, might restore balance to the selection process.

Klix ends by pointing out that the task before psychology is to achieve for cognitive processes what biochemists have managed in their microanalysis of other biological phenomena. Soviet psychological journals-watchers will be agog to see whether the debate on the "microanalysis" of human intelligence along the lines suggested by Klix is continued within the profession. At least the East Germans — who have been quietly using their own intelligence tests for selection for many years — have provided the Russians with an acceptable (that is, foreign) example on which to base the debate.

Elizabeth Roberts

Orlov hunger strike

Dr Yurii Orlov, the Russian physicist, who is now serving a 7-year prison-camp sentence for his activities as chairman of the Moscow "Helsinki Monitoring Group", has gone on a hunger strike to coincide with the reconvening of the Madrid review conference last week. According to his wife, Irina, Dr Orlov made a similar protest last November, when the conference opened, although, during that month, he served two fifteen-day terms in the punishment cell after an alleged argument with a camp officer.

Yurii Orlov — now a fast

The Madrid Conference on Security and Cooperation in Europe opened last week with the prospect of two months of acrimonious debate (see *Nature* 29 January, p.343).

Dr Orlov's protest, said Irina, is an appeal to all governments represented at Madrid to grant amnesty to political prisoners and to reduce secrecy in the flow in all fields of information — social, economic and military.

So far, however, the Soviet Union seems unwilling to relax its restrictions on information flow. During the Madrid recess, two scientists, Aleksandr Lavut, a Moscow geologist, and Mark Niklus, an Estonian biologist, received sentences of 3 and 15 years respectively for publicizing abroad what they see as breaches of the Helsinki Accords on human rights. "Secrecy", too, is a frequent Soviet excuse for not allowing would-be emigrants to leave the country. The latest to be denied an exit visa on the grounds that he had had access to classified information, is Dr David Goldfarb, who until he resigned his post last year when filing his emigration application had been head of the Laboratory of Molecular Genetics of Bacteria and Bacteriophages of the Soviet Academy of Sciences.

0028-0836/81/060437-01$01.00

CORRESPONDENCE

Laser war games

Sir — Zoological and anthropological evidence suggests that old conflict systems never die — they are ritualized. Antagonistic relationships are maintained in principle, but rendered progressively less dangerous as destructive behaviour gives way to display.

If increasing proportions of United States and Soviet military budgets are to be devoted to "laser weapons" (*Nature* 15 January, pages 109–111), this trend should be welcomed as a real sign of international relaxation. Strikingly coloured laser beams of spectacular power can be directed harmlessly into space at regular intervals, with none of the unfortunate ambiguity of intention and inelegance of effect which attend the launching of nuclear missiles. In due course, as Capitalist and Communist take their honoured places in history with Royalist and Roundhead, the "Firing of the Lasers" will no doubt become a public spectacle in the same class as the "Changing of the Guard".

Edward Wheeler

Newtown, Australia

Exhibition policy

Sir — The debate launched by Dr Halstead on the present orientation of the Natural History Museum at South Kensington, having centred on philosophical issues, leaves aside what I consider the main point. That is that because space has been made for new exhibits, the quality of which I will not discuss, many of the established collections are no longer on display. This was a shock to me when I revisited this institution last autumn for the first time in many years. As a kid in the 'fifties my parents took me to London every year and the Natural History Museum was my favourite place to visit. Those visits were certainly important in shaping my vocation for systematic biology. I especially enjoyed those Victorian cabinets full of shells and insects that present managers have eliminated. I believe that for a child it is more exciting to open drawers full of bugs than to push buttons to see clades lighting up. I believe a natural history museum should be a display of as representative as possible a sample of the taxonomic diversity of the living world. Didactic exhibits on the causes of this diversity (evolution) or the techniques used by systematicians should complement the collections and if there is no space available for them, such exhibits could just as well go into the Science Museum.

There is certainly less work involved in preparing displays of stuffed or pickled animals than flashy exhibits on modern biology and maybe the increase (Parkinsonian?) in staff specialized in exhibit preparation, as testified by position openings advertised in *Nature*, is more relevant to the disappearance of collections from the public galleries of the British Museum than are ideologies impregnating the staff.

V. Demoulin

Department of Botany,
University of Liège, Belgium

Corrigendum: In the letter "Energetic consensus" from F.H. Malpress, page 335 in *Nature* of 22 January, the units in the third equation should be kcal mol^{-1}, and not kcal.

Sir — How charming that theological and political issues have come back into zoology[1]. Halstead[2] says he is not worried if Marxism creeps into the Natural History Museum, though he does object to "unsubstantiated assertion" while at the same time he objects to different views presented by various sections of the museum — does this not show a due eclecticism on the museum's part?

Halstead's latest contribution[2] is a direct criticism of the museum's Public Services Department. May I mention my own experience with this department, and its head, Dr Roger Miles? Having been asked some time ago to advise on an exhibition concerned with human perception, I later wrote a fairly detailed criticism of the results, in an editorial of the journal *Perception*[3]. The response was not the usual rebuttal, but quite the reverse — Dr Miles immediately wrote inviting me to suggest plans for a complete redesign of this exhibition, and to attend the planning meetings and essentially to write the commentaries. This we have done. Whatever the result when it appears, this is evidence that the museum takes criticism seriously and acts with unusual generosity in seeking the help and advice of people outside its staff. Having also just given the museum's Christmas lectures, and so interacted again with the Public Services Department, I must say that in my opinion they have wholly commendable enthusiasm, and scholarship, as well as willingness to accept and act on well meant criticism.

Possibly scientists and writers who have not had experience designing exhibitions do not realize the difficulties. In a book, one can give graded qualifications, and cite rival views; and books are written for particular readerships whose background knowledge and interests may be assumed. But large public exhibitions must cater for children and expert authorities. They should be authoritative and balanced according to present knowledge, while also stimulating naive questions and deep questions for future research. To achieve this with an absolute minimum of text is possible only within limits, which we would all surely like to extend. The Natural History Museum should not merely be preserved as a museum of itself.

R. L. Gregory

Department of Anatomy,
The Medical School, Bristol, UK

1. Halstead, L. B. *Nature* **288**, 208 (1980).
2. Halstead, L. B. *Nature* **289**, 106–107 (1981).
3. Gregory, R. L. *Perception* **7**, 1 (1978).

Sir — May I, as a voluntary worker in the Education Department of the Natural History Museum, add a word to the current discussion in your pages.

I understand as little of cladistics as some of your correspondents seem to, but I wish to put in an ardent plea against the steady destruction of the museum by the Public Services Department. The present policy of tearing up by the roots so many of the excellent, clear, logical and didactically ideal displays and replacing them with gimmicky exhibitions that certainly amuse, but do not instruct, is painful to observe. All is now flashing lights, obscure working-models (all too frequently out of order from over-use by the under-tens), complicated texts that appear on screens only to disappear when you take your finger off the button before having read or digested them and strange puzzles that nobody has yet understood. These new, trendy, expensive displays, in which, as D. T. Donovan so rightly points out (*Nature* 1/8 January, p.105), original specimens hardly figure or are replaced by colour-photographs or plastic models, reach their tasteless peak in the disco/fun-fair atmosphere of the Human Biology Hall and provide mainly pseudo-information from which little is learnt and even less retained.

I must except from this criticism the excellent new ecology exhibit. It is a pity that it has been relegated to a long narrow hall and disposed in zig-zag fashion so that visitors are constantly colliding as they slalom their way from side to side, missing many of the showcases in the process.

The loss of the remarkable comparative anatomy section as a teaching-aid on adaptation is a tragedy . . . or is its disappearance really a confirmation of more sinister motives?

As for the scattering of the dinosaurs, a logical teaching tour has become a magical mystery tour, with specimens appearing and vanishing from week to week. Poor *Tyrannosaurus rex* remains in splendid isolation in the old hall; if you can find him. Our splendid *Diplodocus* is completely dwarfed by the enormous proportions of the great central hall, yet he cannot even stretch out his tail as in the old gallery, and his head, inserted with difficulty under the bridge, all but protrudes out of the front entrance, where it can only be studied by obstructing and annoying the incoming visitors. This break-up of the fossil collections, for which the right wing of the museum was specifically designed, is a major disaster and if they really mean to dismantle the fossil mammal gallery, I for one will give up and go, much as I love the work.
(Name and address withheld — ED. Nature)

Soviet rumbles

Sir — Ms Vera Rich has given an inaccurate account of the status of plate tectonics in the Soviet Union (see *Nature* 14 August 1980, p.652). Professor V. V. Beloussov (who is a Corresponding Member of the Academy, not a full Academician, and my close personal friend) has no control over what his fellow members of the Academy write or state about plate tectonics. Academician Peyve, also a close personal friend and director of the Institute of Geology of the Academy of Sciences, has published pro-plate tectonics articles with more than 30 of his colleagues since 1966. There are no restrictions whatsoever within the Academy against publishing papers on plate tectonics, and more than 3,000 pro-plate tectonics articles a year are published in the Soviet Union by members, not only of the Academy of Sciences and its branches, but also of regional institutes and academies.

I am an American citizen, not a Soviet citizen, and am fairly well known for my views against plate tectonics. However, I wish to see the scientists of the Soviet Union given their due. Some of the finest pro-plate tectonics literature in the world is being published in the Soviet Union.

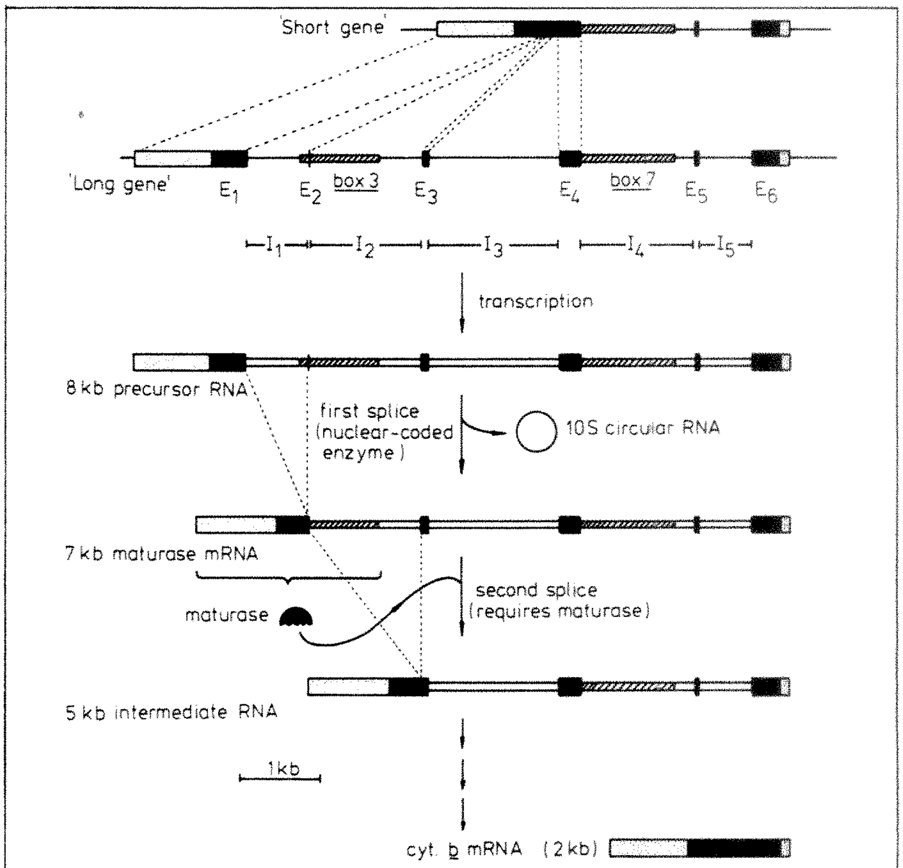
One gene's intron is another gene's exon

from Piet Borst and Leslie A. Grivell

In 1977 Slonimski and co-workers[1] predicted from an impressive genetic analysis that the gene for apocytochrome *b* in yeast mitochondria would be split and that some of the introns would encode separate functions required for the synthesis of *b* (see review in ref. 2). The split nature of the gene was rapidly confirmed by electron microscopy of DNA–RNA hybrids between this gene and its major transcript, an 18S RNA with mRNA activity for *b* (refs 3,4). The nature of the intron-encoded functions remained elusive, however. Initially, Slonimski pushed the idea that the introns code for 'guide' RNAs, that is, RNAs complementary to exon–intron boundaries in precursor RNA and required for removal of intron sequences[2,5]. More recently, however, several groups[6–12] inferred from indirect evidence that some of the introns in the *b* gene code for proteins required for RNA splicing. Although the splicing activity of these proteins remains to be demonstrated directly, a recent paper from Slonimski's laboratory[13] goes a long way towards proving that their synthesis is essential for the proper processing of *b* gene transcripts.

Our present knowledge of the *b* gene in yeast mitochondria is depicted in the figure. There are two versions of the gene in laboratory yeast strains[4,14,15]. The 'long' gene contains six exons (E1–6), five introns (I1–5) and two long open reading frames in introns (hatched) which are continuous with the preceding exon. The 'short' gene lacks the first three introns. An early step in the processing of the primary transcript of the long gene is the removal of I1, giving rise to a small circular RNA (10S, refs 5,11,16). Although the exact site of fusion is now known, the effect of this step is to link exon E1 with the tiny (14-base pair) exon E2 (ref. 13) and the open reading frame fused to it. This allows the synthesis of a fusion protein of molecular weight 42,000, called the *box3* RNA maturase by Lazowska *et al.*[13]. This protein helps to catalyse the excision of the I2 intron and therefore destroys the mRNA which directed its synthesis. Mutations that interfere with maturase function prevent this destruction and lead to overproduction of defective maturase.

The presence of a long open reading frame in the I2 intron was first inferred from the observation that *box3* mutants produce new proteins that look larger than *b* and react with antibodies against *b* (refs 6,7). Since the splicing of precursor RNAs is blocked in these mutants beyond the excision of the 10S RNA circles (see figure), these proteins must arise by readthrough of ribosomes from E1 into a larger open reading frame in I2. This has now been confirmed directly by Lazowska *et al*[13] through sequence analysis of the intron. They go on to show that splicing deficiency in three *box3* mutants is in each case correlated with sequence alterations in the I2 reading frame, both missense and nonsense mutations being effective in preventing splicing. Some of these mutants can be suppressed by paromomycin[17], presumably because this drug induces



The structure of the 'long' and 'short' versions of the gene for apocytochrome *b* and of the mRNAs transcribed from the 'long' gene. Black boxes correspond to the exons E1–E6 which specify the amino acid sequence of *b*; dotted blocks correspond to the non-translated regions of *b* mRNA; hatched blocks represent long open reading frames in the introns of the *b* gene. Whether the 8-kilobase precursor RNA is the primary transcript or not is uncertain. See text for further explanation. Redrawn from refs 4, 13 and 14. Kb, Kilobases or kilobase pairs.

Piet Borst and Leslie A. Grivell are in the Section for Medical Enzymology and Molecular Biology of the Laboratory of Biochemistry, University of Amsterdam.

sloppy reading of mRNAs by mitochondrial ribosomes. Since maturase is thought to act catalytically in promoting splicing, a minute amount of misreading should be sufficient to overcome the *box3* mutation.

These results prove that translation of the open reading frame in I2 is required for the proper splicing of precursor RNAs transcribed from the long *b* gene. Two further observations make it clear that maturase is a chimaeric protein, containing the first 143 amino acid residues of cytochrome *b* fused to the I2 reading frame. First, the defective maturase overproduced in *box3* mutants reacts with antibodies against *b* (refs 6,7). Second, chain-terminating mutations in the E1 exon abolish synthesis of maturase[10,13]. The E1 part of the maturase displays high hydrophobicity, typical of integral membrane proteins like *b*, but may not contribute much to its function since missense mutations in E1 that result in synthesis of defective *b* do not interfere with maturase function[10,13].

Whether maturase is a splicing enzyme or only a protein that influences the specificity of other splicing enzymes is not known. In wild-type yeast the protein is present in such low concentrations that it cannot be detected by pulse-labelling (ref. 13 and J. Kreike, personal communication). As pointed out by Lazowska *et al.*[13], it should be possible to find mutants that over-produce wild-type maturase and a full characterization of this protein should not be long in coming. From the DNA sequence it is clear, however, that the *box3* part of the maturase is rather unusual. It is very basic and hydrophobic, and 170 of the 280 amino acid residues are specified by pure AU-codons (Phe, Leu, Ile, Tyr, Asn, Lys). Yeast mtDNA has a mole per cent G + C of 18 and previous work has shown that there must be a strong selective pressure on this genome to maximize A + T content. In genes coding for respiratory chain components there is a strong preference for A or U in the third position[14]; the rRNAs are with 23 per cent G + C the most AU-rich known and intergenic regions are often more than 90 per cent A + T (see ref. 18). The mitochondrial genes coding for major proteins in yeast still contain 27–31 per cent G + C (see ref. 14). Apparently the requirements for maturase function are lax enough to allow the use of 60 per cent pure AU-codons, resulting in a gene containing as little as 18 per cent G + C.

A novel feature in the scheme depicted in the lower half of the figure is that maturase controls its own synthesis, a phenomenon which Lazowska *et al.* call 'splicing homeostasis'[13]. It is likely that this phenomenon is not limited to the *box3* maturase system. The I3 intron also contains a long open reading frame[14]; mutations in this frame (*box7* mutants) are blocked in a late splicing step and also produce novel proteins[10,11,13]. The I4 reading frame may therefore provide the C-terminal part of a second maturase. Several open reading frames have also been found in introns in the *oxi3* region of mtDNA which codes for subunit I of cytochrome *c* oxidase[19]. The set of overlapping transcripts originating from this region is even more complex than the transcripts of the *b* gene[11,20]. This region may therefore give rise to several additional maturases. Slonimski[21] has even suggested that splicing homeostasis also occurs outside mitochondria, but this seems doubtful. His proposal requires the existence within nuclei of a protein-synthesizing system capable of reading the opal stop codon UGA as Trp, as mitochondria do (see ref. 22). At present the existence of such a system is hypothetical.

Another remarkable feature of the intricate *box3* maturase system is that it is dispensable. The information in introns I1–3 is present only in 'long' *b* genes and nowhere else in yeast mtDNA (see ref. 3). Hence, strains with short *b* genes make *b* without the intervention of the *box3* maturase. The I1–3 introns belong to a class of 'optional' introns[23] discovered by Sanders *et al.*[15] in yeast mtDNA. Optional introns are also found in the large rRNA gene and in the gene for subunit I of cytochrome *c* oxidase (see ref. 3). Of course, whether an intron is classified as optional depends on finding a yeast strain that lacks it. Since only a limited number of strains have been looked at, all mitochondrial introns may eventually turn out to be optional.

Why should a simple genome like yeast mtDNA with its 70 kilobase pairs have (optional) introns in three genes and none in all the others? It is clear that many of the explanations advanced for the presence of introns in nuclear genes do not apply here (see ref. 23). It seems possible, however, that the introduction of (additional) splicing steps in the processing of precursor RNAs transcribed from key mitochondrial genes could allow a more complete control over mitochondrial gene expression at the RNA processing level. This might be of use in yeast, which can selectively suppress the synthesis of some mitochondrial components, like cytochrome *c* oxidase or *b*, in anaerobiosis or high glucose. This proposal does not explain the existence of an intron in the rRNA gene, however. Another possibility is that the increased length of intron-containing genes allows more effective recombination within these genes. This could be of advantage in rapidly creating new alleles resistant to yeast inhibitors found in nature. Some of these inhibitors affect *b* (antimycin, mucidin), others the large subunit of the mitochondrial ribosome (chloramphenicol, erythromycin).

Where do these optional introns come from? In their present form they do not have any of the characteristics of insertion elements; each intron is unique and is only found at a single position in mtDNA. It is possible, however, that optional introns have once arisen from insertion elements and that these elements have lost their mobility in the course of evolution. Bacterial transposons usually contain the information for the synthesis of a transposase, which catalyses the replicative transposition of the transposon (see ref. 24). Transposition involves cleavage exactly at the ends of the transposon, analogous to the precise cuts required for the excision of intron sequences from precursor RNAs. The maturases might therefore have evolved from transposases. A transposon which encodes a maturase which can help to excise the RNA transcript of the transposon from larger precursor RNAs could function as a mobile intron. Such mobile introns would allow the effective introduction of new introns into existing genes. It has been suggested[25] that introns in mitochondrial genes reflect the presence of introns in the ancestral primitive endosymbiotic bacterium from which mitochondria are thought to have evolved. It is also possible, however, that (some) introns were a later acquisition of the mitochondrial genome. This could explain why some introns in the *b* gene have strong homology with introns in the gene for subunit I of oxidase, even though this subunit and *b* have no clear homology themselves[14,19]. Such a late acquisition is also compatible with the fact that the introns in the genes for the large rRNAs of yeast mitochondria and *Chlamydomonas* chloroplasts are in different positions in the gene (see ref. 26). □

Beetles in ballast

from R.A. Crowson

In former times, ships commonly sailed from European ports to North America heavily 'in ballast', filling up with cargo for their return trips. Ballast was generally picked up in the form of sand or shingle from conveniently accessible points on the shore, and discharged in the vicinity of American ports, often in or around the St Lawrence estuary. In the process numerous European terrestrial invertebrates were introduced into a new continent, in which many of them became established. Beetles, probably on account of their exceptional adult longevity and endurance are very well represented among these involuntary colonists, and were particularly discussed by C.H. Lindroth in his book *Faunal Connections between Europe and North America* (1957). One species he did not consider is brought to light in an excellent recent revision* of the American species of *Rhyssemus* and *Trichorhyssemus* (Scarabaeidae). The European *Rhyssemus germanus*, apparently first found by the St Lawrence estuary in 1929, is now recorded at several points around the Great Lakes and seems to be spreading. The same species seems to have become at least temporarily established in several other remote parts of the world, no doubt in the same way. As can be seen from the figure, *R. germanus* is not particularly similar to any of the native American species, suggesting that separation of the European and American faunas in this group is fairly old.

A bright nearby supernova

from Roger A. Chevalier

Supernova 1979c was discovered on 19 April 1979 in the galaxy M100 by Johnson (*IAU Circ.* No.3348; 1979). The supernova explosion occurred in a spiral arm of the galaxy implying that it was of Type II — related to the explosions of massive stars. The apparent visual magnitude of the supernova near maximum light was 12, making it the brightest Type II supernova since the supernova 1970g. Observations were made at a variety of wavelengths and have revealed new properties of the Type II supernova emission and enabled a new distance estimate to be made for the Virgo cluster of galaxies.

An initial series of coordinated observations at optical, ultraviolet, X-ray and radio wavelengths was undertaken by an international group of collaborators in the first six weeks after the discovery (Panagia *et al. Mon. Not. R. astr. Soc.* **192,** 861; 1980). The observational facilities included the 5-metre telescope on Mt Palomar, the IUE (International Ultraviolet Explorer) satellite and the VLA (Very Large Array) radio interferometer. The optical properties showed the usual characteristics of a Type II supernova: most of the light was in continuum radiation that could be approximately fitted by a blackbody spectrum with a temperature close to 10,000K. Superposed on the continuum were broad lines of hydrogen and other elements in low stages of ionization. The lines developed P Cygni profiles of emission with blueshifted absorption. If the lines are formed close to the supernova photosphere then the velocity of gas at the photosphere can be deduced from the blueshift of the absorption minimum to be about 8,000 km s^{-1}.

The IUE observations provided the first UV observations of a Type II supernova. The light was dominated by the continuum radiation, although there was excess emission over the blackbody spectrum at low wavelengths. This may be emission from gas heated in the fast shock wave moving into the material surrounding the exploding star (Branch *et al. Astrophys. J.* in the press). Line features were also observed. Of particular interest were symmetric lines of highly ionized atoms (such as N v, Si iv and C iv) with maximum line widths corresponding to velocities of 4,000 km s^{-1}. The lack of occulting effects in the line profiles implies that the emission was at least two photospheric radii from the centre of the star. Panagia *et al.* suggested that the emission was from a circumstellar shell around the presupernova star which had been accelerated by the supernova radiation.

In the months after maximum, the visual light declined with a time scale of about 20 days. Spectra taken in November 1979 and thereafter showed that the light was dominated by a broad Hα line (Branch *et al.;* Kirshner and Chevalier, in preparation). An energy source is required to ionize the gas to produce the Hα line and two possibilities are γ rays from the radioactive decay of isotopes synthesized in the supernova explosion and high-energy emission from a central pulsar. At later times, the IR emission dominated the optical emission. In January 1980, Merrill (*IAU Circ.* No.3444; 1980) found an IR flux about 60 times the flux in the Hα line. He suggested that dust formation occurred in the supernova material, but the mechanism that maintains the ionization in the expanding envelope probably also maintains the gas temperature above the condensation temperature for dust formation. Another possible source of the IR radiation is emission by dust in a circumstellar shell that is heated by the supernova radiation (Bode and Evans *Mon. Not. R. astr. Soc.* **193,** 21; 1980). This model requires an absorption optical depth through the circumstellar shell that is close to the upper limit on the absorption set by observations of the supernova near maximum light, but the properties of the shell are in accord with the known properties of mass loss from red supergiant stars, which are thought to be the progenitors of Type II supernovae.

Radio observations with the VLA in April 1979 did not yield a detection, but gave an upper limit of 0.3 mJy (1 mJy = 10^{-26} erg cm^{-2} s^{-1} Hz^{-1}). However, the observations were repeated in April 1980 at a wavelength of 6 cm and the supernova was clearly detected at a level 5 mJy (Weiler and Sramek *IAU Circ.* No.3485; 1980). The minimum brightness temperature of the emitting region was several times 10^9K if the size of the region was comparable with the radius of the supernova envelope. This indicates that the

Roger A. Chevalier is at the Leander McCormick Observatory of the University of Virginia.

0028-0836/81/060441-02$01.00

emission was nonthermal. It is likely that Type II supernovae do leave pulsar remnants, which are strong nonthermal emitters. However, the observations of the Hα line at the same time as the radio observations indicate that there was sufficient ionized gas to give a large optical depth to free-free absorption. The emission was more likely to be associated with the outer parts of the supernova envelope, but, assuming it was incoherent synchrotron emission, the source of the relativistic electrons and of the magnetic field is not clear.

Besides giving information on the exploding star, observations of the supernova photosphere lead to another important parameter: the distance to the supernova. The technique is to estimate the angular diameter of the supernova photosphere at more than one time from the effective temperature and the total flux from the supernova. The rate of change of the angular diameter, when compared with the actual velocity deduced from the photospheric absorption lines, yields the distance to the supernova. Applying this method Branch *et al.* obtain a distance of 23±5 Mpc. The distance to M100 is especially important because it appears to be a member of the Virgo Cluster, one of the nearest large clusters of galaxies. Distance estimates using more conventional techniques, which depend on nearby distance calibrators, yield distances in the range 12 to 22 Mpc. Distance determinations to supernovae, which are independent of nearby calibrators, should play a fundamental role in determining the distance scale in the universe. □

Negative cooperativity at the insulin receptor

from Alexander Levitzki

In the past five years P. De Meyts and his colleagues have accumulated an impressive amount of experimental evidence suggesting that negative cooperativity is seen in the binding of insulin to its receptor, that is, as the proportion of cell-surface receptors occupied by insulin increases there is a progressive decrease in the affinity of individual receptors for insulin. In the past two years, however, several reports have questioned this concept and, because the behaviour of insulin may be representative of other peptides and proteins binding to cell-surface receptors, it is of some interest to assess its current status.

De Meyts *et al.* have obtained evidence in favour of negative cooperativity both from an equilibrium binding approach and from measuring the rate of dissociation of ^{125}I-insulin as a function of increasing receptor occupancy. Furthermore, in a study of twenty-four different insulin analogues they showed that while some insulins bind with negative cooperativity, others do not reveal negative cooperativity in either binding or in their kinetics of dissociation in the same experimental system[1]. The recent objections to invoking negative cooperativity as the explanation of the data accumulated by De Meyts *et al.* have been of three main kinds.

First, several observations seem to suggest that the enhanced ^{125}I-insulin dissociation at increasing occupancy is not an unambiguous proof of the negatively cooperative model. For example, ^{125}I-TSH (thyroid-stimulating hormone) binds in a non-cooperative manner to cultured thyroid cells, giving linear Scatchard plots, but its rate of dissociation from the receptor is enhanced by increasing concentrations of the unlabelled hormone[2]. Similarly, the enhancement at 10 °C of the dissociation of ^{3}H-dihydroalprenolol from frog β-receptors by native alprenolol occurs at a range of ligand concentration that yields non-cooperative binding (Hill coefficient of 1.0)[3]. In addition, recent studies by Pollet *et al.*[4] reveal no negative cooperativity in the same frog erythrocyte β-receptor system studied by Limbrid *et al.* An enhanced rate of dissociation has also been observed for biologically inert substances. For example, insulin enhances the rate of dissociation of ^{125}I-insulin from talc[5] and similarly, the rate of dissociation of ^{125}I-abrin from Sephadex particles is enhanced by unlabelled lectin or lactose[6]. In addition, difficulty arises from the claim of Pollet *et al.*[7] that no enhancement of ^{125}I-insulin dissociation is obtained at increasing receptor occupancy in the same IM-9 lymphocytes as those studied by De Meyts *et al.* The latter findings are in direct conflict with those reported by De Meyts and his colleagues[8] which were recently confirmed, on the same cell line, by Sonne and Gliemann[9]. The main conclusion from these different studies is that one must recognize that the existence of an enhanced dissociation of a ligand from its receptor in the presence of excess ligand, in cases where negative cooperativity clearly does not occur, eliminates this method as a definitive tool. It has been recently suggested how it might be possible to obtain a definitive interpretation by means of a new type of equilibrium measurement[10].

A second objection is raised by a recent study which claims that the existence of high- and low-affinity sites represents heterogeneity and not negative cooperativity[11]. The authors demonstrate that the binding isotherm of ^{125}I-insulin to human red cells is fitted well by a model which assumes two classes of sites: each cell reveals one high-affinity site ($K_d \sim 71$ pM). The authors further show that the high-affinity site can be completely blocked by the binding of concanavalin A, leaving the low-affinity sites intact. This finding is not compatible with the negative cooperativity model of De Meyts *et al.* One must remember, however, that a sample of human erythrocytes is always heterogeneous, certainly in their age. It would not be surprising if one were to find that the high-affinity sites and the low-affinity sites do not reside on the same erythrocyte, in which case the entire argument of Herzberg *et al.* is invalid. It is also difficult to use an experimental system that exhibits ony one high-affinity site per cell and in which it is not clear whether the insulin receptors are functional.

The final complication was pointed out recently by Donner[12]. ^{125}I-insulin is degraded rapidly by intact hepatocytes into ^{125}I-insulin fragments. These fragments possess a spectrum of affinities that is manifested in curvilinear Scatchard plot for ^{125}I-insulin binding to the intact hepatocytes. When the authors correct for the true intact ^{125}I-insulin, the binding pattern is converted into a non-cooperative one, represented by a linear Scatchard plot. Thus, when one does not correct for ^{125}I-insulin, one observes about 30,000 high-affinity sites per cell ($K_d \sim 1.0$ nM) and about 600,000 sites per cell ($K_d \sim 60$ nM). When such a correction is made, only 36,000 sites per cell ($K_d \sim 0.4$ nM) are observed. These results also fit with the common observation that the biochemical response of these cells to insulin is of a non-cooperative Michaelian type. The authors, in fact, confirm earlier reports[13] in which it was reported that ^{125}I-insulin is degraded to fragments by intact hepatocytes.

Although Donner's findings are relevant to intact hepatocyte cells which are obviously loaded with degradative

enzymes, his conclusion cannot be extrapolated to the purified membrane systems studied by De Meyts and his colleagues, and most probably does not apply to other cell systems. Indeed, only recently Sonne and Gliemann[9] have shown that ^{125}I-insulin is not degraded at all by the IM-9 lymphocytes, even at 37 °C. This cell line exhibits strong negative cooperativity towards ^{125}I-insulin, as judged both by binding studies and by accelerated dissociation of ^{125}I-insulin[1,9] at all temperatures including physiological ones.

To summarize, the most important point raised by the critics of the negative cooperativity model for insulin receptors is the demonstration that the accelerated rate of dissociation of a ligand from its receptor at increasing occupancy is not a definitive proof for negative cooperativity. Thus, in order to demonstrate negative cooperativity (or its absence) one must resort to other methods as well. For insulin itself, it seems that the experimental evidence for negative cooperativity in quite a number of systems is still very convincing. □

The Trigger experiment: simulating auroral processes

from Daniel W. Swift and Hans C. Stenbaek-Nielsen

TO INVESTIGATE the possibility of triggering auroral processes, a rocket experiment, appropriately code named 'Trigger', was designed and carried out by a group of Swedish and United States auroral researchers. In Trigger the electrical properties of the ionosphere were artificially perturbed by an explosive release of caesium metal and the effects were observed by a wide range of both rocket-borne and ground-based instruments. The experiment took place in February 1977 with launch from Esrange near Kiruna, Sweden, and indeed, the results have recently appeared in the *Journal of Geophysical Research* (10 October, 1980).

Traditionally, the ionosphere has been considered an entirely passive medium and the aurora to be little more than the ionospheric imprint of processes taking place out in the magnetosphere. But the ionosphere is electrically coupled to the magnetosphere with large currents flowing between the two regions and recent data indicate that these two currents are important for auroral processes. Thus it would seem reasonable to expect that events taking place in the ionosphere may affect magnetospheric processes. Evidence for a less passive ionosphere has also been found in observations on some chemical releases, although these experiments were never intended to produce such effects; an example is pulsating auroras apparently stimulated by a barium release (Deehr and Romick *Nature* **267**, 135; 1977).

While we have long known that the optical emissions forming the aurora are for the most part due to energetic electrons precipitating into the upper atmosphere, it is only within recent years that we have begun to understand the mechanisms which are responsible for this precipitation and the role played by the ionosphere.

It appears that two general processes are responsible for the precipitation of auroral electrons. The first process is the result of leakage of energetic electrons from the Earth's radiation belts into the atmosphere. This leakage is greatly enhanced by very low-frequency radio emissions and electrostatic waves which can be generated spontaneously within the radiation belts or stimulated from the outside. Processes of this type were among the earliest suggested and are to a large extent responsible for the diffuse aurora.

The other category of processes is associated with the discrete aurora, for example, the spectacular arcs and bands often observed in the late evening and along the poleward edge of the auroral oval. The main characteristic is potential differences set up along the magnetic field lines in which electrons are accelerated in much the same way as in the electron gun of a television tube. These potential structures are located in the near-Earth magnetosphere and their existence has only recently been verified experimentally.

Although the Trigger experiment did not actually create an artificial aurora, measurements of energetic electron fluxes in the neighbourhood of the plasma release gave indications of both types of auroral precipitation processes.

The caesium plasma was created by a 12-kg mixture of TNT-AlO-CsNO$_3$ which was explosively released at an altitude of 164 km. Caesium is a metal that easily ionizes to form a plasma and thus the release resulted in the rapid motion of an electrically conducting plasma cloud across the Earth's magnetic field. The motion of a conducter across the magnetic field lines constitutes an electrical dynamo which generates electrical voltages capable of accelerating electrons. In addition, the Trigger experiment creates a number of waves which may travel out into the magnetosphere and it leaves in its wake an enhanced level of ionization that can also affect plasma processes which occur on magnetic field lines passing through the plasma cloud.

An instrumented payload was sent up with the payload containing the explosive charge, but separated from the charge before the burst, so that when the explosion occurred, it was separated by 1.5 km and on a magnetic field displaced by about 0.5 km from the instrumented payload. A large peak in the electric field

Photograph taken from the optical observing site at Andoya Rocket Range, northern Norway, of a natural aurora showing auroral arcs (with a little local cloud in front of them), which stretched from the eastern horizon to the western horizon (behind the mountains). (Taken by H.L. Collin of the Geophysical Institute.)

0028-0836/81/060443-02$01.00

was seen about the time the blast wave should have crossed the magnetic field line intersecting the payload. Nearly coincident with this, electron fluxes of 2-kV were seen moving up and down the field lines, but the electrons did not actually seem to reach the atmosphere. The currents generated by the electric field apparently set up reflecting electric shocks both above and below the burst point, and the electrons were probably trapped between them.

The discrete auroras are believed to be caused by electrons accelerated through similar shocks, or double layers, also set up by currents flowing parallel to magnetic field lines; but although the current-driven shocks play roles in both the natural aurora and the Trigger experiment, their roles are quite different.

The instrument package also observed electron fluxes with energies greater than 40 kiloelectron volts (keV). There was a prompt burst followed a second later by sustained fluxes of electrons. Fluxes greater than 40 keV are believed to be responsible for the patchy and pulsating aurora seen in the early morning hours in the diffuse aurora (see review by A.D. Johnstone *Nature* **119**, 274; 1978). The natural precipitation is also accompanied by electromagnetic wave emissions called chorus. The chorus emission is in the audio frequency range, 0.5 to 2 kHz, and when amplified sounds like the chirping of birds. The precipitation can be enhanced by increasing the ambient ionization because the ambient ionization makes the trapped electrons more unstable to precipitation caused by the electromagnetic emissions.

It is tempting to attribute the delayed precipitation of electrons of energy greater than 40 keV in Trigger to the enhanced ionization density left by the caesium in the wake of the Trigger blast wave. The delayed fluxes were accompanied by wave emissions, but the emissions were electrostatic, rather than electromagnetic, and so would not probably be able to cause precipitation of trapped fluxes. Moreover, the Trigger fluxes were primarily field aligned, which is again inconsistent with a wave-particle diffusion process. The experimenters attribute most of the enhancement to noise contamination of the magnetic field-aligned detector. However, an X-ray detector suspended from a parachute that was deployed by a second rocket did observe 0.13-Hz pulsations in X-ray fluxes some two minutes after the event. This frequency is comparable with pulsation frequencies observed in natural aurora.

The prompt energetic electron fluxes are believed to be real, and they are accompanied by an electromagnetic pulse. However, as the electron fluxes are also primarily field aligned, the acceleration mechanism would have to be a stochastic process, since the electric potentials generated by the explosion are considerably less than the observed electron energies.

The Trigger experiment initiated a number of interesting plasma processes, some of which are similar to those responsible for the aurora. However, the natural aurora and the events observed in Trigger are not similar enough for the Trigger results to be applied in a direct way towards understanding the aurora; but after further theoretical interpretation it may turn out that the experiment has provided a number of useful clues to understanding processes in the natural aurora.

Certainly, the concept of the Trigger experiment is very appealing. Not only does the technique of artifically perturbing the ionosphere or magnetosphere allow the study of a wide range of general plasma processes, it also makes it possible to separate cause and effect, an often serious problem in the interpretation of auroral observations.

The use of chemical releases in space research will increase; groups from many countries are now proposing that such release experiments be conducted from a 'chemical release module' which will be be launched through the US space shuttle programme sometime in the mid-eighties. □

Are membrane proteins introverted?

from N. Michael Green

THE PURPLE MEMBRANE of *Halobacterium halobium* has become a test bed for sophisticated new techniques. These, in turn, have given exciting new information about the structure and function of the major protein of the purple membrane, bacterial rhodopsin. The most recent technique, neutron diffraction, shows that rhodopsin is an "inside-out" protein. Six years ago a combination of novel electron microscopic techniques with X-ray diffraction gave a picture of the structure at 7 Å resolution (Henderson and Unwin *Nature* **257**, 28; 1975). Then last year, a correlation of the electron density distribution with the amino acid sequence of appropriate helical segments produced a tentative model structure (Engelman *et al.* *Proc. natn. Acad. Sci. U.S.A.* **77**, 2023; 1980). It is this model which now receives strong support from some elegant neutron diffraction experiments (Engelman and Zaccai *Proc. natn. Acad. Sci. U.S.A.* **77**, 5894; 1980). This method, based on the great difference between neutron scattering by protons and deuterons, has also been used to show that there are no detectable aqueous channels in the membrane (Zaccai *J. molec. Biol* **132**, 181; 1979; Rogan and Zaccai *J. molec. Biol.* **145**, 281; 1980.).

Purple membranes were prepared in which all of either the valine or the phenylalanine residues had been replaced by their fully deuterated analogues and the neutron diffraction patterns were compared with that from normal membrane. From the latter a neutron density map was constructed which closely resembled the electron density map. Difference Fourier maps relative to the deuterated preparations were computed and showed that valine and phenylalanine residues were concentrated in different regions. This was to be expected, since these residues have rather different distributions both between the seven transmembrane helices and azimuthally within each helix. The peak density differences for both valine and phenylalanine side chains were off the helix axes, as would be expected, but whereas the valine peaks were displaced towards the exterior of the molecule those of phenylalanine were nearer to the interior, in the region where many of the charged groups had been placed in the tentative structure of Engelman *et al.* This differential distribution was consistent with the relative azimuthal distributions of valine and phenylalanine derived from the sequences of the previously assigned helices.

Comparison of the sequence-based azimuthal distributions with those of the charged residues confirms that valines (17 out of 19) are on the opposite sides of helices from phenylalanines (9 out of 11), and that the buried charged groups go with the phenylalanines. Moreover, the previously assigned locations of helices rich in valine or phenylalanine were consistent with the Fourier difference maps derived from neutron scattering, though the authors refrain from any detailed interpretation of this at the moment. The consistency of these new results with the earlier model is impressive and gives confidence in the validity of the arguments used in support of the previous assignments.

A firm picture is beginning to emerge of an 'inside-out' protein molecule with buried polar and charged groups located predominantly between helices and with most of the interface between lipid methylene groups and the protein being occupied by hydrophobic aliphatic chains. The authors suggest that in addition to a possible role in providing sites for proton translocation, the charged and polar groups would be an important stabilizing element in such a predominantly hydrophobic structure, since in their absence interactions between hydrophobic helices immersed in a hydrophobic solvent are very weak. □

African lithosphere

from Paul Mohr

ONE reason for the temporary demise of continental drift as a respectable scientific hypothesis was that the rigidity of planet Earth appeared too great for such drift to be possible. However, by 1948 the seismologist Beno Gutenberg was able to confidently state that a 'Low Velocity Zone' existed within the Earth's upper mantle. From seismic shear-wave velocity measurements the zone is estimated to extend between depths of about 120 and 200km. Its physical properties are consistent with incipient melting of mantle peridotite rock, and thus the term asthenosphere (zone of weakness) is appropriate. The overlying lithosphere, comprising the crust and topmost mantle, contrasts physically with the asthenosphere in being stronger and more rigid. The lithosphere has become identified with the plates of plate-tectonic theory and these plates are believed to move over the asthenosphere.

The global pattern of motions of the lithospheric plates has now been measured (see ref.1) and the manner of plate generation at sea-floor spreading axes, together with the ensuing thickening of the sub-oceanic lithosphere are well known. Much less well known is the thickness of the lithosphere under continental sectors of plates, and the means by which such lithosphere becomes attenuated where a plate begins to split, as, for example, along the African Rift System.

Early insights into African lithospheric thickness came from surface-wave dispersion studies[2-5] and in 1976 one could say, in summary, that under the undeformed interior of Africa, the top of the asthenosphere lies near 120km depth, but near the margins of the rift system it rises to an average depth of about 80km. Thin though the data were, with the addition of seismic profiling studies of the African crust they provided essential constraints for interpreting the more extensive data derived from other geophysical techniques.

Gravity surveys in eastern Africa have firmly established that lithospheric thinning is associated with the rifting of a continent. Sowerbutts[6] proposed the existence in Kenya of a low-density astenospheric 'cushion' underlying an unthinned lithosphere, but Girdler *et al.*[7] explained the same gravity data solely in terms of lithospheric thinning. More recent work has led to a combination of these two ideas, using a starting thickness for the unattenuated lithosphere of 80-100km[8] or 120km[9]. The asthenospheric 'cushion' beneath the Rift System may have a prism-like cross-section, according both to seismic array[10] and geomagnetic sounding[11] studies, with the lithosphere-asthenosphere boundary initially dipping steeply away from the rift valleys.

A particularly bold contribution to African lithospheric studies has come from combining continent-wide gravity data, based on the 1973 US Defense Mapping Agency's Bouguer-anomaly map of Africa, with observed teleseismic delay-times for Soviet underground nuclear explosions recorded at African seismological stations. Fairhead and Reeves'[12] resulting map of lithospheric thickness, derived from empirical linear relationships among delay-time, station elevation and Bouguer anomaly, reveals a broad zone of thinning coincident with the Rift System, from Ethiopia through Kenya and Tanzania to Angola. To the northwest, across Zaire and the Sahara, the lithosphere purportedly averages 200km thickness (less for the Tibesti-Jebel Marra line), while in southern Africa, southeast of the Rift System, the thickness lies between 175 and 150km. These values are indeed appreciably higher than indicated from the more direct approach of surface-wave dispersion analysis.

An almost identical picture, but with very different absolute values for lithospheric thickness, is most recently provided from a reinterpretation of the US Defense Agency gravity map following on a convincing demonstration of the accuracy of the map[13,14]. Detailed analysis shows that lithospheric thickness associated with the rift valleys and their bordering plateaux is less than 50km, and is less than 70km for a substantial part of southern Africa. These values are significantly less than those derived from seismic-wave studies.

How can such divergent conclusions be reached from essentially the same data base? One obvious reason is that seismological constraints are still not adequate to provide a firm model of density-depth gradients, and thus facilitate a unique interpretation of gravity profiles. Brown and Girdler[14] agree with Fairhead[8] in obtaining a density contrast of 0.05g cm^{-3} at the lithosphere-asthenosphere boundary, but in retaining the fundamental assumption of Girdler *et al.*[7] that the longer-wavelength Bouguer anomalies of Africa are caused entirely by variations in lithospheric thickness. That is to say, there is no contribution to the gravity-field from lateral changes in density below the lithosphere — there is no asthenospheric 'cushion'.

What is the evidence for an asthenospheric 'cushion', that is, for steeper and more profound asthenospheric boundaries than thus far provided by any of the published gravity interpretations? Seismic-array investigations in Kenya indicate that the sub-Rift System asthenosphere remains laterally distinct from 'normal' asthenosphere down to depths of 250km, far below the base of even unattenuated lithosphere[10]. The asthenosphere beneath the Rift System could therefore be hotter, more melted and even less dense than 'normal' asthenosphere under the rest of Africa. Here we approach the crux of the problem.

All agree that volcanism and high heat-flow in Africa are associated with zones of lithospheric thinning. But is this merely the result of passive upwelling of asthenospheric material as the plates begin to separate? This thesis is the rationale for and the explicit conclusion of Brown and Girdler's[14] interpretation of gravity. It is also the conclusion, reached on the entirely different premises of isotope geochemistry of volcanic rocks in Afar, of Barberi *et al.*[15]. Alternatively, are there 'hot spots' or deep mantle plumes impinging on the underside of the African lithosphere, involving vertical mass-transfer that could well derive from the mesosphere at depths of 400km or more[16,17]. This crucial issue is unresolved.

The questions of how thick is the African lithosphere, and the manner of lithospheric thinning as Africa splits, remain to test the best of the next generation of earth-scientists. Further questions arise: How deep and wide is the column of mantle perturbation below the Rift System, and do phase-changes below 400km depth contribute to the gravity field? What is the variation with depth of lateral density gradients within the asthenosphere under eastern Africa? And closer to the surface:

Paul Mohr is Professor of Geology at University College Galway, Ireland.

How does plateau crust, thickening as the rift margins are approached, join with the attenuated crust of the rift floors? Does the rift Moho, evolve in nature and depth in the way proposed by Mueller[18]? Finally, is it possible that the detailed gravity signature for Africa expresses sublithospheric mantle convection (as postulated on other grounds by Thiessen *et al.*[19] with horizontal dimensions of about 1,000 km? A rather similar figure has recently been derived from bathymetry-geoid measurements for the Pacific by McKenzie *et al.*[20], hinting that mantle convection beneath oceans and continents is of similar if not identical form. □

Is fibroblast interferon antigenic for man?

from D. A. J. Tyrell

In this issue of *Nature* (p.496) Vallbracht *et al.* report the treatment of a child with interferon β for the malignant disease, neuroblastoma. Interferons are known to act against experimental tumours, possibly by inhibiting cell division and enhancing immune activity, for example by activating natural killer cells. As fibroblast interferon is not usually found in the circulation after intramuscular or subcutaneous injection, possibly because it is bound by tissues, it is given intravenously when a systemic effect is required in clinical studies. In the case reported by Vallbracht *et al.* there was a poor clinical response and while monitoring the pharmacokinetics of the injected interferon it was found that there was no interferon in the blood. An anti-interferon globulin was detected in the circulation, apparently in consequence of the repeated interferon injections. This did not appear in other patients. What does this mean?

From analysis of cloned human genes it is clear that interferons are families of molecules. Apparently there are distinct genes for eight different forms of interferon α (IFN-α or leukocyte interferon), and IFN-β (fibroblast interferon) may also be the product of more than one gene. All interferons do, however, seem to be 'poor' antigens — in the practical sense that it is difficult to make antisera against them.

Nevertheless, antibodies against interferons have been produced by inoculating them into foreign species, and in a recent example a mouse immunized against human IFN-α — exactly which one we do not know — provided a monoclonal antibody-producing hybridoma. Immunoglobulin from the hybridoma has been used to purify interferon for clinical study (Secher and Burke *Nature* **285**, 446; 1980), and may also be used for radioimmunoassay.

One would not expect to be able to produce antibodies by inoculating an interferon into the same species as the one which produced it. In general, immune responses are not mounted against normal constitutuents of cells because of a 'self/non-self' recognition mechanism which distinguishes between normal tissue components and novel and presumably extraneous antigens. However, as a transient response to tissue damage and as part of the 'autoimmune' diseases antibodies can be produced against normal tissue constitutents. This reaction seems particularly likely when the tissue component, for instance thyroglobulin, does not ordinarily enter the circulation and encounter cells of the immune system.

Did the patient treated by Vallbracht *et al.* have some impairment of the self/non-self mechanism and thus react in this way? Is IFN-β normally found only in or near to producing cells, so it is recognized as foreign when it enters the circulation? Was the IFN-β given subtly different from the patient's own IFN-β, perhaps because it was the product of a different gene or because it was modified or denatured during manufacture? It remains to be seen whether anti-interferon antibodies are anything but an occasional nuisance when trying to treat patients with interferon — no such trouble seems to have arisen during the treatment of substantial numbers of patients with IFN-α. However, the single case report stimulates us to ask questions about the biology of interferon which we might otherwise not have thought of asking, and that must be a good thing. □

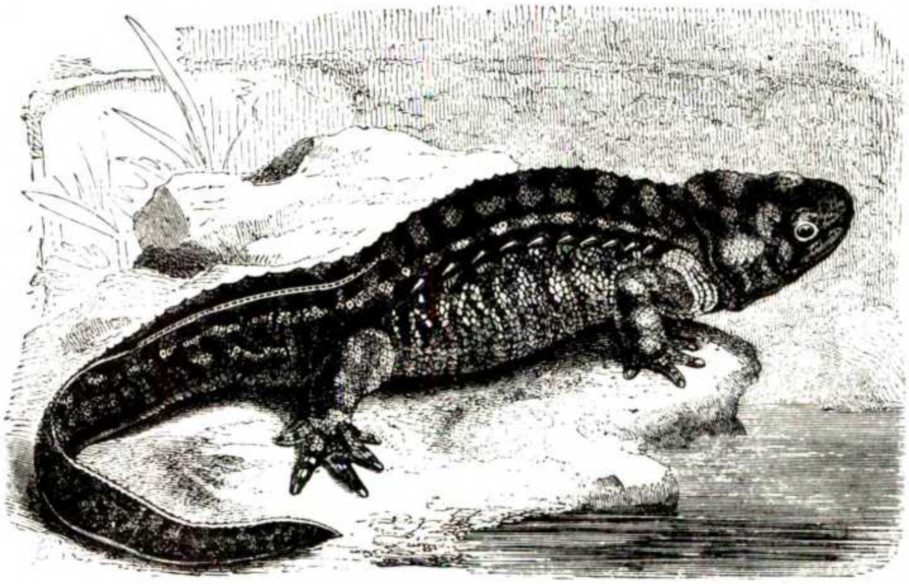
NATURE

100 years ago

Dr. Lenz, the German traveller who lately accomplished the feat of reaching Timbuctoo from the north, has arrived at Bordeaux, and is expected at Berlin soon to give an account of his explorations.

News from Cairo states that to the north of Memphis, near Saggarah, two pyramids have been discovered which were constructed by kings of the sixth dynasty, and the rooms and passages of which are covered with thousands of inscriptions. The discovery is said to be of the greatest scientific importance.



Pleurodeles waltlii

The habits of the Pleurodeles seem to be more or less like that of our native Tritons. During the procreative season they remain upright in the water; later they leave it and hide themselves in damp places under stones. Like the Water Newts, they posses a sort of cry; when frightened, as on being suddenly seized, they emit a low, short, almost squeaking sound, generally repeated several times. This seemed to come not so much from the throat as to be caused by a rapid expulsion of air through the openings of the nose — in fact, to be a sort of snort.

It would almost seem worth one's while to pay a visit to those Andalusian tanks, and by their semi-limpid sides and under the shelter of their surrounding fig and olive-trees work out the complete history of this interesting little form.

Apparent thickness of Saturn's rings

André Brahic & Bruno Sicardy
Observatoire de Paris, Université Paris VII, 92190 Meudon, France

The determination of the physical thickness of Saturn's rings is crucial for a better understanding of the nature, the dynamics and the evolution of a system of colliding ring particles. Ground-based observations with electronographic cameras and CCD during the transit of the Earth through the ring plane in March 1980, reveal a photometric apparent thickness of 1.4 ± 0.3 km. This value is only an upper limit of the local ring thickness, which is not observable from the Earth or from flybys. The observed brightness includes the contribution of the E ring, of large chunks and condensations and of the warping of the disk. Theory predicts a local thickness of the order of only a few mean particles radii.

We know of three dissimilar systems of planetary rings. Saturn has bright, broad rings separated by narrow gaps; the rings of Uranus are dark, narrow and widely spaced while the main jovian ring, closer to its central planet, is intermediate in size and has a three-dimensional halo. These rings are the nearest disk-like systems we have, and should offer valuable insights into the dynamics of more exotic and less accessible flat systems such as spiral galaxies, accretion disks and the primordial Solar System.

Following the discoveries of Uranus' and Jupiter's ring in March 1977 and March 1979, respectively[1,2], Saturn's system is now being intensively observed. Pioneer 11 became the first spacecraft[3] to reach Saturn on 1 September 1979, and the Voyager spacecraft has produced much interesting data, and more discoveries can be expected on its next encounter (27 August 1981). In between these encounters, ground-based observations during the ring plane crossing have revealed new inner satellites[4,5,7], new rings[6,8], and that the surroundings of Saturn are much more 'crowded' than foreseen.

Observations at very low elevations may supply important new information on the shape and the nature of the rings. In particular, when the rings are seen edge-on as a very faint line, the measurement of the brightness of this line may enable us to estimate the physical thickness of the rings.

Photometric determination of the thickness of Saturn's rings

The main problem is the evaluation of the physical thickness z of Saturn's rings, which lies far below the optical resolution of any instrument ($z \sim 1$ km whereas the resolution, from the Earth, is ~6,000 km). Nevertheless, photometric measurements of the rings, even though taken close to a much brighter planet, enable z to be determined.

On the plates we have examined, the Sun and the Earth are on opposite sides of the ring plane, so that the side S we can observe is dark in comparison with the edge E (Fig. 1*a*). The plates we have reduced were taken by Laques *et al.*[9], with the 1.06-m reflector of the Observatoire du Pic-du-Midi, and by Wlérick *et al.*[10], with the 1.93-m reflector of the Observatoire de Haute-Provence. In both cases, the receiver was an electronographic camera built at the Paris Observatory. Table 1 summarizes the reduced observations and provides details about receptors and conditions of observations. A microdensitometry of these plates provides ϕ, the luminous flux per unit length (1 arc s), of the rings (Fig. 1*a*). This flux is compared with that of a satellite which is not overexposed on the plate. Depending on the plate, the reference satellite is Tethys, Enceladus, Hyperion or Mimas. Our photometric measurements agree within an accuracy of 0.15 mag with known data[11].

By using the simplest model of the rings, that is, a plane parallel homogeneous scattering layer with a rectangular cross-section[12] in which light undergoes multiple isotropic scattering, it is then possible to separate ϕ into two parts: ϕ_E, the flux from the edge E, and ϕ_S, from the dark side S. In the ideal case where the rings are just seen edge-on, we obtain $\phi = \phi_E$. Actually this is not observed, so we had to extrapolate $\phi = \phi_E + \phi_S$ from the observed geometries to its minimum value ϕ_E at the edge-on geometry.

For this extrapolation we then need b_E, the brightness of the edge, or the mag/arc s^2 m_E of the edge ($b_E = 10^{-0.4 m_E}$) because $z\,(\text{arc s}) = \phi_E / b_E$.

The tables in ref. 13 provide observed brightness m_v and m_B (mag/arc s^2) of the illuminated side, in visible and blue light respectively at different points of the rings, with a theoretical estimation of τ (perpendicular optical thickness) at these points. The elevation angles B of the Earth and B' of the Sun are then equal to $B \simeq B' \simeq 26°$, and the phase angle $\alpha = 0.094°$. A large optical thickness is derived at the brightest part of B ring ($\tau \simeq 1$),

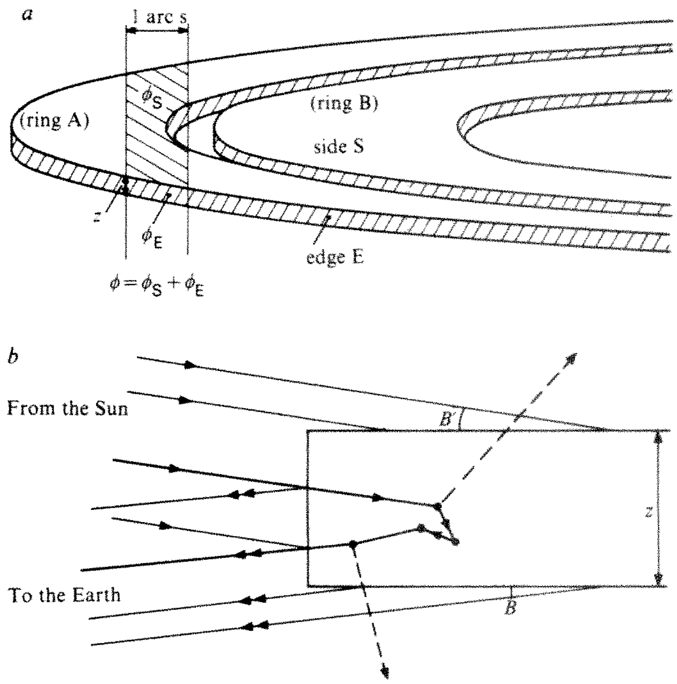

Fig. 1 *a*, Plane-parallel model of Saturn's rings. The thickness has been magnified compared to radial dimensions. *b*, The tilt-angle B is much smaller during the 1980 observations so that the rings appear as a line only.

$\mu = \sin B$ and $\mu_0 = \sin B'$ where B and B' are the elevation of the Earth and the Sun respectively above the ring plane. α is the phase angle. NF, no filter; we used B mag to derive a value of the thickness. (E) and (W) refer to eastern and western ansae of ring. The saturnicentric distances of Sun and Earth were respectively 9.44 UA and 8.45 UA over this period.

and thus the limits of $m_v(\infty)$ and $m_B(\infty)$ when τ is infinite are easily obtained from these data. We found $m_v(\infty) = 6.32$ and $m_B(\infty) = 7.22$. These values have to be corrected from solar distance variation and from the so-called 'opposition effect', which occurs at small phase angle[14,15]. It is then possible to estimate the brightness of the illuminated side for an infinite optical thickness, with $B \simeq B' \simeq 26°$ at any phase angle $\alpha \leqslant 1°$. We assumed this brightness to be equal to b_E. In the simplest model (isotropic multiple scattering, no reflected light from Saturn's disk, see below), ϕ_S is approximatively a linear function of the product $B\times B'$, so that the extrapolation of $\phi = \phi_E + KBB'$ to $BB' = 0$ provides $z = \phi_E/b_E$ (Fig. 2).

Figure 2 shows the results of measurements at 20 arc s and 17 arc s from the centre of the planet (2.05 and 1.74 equatorial radii respectively). The ring seems to be systematically brighter in the outer part than in the inner part. We observe in particular a condensation of light around 21.8 arc s (ref. 10), which may be due to 'gaps' in A ring. On the other hand, the inner part is more opaque, and thus darker when transmitted light is observed. We used only the data at 17 arc s (Fig. 2*b*) for the determination of physical thickness z because the residual contribution of dark side at 20 arc s seems to remain significant, even near Earth's transit, on 12 March. The high value of z at $BB' = -0.0219$ (deg)^2 in Fig. 2*b* corresponds to an observation of 29 February (SATU 29.11 on Table 1) when the elevation B of the Earth was relatively large, and was probably due to the contribution of indirect illumination by Saturn's globe. This contribution is not significant at 20 arc s. These data give evidence of the reflected light from Saturn's globe, and cannot be used for a direct determination of the thickness. The vertical error bars on Fig. 2*a*, *b* are due to uncertainties in the microdensitometric measurements only. The horizontal bars are due to uncertainties in the values of B and B', due to an inaccuracy on Saturn's pole position. There are also uncertainties in satellite magnitudes (±0.15 mag), so that we derived from Fig. 2*b*:

$$z = 1.4 \pm 0.3 \text{ km}$$

Note that this is an estimate of the thickness of the model which may not be realistic. Actually, the notion of thickness itself is not evident as the rings may be warped, or surrounded by an 'atmosphere' of small particles, or by a belt of little satellites (two have already been discovered at 2.5 planetary radii whereas ring A terminates at 2.3 radii). Any of these phenomena would significantly contribute to the flux ϕ. These effects might explain the condensations observed in the rings (we notice as well an increase in brightness from the inner to the outer part of the rings on some plates taken on 12, 15 and 16 March)[10]. The cross-section of the edge is probably not rectangular as in Fig. 1, but rather curved or tapered. An upper limit of 1.7 km for the 'photometric apparent thickness' can be confidently claimed. We do not yet know precisely what the quantitative consequence of the edge effect is on the brightness of the edge that is the result of the escape of light through the sides of the ring (dashed rays on Fig. 1*b*). At any rate, the brightness due to single-scattering only is not affected by this edge-effect. The larger the asymmetry parameter g of the particle phase function, the weaker the spreading of light through both sides. The edge effect would be more important in blue light ($g = -0.328$) than in visible light ($g = -0.386$) (refs 14, 15). Preliminary estimates[9] seem to suggest that this effect could lead to an overestimate of b_E, and hence an underestimate of z, whose value could be 40% greater at most.

From the photographic plates of 1966, Focas and Dollfus[16] derived $z = 2.5 \pm 1.4$ km, whereas Lumme and Irvine[17,35] gave $0 < z < 2.8$ km. In 1980, better photometric accuracy of electronographic receptors, sophisticated computer image analysis and larger instruments have produced a more reliable photometry. Furthermore, the conditions of observation in 1980 were better than in 1966 as the crossing of rings plane in 1980 occurred closer to opposition when the elevation B' of the Sun was smaller (0.15° and 2.75° in 1980 and 1966 respectively) so that the side S facing the Earth was darker. There was no significant observation corresponding to BB' smaller than 0.014 in 1966 and thus the extrapolation was less accurate. In particular, we can claim that the 'photometric apparent thickness' is >1 km. The structure, the density and the particle albedo of the E ring are totally unknown. There are probably complicated structures and condensations in the equatorial plane as well as the perpendicular direction. Burns *et al.*[18] have shown that a warping of the Laplace plane can account for an apparent total 'thickness' as much as a few hundred metres. The observed brightness includes non-negligible contributions of the E ring, of large chunks and condensations and of the warping of the disk. In a disk made of a continuous distribution of particles of different sizes, as is the case for Saturn's rings, the contribution of the large particles to the 'apparent photometric thickness' predominates. Thus, observations at ring-plane passage do not necessarily suggest a 'thick' ring as it is often claimed[19] and are not necessarily in contradiction with a ring maintaining a thickness of only a few particles radii as suggested by the study of systems of inelastically colliding particles[20,21]. On the contrary, the 'theoretical thickness' can be larger than a few particles radii.

Thickness of a three-dimensional system of inelastically colliding particles

The controversy over the vertical structure of the rings (see for examples refs 22, 23), whether it is a single layer in thickness, a few layers or many layers thick, is not merely an academic exercise; it has implications for the dynamics and evolution of the rings as well as for the mean sizes and surface topographies of the ring particles[12,20,21].

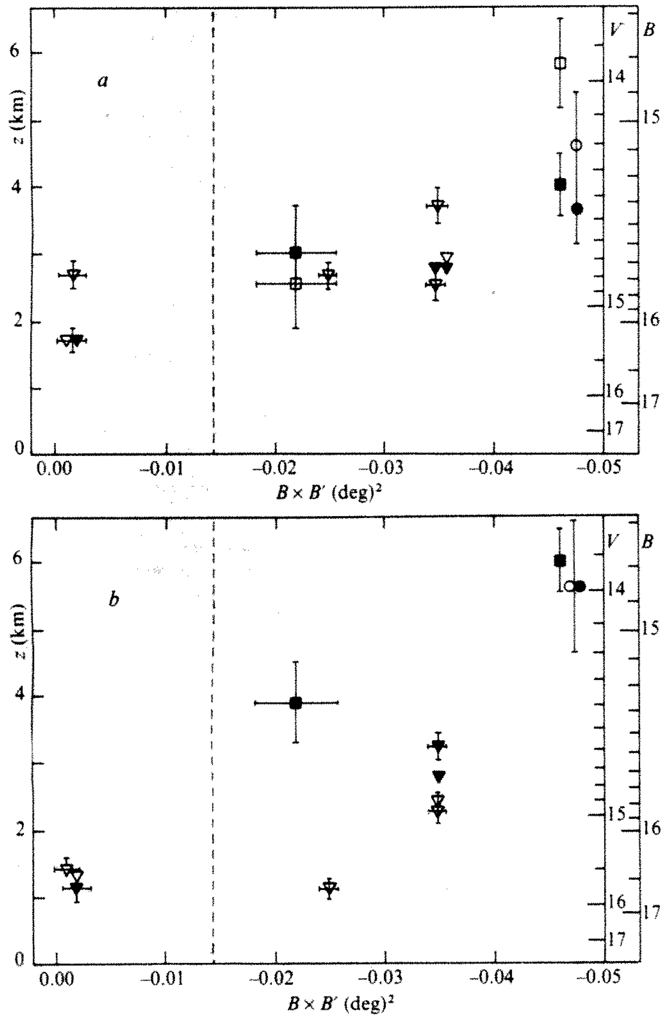

Fig. 2 Thickness ϕ_e/b_e (km) as a function of the date of observation (or of the product of the angle BB' (deg^2)). The quantity ϕ_e/b_e expressed in the text in arc s, has been converted into kilometres. On each plate two scans were made, when possible, at 20 arc s from the centre of the planet (East and West sides), and two at 17 arc s. We have so far reduced plates in blue and visible lights; the scales on the right provide the mag/arc s of the rings in these two lights. The broken line indicates the lowest value of BB' for the observations in 1966. Without data represented by points on the left, the extrapolation to obtain the apparent thickness is much more difficult.

It has been shown[20,21,24] that after a very fast flattening of the order of 20 collisions per particle, a three-dimensional system of inelastically colliding particles reaches a quasi-equilibrium state in which the thickness of the newly formed disk is finite and in which collisions still occur. The combined effect of differential rotation and inelastic collisions, makes the disk spread very slowly, particles moving both inwards and outwards carrying out some angular momentum. For Saturn's rings, the time scale of flattening is of the order of a few weeks, the time scale of the quasi-equilibrium state is of the order of 10^{14} yr and the system reaches a third hypothetical collisionless state in a time scale of the order of 10^{21} yr (refs 20, 21). Although this result disagrees strongly with the time scale obtained by Jeffreys[25], his paper contains an erroneous calculation (see ref. 24, and M. Hénon, personal communication).

To reconcile the 'many-particle thick' conditions apparently required by recent models of ring photometric properties, which are derived from a variety of optical (opposition effect) and radio observations[23,26,27], Burns, Cuzzi *et al.*[18,28,29] have considered several mechanisms as possible sources of energy for continually thickening the rings such as: gravitational perturbations by Saturnian satellites, the Sun, and the oblateness of Saturn; meteoroid bombardments; radiation pressure, and mutual gravitational scattering of particles.

We have recently studied simple models of three-dimensional systems of inelastically colliding particles in which the attraction between particles has been neglected (and so particle orbits are Keplerian around a central mass). In these models particles have the same masses and radii and the loss of energy during a collision does not depend on the relative velocity of the two colliding particles. When a large part of the orbital energy is lost after a collision, an instability phenomenon appears. For very inelastic collisions and contrary to the behaviour of the first models[21] (Fig. 3, zone B), the disk is completely flattened and the system becomes a two-dimensional configuration in which collisions continue to occur (Fig. 3, zone A). A sharp transition L_1 separates zones A and B. A linear stability analysis of the observed behaviour has been made: differential rotation constantly feeds energy into horizontal motions and thus maintains a finite dispersion of horizontal velocities, whilst vertical motions are only a by-product of the horizontal activity and do not necessarily arise[30]. A linear stability analysis of a flat disk of colliding particles gives a condition for stability:

$$\gamma(k-k')^2 < 4(1-k'^{-2}) \qquad (1)$$

where $\gamma = \langle V_r^2/\omega^2 r^2\rangle$ v, is the relative velocity of two particles, r the radius of one particle, ω the angular velocity, $1+k$ and $1-k'$

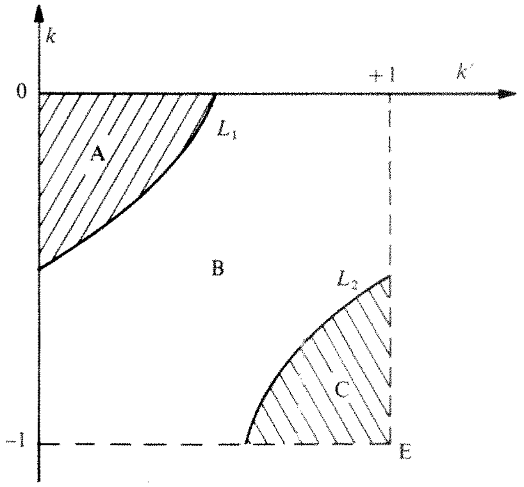

Fig. 3 The flattening of the system is a function of the rebound coefficients k and k'. In zone A, the system is completely flattened. In zone B the thickness of the disk decreases towards a value of the order of a few times the size of a particle. In zone C, the thickness of the disk increases. There exist two sharp limits L_1 and L_2 between the three zones, A, B, and C.

the relative loss of velocity after one collision in the normal and the grazing direction respectively. $(k, k') = (0, 0)$ corresponds to a complete inelastic collision and $(k, k') = (-1+1)$ to an elastic collision. The evolution of models with velocity dependance of k, k' is essentially the same[31]. There is a second sharp transition L_2 between zone B and zone C (Fig. 3). In zone B, the thickness of the disk decreases and reaches a value of the order of r/R, where r is the radius of a particle and R some characteristic dimension of the system. In zone C, the thickness of the disk increases and the system becomes a true three-dimensional system. On the one hand, keplerian motion tends to establish an anisotropic distribution of velocities with a velocity twice as large in the radial direction than in the transverse direction. On the other hand, collisions tend to establish an isotropic distribution of velocities. If the degree of inelasticity is larger (Fig. 3, zones A and B), a smaller quantity of energy is extracted from the ordered motion and the orbits become more and more circular and co-planar. A crude calculation of the equilibrium between these two phenomena gives the equation:

$$L_2\colon k^2 + k'^2 = 1.28 \qquad (2)$$

(For L_2 see ref. 31.) Zone C probably does not correspond to the Saturn case, unless nonlinear effects damp the vertical motions when the system becomes very thick.

In a real system, most collisions would be between particles of very unequal size[32]. We shall give here only those results concerning the mutual evolution of two different sized particles. Generally, the two groups of particles evolve in essentially the same way. There is no real equipartition of energy, but rather a kind of separation. The mean inclination and the mean eccentricity of the large particles is smaller than the mean inclination and the mean eccentricity of the small particles (Fig. 4). The evolution is essentially similar to that of the first models. The more elastic the collisions, the bigger the separation; the larger the mass ratio, the bigger the separation; there would not seem to be any separation in the plane of the disk. One can see numerically and by a crude calculation[33] that the mean velocity $\langle v_l \rangle$ of the large particles is proportional to the mean velocity $\langle v_s \rangle$ of the small particles:

$$\langle v_s \rangle \propto \frac{1}{(1-k^2)^{1/2}} \langle v_l \rangle \qquad (3)$$

Generally the massive particles evolve faster than the lighter ones. The relation ($ar^2 < 3 \times 10^{10}$ yr m^2) between the size r of the particles and the age a of the system, shown—for systems of identical particles[21], remains valid for each component individually. To the extent that Saturn's rings may be modelled in this way, then if the rings are as old as the Solar System, the maximum size of the particles is 2.5 m. A system made essentially of large particles, would presumably have been created much later. Cuzzi *et al.*[29] have shown that the ring systems attains a steady state in which gravitational scattering (not considered here) by the large particles impacts random velocity components to the small particles while inelastic collisions (not quantitatively treated in the Cuzzi's model) descrease these random velocities.

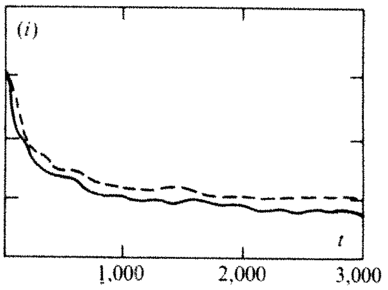

Fig. 4 Variations as a function of time of the mean inclination of the particles (which is a good measure of the flattening of the system). The results for large particles are shown by a solid line and those for small particles are given by the dashed line. The particles have the same density.

We have studied systems in which a satellite orbits around the primary on an orbit inclined with respect to a disk of colliding particles. The influence of the satellite on the thickness is negligible. Detailed results on small changes in the mean plane's location due to the action of the satellite are given elsewhere[34].

Conclusion

The main results of our numerical simulation are:

(1) In the case of almost elastic collisions, a disk of colliding particles can expand vertically to become a three-dimensional system.

(2) When particles of different masses and sizes collide there is no real equipartition of energy, but rather a kind of separation between the different populations.

(3) Satellite perturbations are not very efficient in thickening a disk of colliding particles.

The 'local' thickness of the rings is probably of the order of a few particles radii or some tens of metres[21]. Unless some as yet not understood mechanism reduces the vertical motions, the phenomenon observed in zone C of Fig. 3 is apparently not present in Saturn's rings, as it would lead to a much larger thickness. Contrary to what one could deduce from a relative velocity of the order of only 10^{-2} cm s^{-1} for 2-m sized colliding particles in Saturn's rings, there is enough energy lost during the collisions. If not the rings would be much thicker. On a large scale, the rings are probably slightly warped[18] and are possibly surrounded by an atmosphere[19] and by small satellites or large chunks of matter just outside (as discovered in March 1980)[4,5] or even inside the rings. This would produce on average an apparent edge-on thickness of several hundred metres and would make the true physical thickness (a local vertical scale height of the rings) impossible to determine from ring-passage observations from the Earth or from fly-bys.

We thank M. Hénon for helpful advice on the theoretical studies; J. Lecacheux, P. Laques, R. Despiau, G. Wlérick, B. Servan, D. Michet, L. Renard, and A. Bijaoui for observations and assistance, and A. Cazenave, J. Burns and R. Greenberg for stimulating discussions. Much of this work was supported by the RCP 544 'Anneaux' and the ATP 'Planétologie' of the CNRS.

New data base for climate studies

Michael Matson & Donald R. Wiesnet

NOAA/National Earth Satellite Service, Washington DC 20233

Until the advent of satellite data it had been impractical to measure continental snow cover. Beginning with the ESSA 3 satellite in late 1966, and continuing to the present NOAA and GOES series satellites, Northern Hemisphere continental snow cover has been routinely mapped by the National Oceanic and Atmospheric Administration (NOAA). This mapping has produced a reliable, timely and relatively unbiased continental snow-cover data base for use in climate studies.

IN recent years the impact of global snow and ice cover on climatic processes has received increased attention[1-5]. Kukla[6] stated that "to understand properly the mechanisms of weather and climate variability we need to understand the variability of snow and pack-ice fields". The Global Atmospheric Research Program (GARP) has recommended that sensitivity studies of the climatic effects of global and regional anomalies of snow and ice cover be performed with various types of general circulation models[7]. Specifically, continental snow cover has important climatic impacts on the radiation balance, surface and air temperature, cloudiness, soil moisture, water storage and precipitation. Continental snow cover can also have an impact on energy requirements, transportation systems and food supplies.

Because of the climatic–economic importance of continental snow cover, GARP[7], the Committee on Space Research (COSPAR)[8], and the United States Climate Program Plan[9], have recommended that global monitoring of the extent of snow cover be included in both short- and long-term observational programmes. Until 1966, however, the monitoring of the areal extent of continental snow cover was limited to point measurements and extrapolation between these often widely separated points. Mountainous and sparsely inhabited areas were poorly represented in this type of monitoring. In November 1966 the first satellite-derived Northern Hemisphere Weekly Snow and Ice Cover Chart was produced by the National Environmental Satellite Service (NESS) of NOAA. Since then, continental snow-cover extent has been monitored on a weekly basis by satellites. In this article we demonstrate the ability of satellites to monitor an important climatic parameter and discuss the 14-yr satellite record of continental snow cover.

The NOAA/NESS satellite capability

The NOAA/NESS satellites and sensors used in mapping Northern Hemisphere continental snow cover are listed in Table 1. Note that the high-resolution VHRR, AVHRR and VISSR data are primarily available only for North America. Table 1 shows that satellite data were available at all times from late 1966 to the present for monitoring continental snow cover. Of course, the snow-cover data have come from a variety of satellites and sensors, all subject to instrumental variation, degradation and drift. The impact of these factors on mapping continental snow cover, however, has been negligible.

Table 1 NOAA/NESS satellites and sensors used in mapping Northern Hemisphere snow and ice cover

The NOAA/NESS Northern Hemisphere snow-cover data base

Since November 1966, using the visual band sensors listed in Table 1, the Synoptic Analysis Branch (SAB) of NESS has prepared the Northern Hemisphere Weekly Snow and Ice Cover Chart (Fig. 1). These charts, at a scale of 1:62,500,000, show the areal extent and brightness of continental snow cover but do not indicate snow depth. The preparation of the charts and the definition of terms used in the analysis have been described in detail in an unpublished report by SAB; we give here only brief details.

Early in the week the analyst, a satellite meteorologist, makes a pencil trace of the previous week's chart. Daily he collects all of the visual band data received during the previous day, compares snow and ice cover interpreted from the imagery with snow cover on the previous week's chart, and makes changes. Each area of the new chart is therefore the latest cloud-free snow observation of that particular area of the world. If an area is cloud covered for several days, the analysis of snow cover for

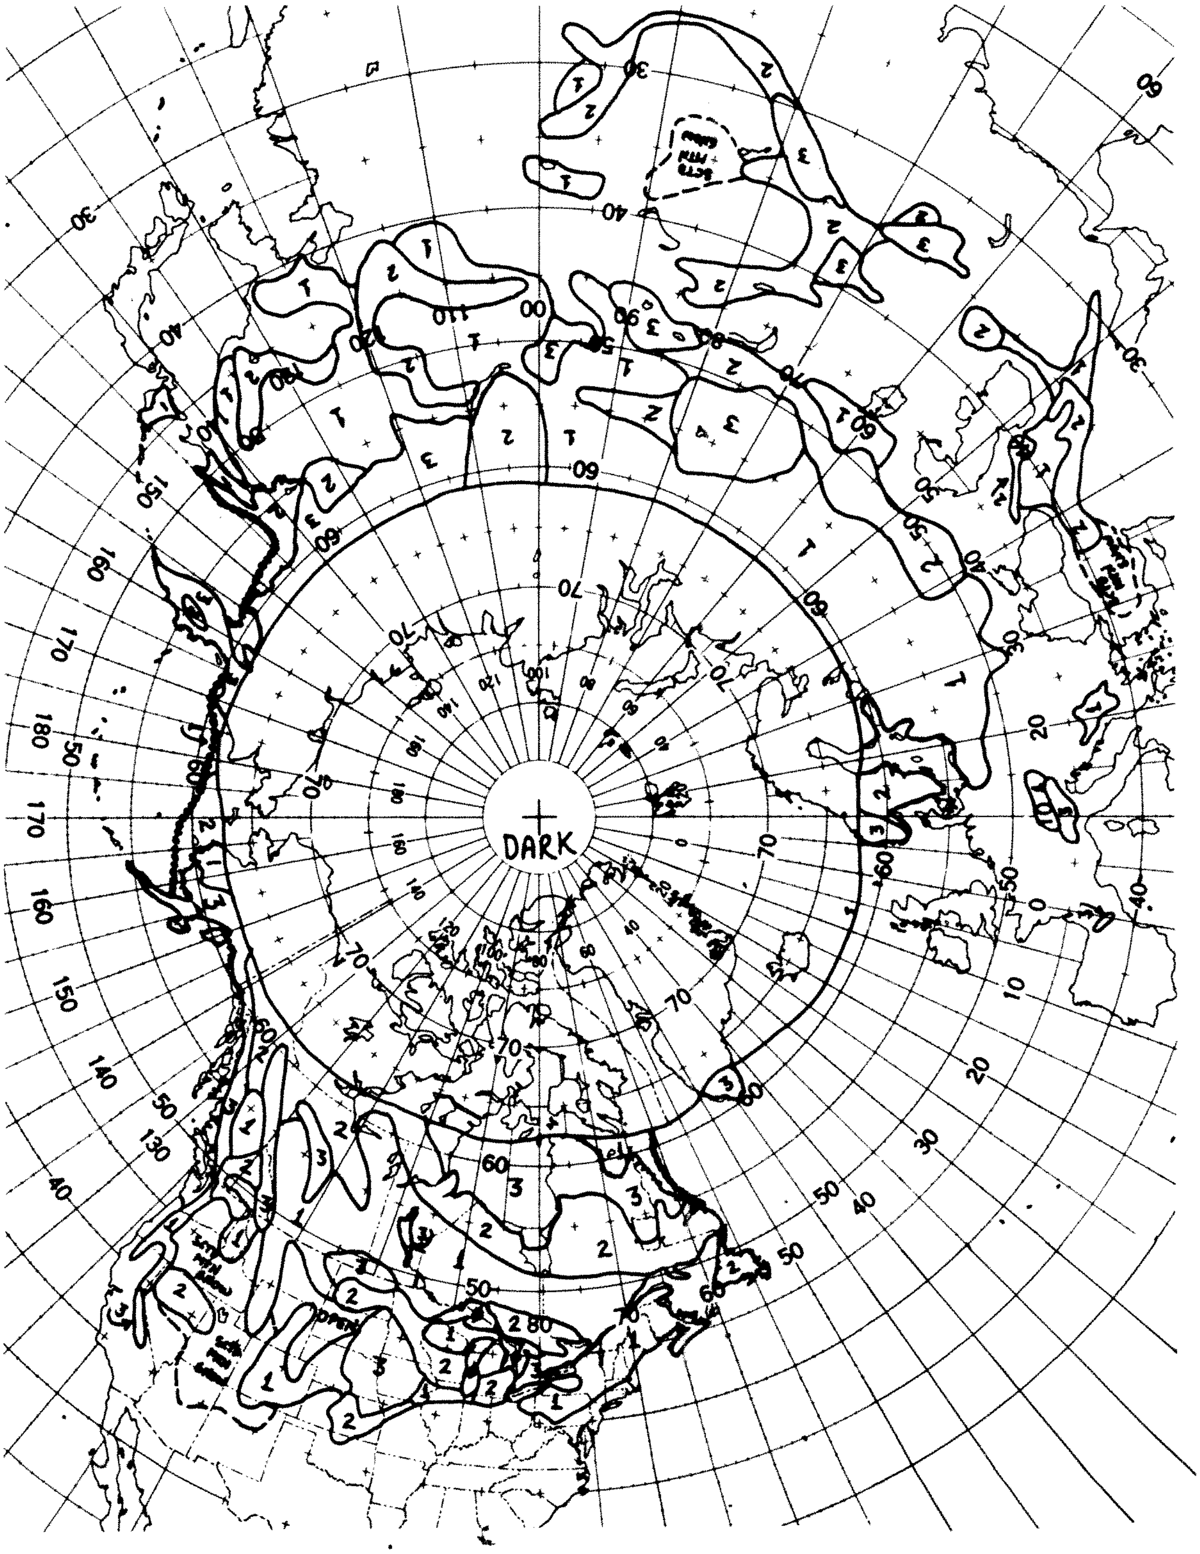

Fig. 1 Typical snow and ice chart of the Northern Hemisphere for the period 29 December 1974 to 4 January 1975 (scale 1:62,500,000), prepared by the Synoptic Analysis Branch, NOAA/NESS. Reflectivities: 1, lowest; 2, moderate; 3, highest. —, snow; ○, ice. Note the 'dark' area where visible data cannot be collected during the polar winter.

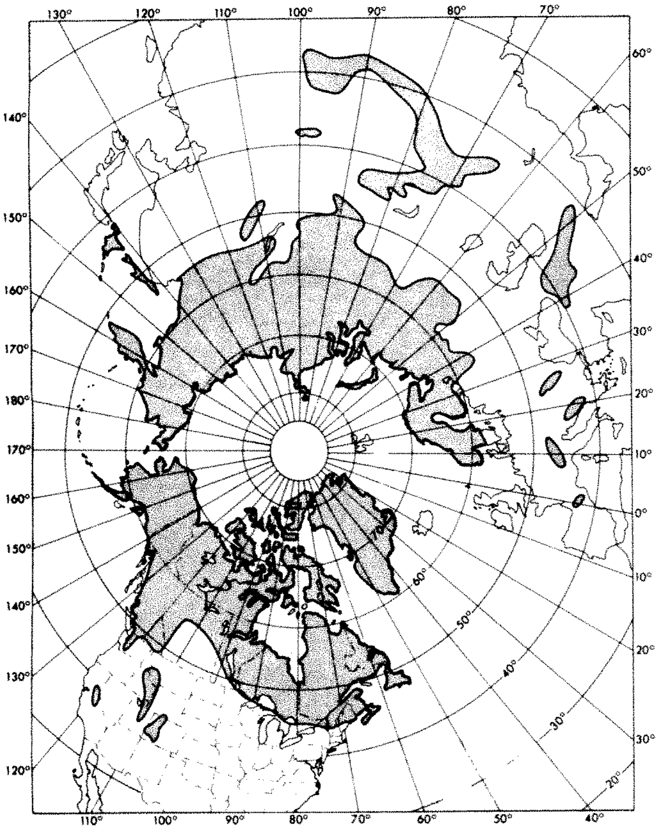

Fig. 2 Monthly mean snow cover chart of the Northern Hemisphere for April 1978 on a stereopolar projection at a ~1:100,000,000 scale. This chart was prepared from the weekly charts.

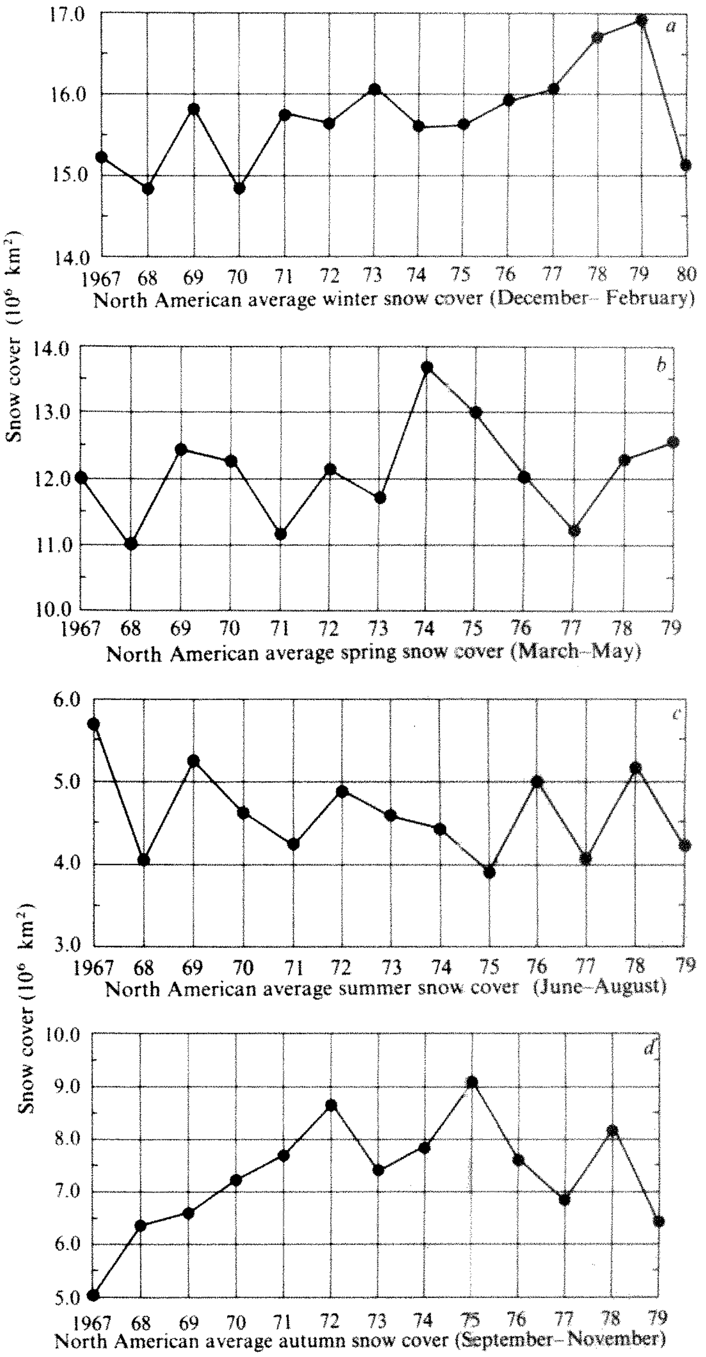
that area will necessarily be several days old. If the area remains cloud covered for the entire week, the previous week's analysis is carried over to the new chart. Finally, the analyst compares his chart with the surface synoptic reports to check for errors or to confirm drastic changes in snow cover, as can result from a new snowfall or rapid snow melt. At the end of the week the new chart is rendered in final form and transmitted to the user community. Solid lines on the chart indicate boundaries between areas of substantially differing brightness (reflectance) of the snow field. The chart is divided into three categories of brightness: (1) lowest reflectivity; (2) moderate reflectivity; and (3) highest reflectivity. These categories are subjective and are chosen by the analyst. Guidelines aiding the analyst in assigning these reflectivity classes include the following. First, the designated reflectivity of a given snow area is the average reflectivity within that boundary, that is, a category (2) could be the average of a small area of category (3) and a small area of category (1), or the entire area could be a category (2) reflectivity. Second, the reflectivity of categories is relative to their surroundings at a particular time of year. For example, although it is much less bright in the winter due to reduced solar illumination, the Greenland icecap is labelled category (3) in both summer and winter. It is, however, much brighter than its surroundings even at this time. Third, when snow-covered mountain tops are seen in large open areas that average less than category (1), the area is labelled as scattered mountain snow. Fourth, when the distinction in reflectivity between small areas of land and water is great, such as over Arctic Canada in early summer, the entire area is labelled 3 over water and 1 over land.

In winter much of the far northern latitudes lies in total darkness or near darkness. Consequently, the visual-band sensors on the satellite are inoperative, and areas around the pole are shown as 'dark'. At the winter solstice the snow and ice chart is labelled 'dark' north of about 55 °N.

The quality of the weekly charts is affected by several factors: The charts are based on interpretations by a variety of observers,



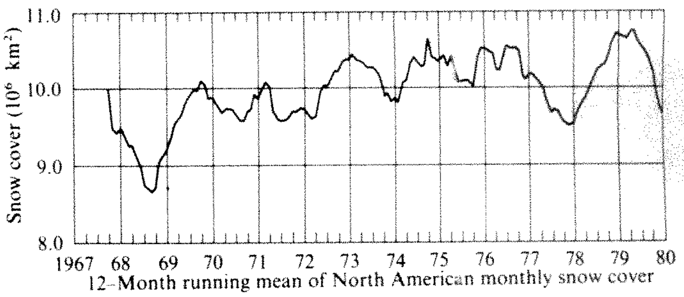
North American average winter snow cover (December–February)

North American average spring snow cover (March–May)

North American average summer snow cover (June–August)

North American average autumn snow cover (September–November)

Fig. 3 *a*, Average North American winter snow cover for the period 1967–1980. Calendar year notation is such that 79 represents the winter of 1978–79. *b*, Average North American spring snow cover for the period 1967–79. *c*, Average North American summer snow cover for the period 1967–79. *d*, Average North American autumn snow cover for the period 1967–79.



12-Month running mean of North American monthly snow cover

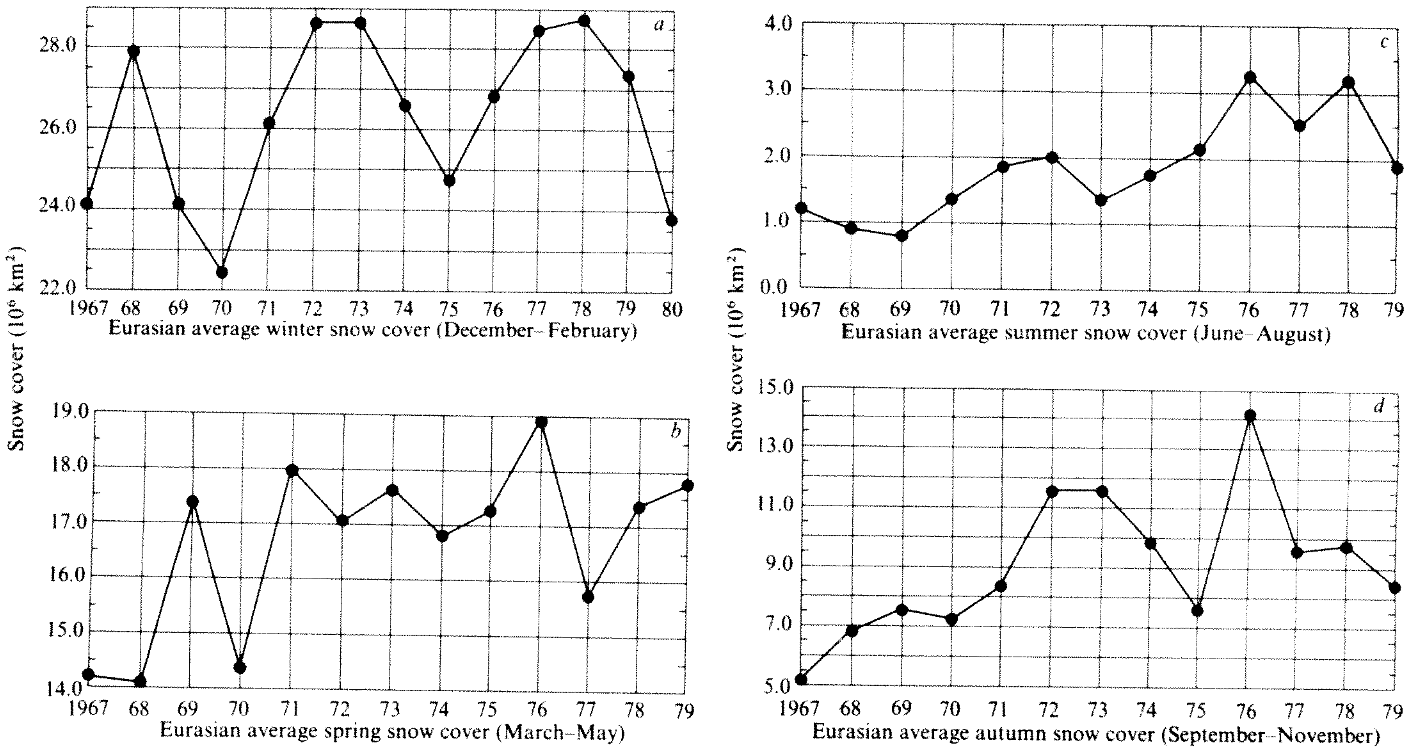

Fig. 5 *a*, Average Eurasian winter snow cover for the period 1967–80. Calendar year notation is such that 79 represents the winter of 1978–79. b, Average Eurasian spring snow cover for the period 1967–79. *c*, Average Eurasian summer snow cover for the period 1967–79. *d*, Average Eurasian autumn snow cover for the period 1967–79.

thus operator bias is undoubtedly present; the scale of the charts limits the precision of snow line positioning to about 20–50 km (ref. 10); Himalayan snow cover was not consistently mapped during the 1966–74 period; the charts show three levels of increasing improvement in consistency and detail—1966–70, 1971–73, and 1974 to the present. Kukla and Robinson[11] analysed the accuracy of the NOAA/NESS weekly charts by comparing them with an independent daily analysis of weekly snow cover based on satellite data and ground station reports for the United States. The analysis covered periods for November 1975, February 1977 and February 1978. After measuring the areal extent of snow cover derived from both the NOAA/NESS and independent analysis, they concluded that: the areal differences tend to be smaller in the more recent charts; the average areal differences are usually less than 10%; the accuracy of the NOAA/NESS weekly charts is adequate for climate-related studies on a continental or hemispheric scale.

Monthly mean snow-cover charts (Fig. 2) have been constructed from the weekly charts for all months from November 1966. The winter (December to March) monthly snow-cover maps from 1966 to 1976 have been published[12] and a digitized atlas of all of the monthly maps is being prepared. The monthly charts are constructed by deriving a subjective average of the NOAA/NESS weekly chart boundaries of each month. The areal extent of continental snow cover within this average monthly snow-cover boundary is then measured and recorded. All continental areas within the 'dark' zone are assumed to be completely snow-covered and are measured as such. The snow-cover values are corrected to represent true surface area coverage. The error in the value of areal snow cover owing to the analogue averaging of weekly data to derive the monthly snow line is approximately 2–5% and randomly distributed[2].

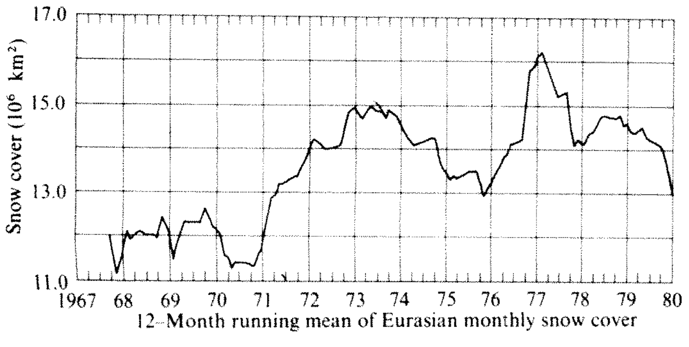

Fig. 6 Twelve-month running mean of Eurasian monthly mean snow cover. The data are plotted on the last month of the 12-month period.

A look at the record

Figure 3 shows a graphical record of North American seasonal snow cover from 1967 to 1980. The average winter snow cover (Fig. 3*a*) rose steadily from 1975 to 1979—an 8% increase when 1979 is compared with 1975. The winters of 1977, 1978 and 1979 are discussed in more detail elsewhere[13–15]. During the severe North American winter of 1978 nearly 70% of the continent was snow-covered. Although characterized by marked fluctuations, spring (Fig. 3*b*) and summer (Fig. 3*c*) average snow cover has been around 12.1×10^6 km^2 and 4.6×10^6 km^2, respectively. Autumn average snow cover (Fig. 3*d*) shows two distinct periods: a period of increase from 1967 to 1972 and a period of levelling off with sharp annual fluctuations from 1972 to 1978. Figure 4 is a 12-month running mean (to remove the annual cycle) of North American monthly snow cover and it shows a slight tend towards increasing snow cover for the continent.

As Eurasia is a larger continent than North America, Eurasian seasonal snow-cover fluctuations exhibit a wider range of values, as revealed by Fig. 5. Winter snow cover (Fig. 5*a*) has an interesting cyclic pattern but the data set is too short to confirm the apparent repeatability. Very large areas of the continent were covered by snow during the winters of 1972, 1973, 1977 and 1978. At these times over 50% of the Eurasian land mass was snow-covered. Spring snow cover (Fig. 5*b*) varies markedly, showing especially large annual changes from 1968 to

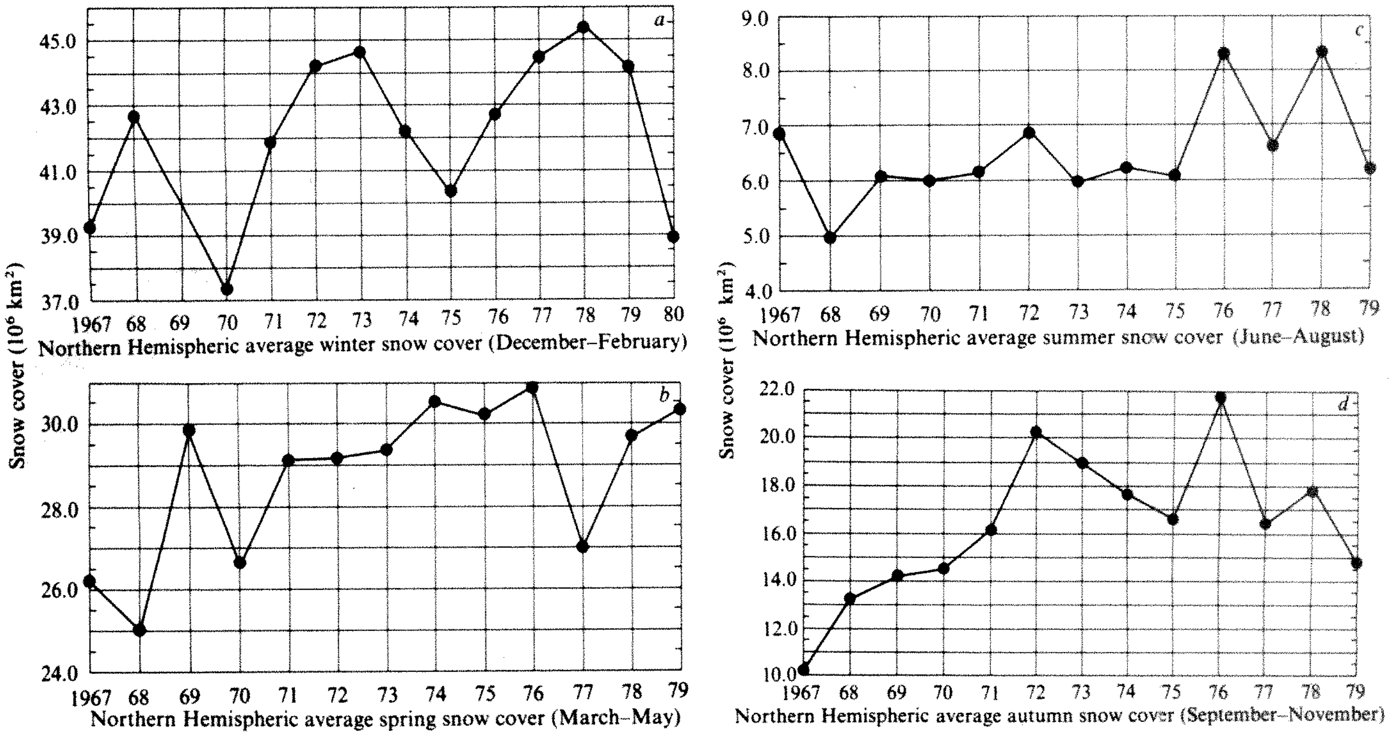

Fig. 7 *a*, Average Northern Hemisphere winter snow cover for the period 1967–80. Calendar year notation is such that 79 represents the winter of 1978–79. *b*, Average Northern Hemisphere spring snow cover for the period 1967–79. *c*, Average Northern Hemisphere summer snow cover for the period 1967–79. *d*, Average Northern Hemisphere autumn snow cover for the period 1967–79.

1971 and 1975 to 1978. Although Eurasian summer snow cover (Fig. 5*c*) shows an increasing trend, the reality of that trend is dubious because of the previously mentioned inconsistency in mapping Himalayan snow cover during the 1966–74 period. The average of the summer snow-cover values from 1975 to 1979, 2.6×10^6 km^2, is probably a more realistic value than the earlier summer values. Autumn snow cover (Fig. 5*d*) also shows an increasing trend over the whole satellite record with a particularly sharp increase in 1976. This increase was in a large part due to a satellite-based record high October snow cover of 19.7×10^6 km^2 compared with a 10-yr (1967–76) average of 9.6×10^6 km^2. Most of this record snow cover occurred from 11 to 17 October when the snow line advanced from 60 to 50 °N in an area longitudinally bordered by 30 °E and 80 °E. This area represents more than 3×10^6 km^2 of snow cover, all in a 1-week period. The snow cover certainly contributed to the high (45%) satellite-derived October zonal albedo value for the area 0–117.5 °E and 60–50 °N (ref. 16). Once established the snow cover persisted throughout the autumn and into the winter. The effect of this anomalous and sudden snow cover on the radiation balance and atmospheric circulation would be interesting for researchers concerned with climate feedback mechanisms.

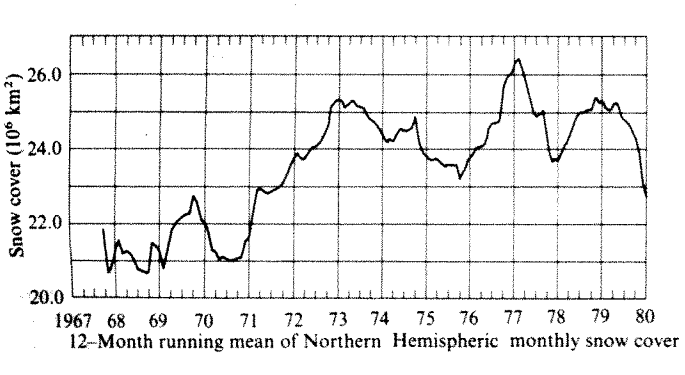

Fig. 8 Twelve-month running mean of Northern Hemisphere monthly mean snow cover. The data are plotted on the last month of the 12-month period.

The Eurasian 12-month running mean of monthly snow cover is shown in Fig. 6. During the satellite record Eurasia has experienced two periods of large increases in snow-cover extent, one from 1971 to 1973, the other from 1976 to 1977. The running mean for Eurasia also shows an overall upward trend.

Except for summer, the proportionally larger variations in Eurasian snow cover dominate the North American variations. The result is that trends in the Northern Hemisphere and Eurasian data for the winter, spring and autumn are similar (Fig. 7*a*, *b*, *d*). During the summer season most of the Northern Hemisphere snow cover is in Greenland and the Canadian archipelago, as shown by the similarities in the graphs of Fig. 3*c* and Fig. 7*c*. The 12-month running mean of Northern Hemisphere snow cover (Fig. 8) is also dominated by the Eurasian snow cover (Fig. 6), both showing similar trends and fluctuations. From these similarities one may conclude that in any study of hemispheric climatic feedback mechanisms involving snow cover, Eurasia has a greater feedback potential than North America.

Conclusions

The present satellite-derived data provide a rapid and timely synthesis of global snow-cover information to assess current conditions. This accumulation of a reliable and relatively unbiased continental snow-cover climatic data base has application in seasonal weather forecasting and in global and regional modelling. As the satellite snow-cover record is extended temporally, it should provide a new understanding of the dynamics of global and regional climate.

We thank Paul McClain for his review, Dennis Haller of SAB for the unpublished description of the construction of the Northern Hemisphere Weekly Snow and Ice Cover Charts, George Kukla for his continued support, Craig Berg for his analysis of the snow cover data during 1978–79, and Mrs Olivia Smith for assistance.

Identification of a glycophorin-like molecule at the cell surface of rat thymocytes

William R. A. Brown, A. Neil Barclay, Christopher A. Sunderland* & Alan F. Williams

MRC Cellular Immunology Unit, Sir William Dunn School of Pathology, University of Oxford, Oxford OX1 3RE, UK

There are three predominant glycoproteins in the rat thymocyte plasma membrane. Two of these have carbohydrate compositions that are characteristic of structures N*-glycosidically linked to protein. The other glycoprotein is very different, having about 20* O*-glycosidically linked carbohydrate units per 100 amino acids. It has similarities to the major sialoglycoprotein of human erythrocytes.*

CELL-SURFACE glycoproteins with large amounts of carbohydrate are found on most eukaryotic cell types. Although little is known of the structure and functions of these molecules, it is widely thought that they may be involved in determining interactions between cells[1,2]. We have now completed the initial characterization of the predominant glycoproteins of rat lymphoid cells.

Much of the membrane carbohydrate on rodent lymphoid cells is found on a small number of cell-surface glycoproteins. These can be identified on intact cells by labelling sialic acid residues with ^{3}H-borohydride after mild periodate oxidation[3]. In the rat and mouse the glycoproteins so labelled are very similar in apparent molecular weight (MW) when analysed by SDS-polyacrylamide gel electrophoresis (PAGE)[4,5]. Figure 1 shows the patterns for rat T and B lymphocytes and thymocytes. T lymphocytes have bands of 170,000 and 95,000 apparent MW (Fig. 1, track 1) and B lymphocytes have one major band of 200,000 apparent MW (Fig. 1, track 2). Thymocytes have predominant bands of 150,000, 95,000 and 25,000 apparent MW (Fig. 1, track 3). The periodic acid Schiff (PAS) staining method identifies similar glycoprotein bands in lymphoid cell membranes analysed by SDS-PAGE[6].

Conventional or monoclonal antibodies against these glycoproteins were prepared and used for analysis and purification of the antigens. The 25,000 apparent MW glycoprotein of thymocytes is the Thy-1 antigen[7]. This molecule is an abundant glycoprotein of rodent thymus (10^6 molecules per thymocyte) and brain and occurs in two allotypic forms in the mouse (reviewed in ref. 8). The correct MW of thymocyte Thy-1 is 18,700 (ref. 9), of which 30% is carbohydrate. The polypeptide of rat brain Thy-1 has been sequenced and the attachment points for three *N*-linked carbohydrate structures have been identified[10]. The Thy-1 antigen seems to be structurally homologous to an immunoglobulin domain[11,12].

The 150,000, 170,000 and 200,000 apparent MW glycoproteins of thymocytes, T cells and B cells share antigenic determinants. These glycoproteins seem to be specific to haematopoietic cells and are synonymous with the leukocyte-common (L-C) antigen in the rat[13] and the T200 glycoprotein in the mouse[14]. In both rat and mouse these molecules bear allotypic determinants – the Ly-5 mouse alloantigen is the T200 glycoprotein[15] and the ART and Ly-1 rat alloantigens are the L-C antigen[16]. The rat thymocyte L-C antigen has been purified using a monoclonal antibody affinity column. There are about 70,000 molecules of antigen per thymocyte[13].

The 95,000 apparent MW bands found on rat thymocytes and T cells share an antigenic determinant recognized by a mouse anti-rat monoclonal antibody called W3/13 (ref. 5). This antibody was prepared after immunization of mice with rat thymocyte plasma membrane[17]. The W3/13 antigen is found on thymocytes, T (but not B) lymphocytes, bone marrow neutrophils and brain, and also on plasma and myeloma cells (ref. 17 and D. Secher, personal communication). The antigen from haematopoietic cells is in every case a glycoprotein of apparent MW 95,000 which is heavily labelled by NaB^{3}H$_4$ after mild periodate oxidation (ref. 5 and W.R.A.B., unpublished data for rat myeloma cells). Brain W3/13 antigen has not been characterized. The 95,000 MW glycoprotein is notable because it does not bind at all to lentil lectin[5,6] and also because removal of sialic acid with neuraminidase results in an apparent increase in size on SDS-PAGE. The asialo glycoprotein can be labelled with ^{3}H-borohydride after oxidation of galactose with galactose oxidase[4]. The results for rat thymocytes are shown in Fig. 1, track 6. The bands of apparent MW 150,000 and 25,000 are unaffected by neuraminidase treatment but the 95,000 apparent MW band is found at 105,000 apparent MW after removal of sialic acid (compare tracks 3 and 6 in Fig. 1). Both these forms of the molecule bind to affinity columns of W3/13 antibody attached to Sepharose 4B (Fig. 1, tracks 5 and 8). Note that not all of the 95,000 or 105,000 MW bands bind to the antibody column (Fig. 1, tracks 4 and 7); we will discuss this further below.

This paper reports the purification of the W3/13 (95,000 MW) glycoprotein and the amino acid and carbohydrate compositions of this molecule and also of the L-C antigen (glycoprotein 150,000 MW) from rat thymocytes. The compositions are compared with those previously published for rat thymocyte Thy-1 antigen (glycoprotein 25,000 MW)[18] and for glycophorin A, the major sialoglycoprotein of human erythrocytes[19].

Table 1 Purification of thymocyte W3/13 antigen

Fraction	Antigenic activity (units $\times10^{-4}$)	Protein (mg)	Relative specific activity	Yield of antigenic activity (%)
Cells (2.82×10^{11}) + Brij 96	9.7	4,825	1	100
Brij 96 extract	9.7	2,594	1.9	100
Brij 96-deoxycholate extract	9.0	1,979	2.3	93
Sepharose 4B–W3/13 antibody unbound fraction	0	1,802	0	0
Sepharose 4B–W3/13 antibody bound and eluted fraction (1st)	7.6	—	—	78
Sepharose 4B–W3/13 antibody bound and eluted fraction (2nd)	7.2	—	—	74
After Sephacryl S300 chromatography	3.7	—	—	38
After ethanol precipitation	2.8	0.198	7,000	29

Thymocytes from Sprague–Dawley rats (OLAC 76) were teased into Dulbecco's A and B buffer, *p*H 8.4. To 2.82×10^{11} cells in 170 ml were added 73 ml of 10% Brij 96 (Sigma), 10 mM iodoacetamide (IAA) and 10 mM diisopropyl fluorophosphate (DFP) in Dulbecco's A and B buffer, *p*H 8.4. The mixture was stirred on ice for 30 min, homogenized with six strokes of a Potter–Elvehjem homogenizer and then centrifuged at 6,300*g* for 20 min. The supernatant (205 ml, Brij 96 extract) was added to 102 ml of 3% sodium deoxycholate and 10 mM Tris-HCl, *p*H 8.0, and the mixture was centrifuged at 70,000*g* for 45 min. The supernatant (285 ml, Brij 96 sodium deoxycholate extract) was then passed at a flow rate of about 20 ml h^{-1} through a control column of mouse immunoglobulin coupled to Sepharose 4B and an 8-ml affinity column of 120 mg of the W3/13 antibody coupled to Sepharose 4B (refs 38, 39). After washing with 2% sodium deoxycholate, 10 mM Tris-HCl, 2 mM IAA and 2 mM DFP, the affinity column was eluted with 50 mM diethylamine–0.5% sodium deoxycholate, *p*H 11.5. The eluate was brought to *p*H 8.6 by the addition of glycine. This eluate was not pure W3/13 antigen and so was passed through the affinity column as above. The material specifically bound and eluted from the column a second time was then concentrated by ultrafiltration over an Amicon PM 10 membrane and chromatographed on Sephacryl S300 in 0.5% sodium deoxycholate and 10 mM Tris-HCl, *p*H 8.4. The eluted material containing the W3/13 antigen was concentrated before precipitation with 75% ethanol[18] at −20 °C. One unit of antigenic activity is the amount of antigen needed to give 50% inhibition of the indirect radioactive binding assay for W3/13 (ref. 17). Protein was assayed by the Lowry method[40] for detergent extracts and by amino acid analysis for the pure glycoprotein. All procedures were carried out at 4 °C.

Purification of the W3/13 antigen (glycoprotein 95,000 MW)

The W3/13 antigen was purified from rat thymocytes using a monoclonal antibody affinity column. In previous purifications of the Thy-1 (ref. 7) and L-C (ref. 13) antigens a plasma membrane fraction was first prepared and then solubilized in deoxycholate to give an extract which was passed through an antibody affinity column. Bound antigen was eluted from the column with high *p*H. This scheme posed problems with the W3/13 antigen because the glycoprotein was very susceptible to proteolysis, yielding a form with an apparent MW of 82,000 as shown in Fig. 1, track 9. This degradation occurred extensively when membranes were prepared using the Tween 40 method[6] even though neither Thy-1 nor L-C antigen showed autolysis during this procedure. The addition of iodoacetamide and diisopropyl fluorophosphate minimized this degradation (Fig. 1, track 10) and we also found that direct solubilization of membrane from whole cells with the non-ionic detergent Brij 96 gave less autolysis. This step also resulted in the recovery of more antigenic activity than when membranes were prepared. The only disadvantage of using the non-ionic detergent was that in antibody affinity chromatography more non-antigenic proteins were adsorbed to the columns than when deoxycholate was used. To minimize this, deoxycholate was added to the Brij 96 extract and the affinity column step was carried out twice.

Table 1 legend describes the purification of the W3/13 antigen. All the antigenic activity was bound by the column and 85% of the applied activity was recovered in the high *p*H eluate. After repeating the affinity column step and carrying out gel filtration, about 30% of the original antigenic activity was recovered at a final purification of ~7,000-fold. It is most unlikely that such a purification could have been achieved by any known procedure other than antibody affinity chromatography.

The purification factor is of the right order of magnitude for obtaining pure W3/13 antigen. If it is assumed that the whole

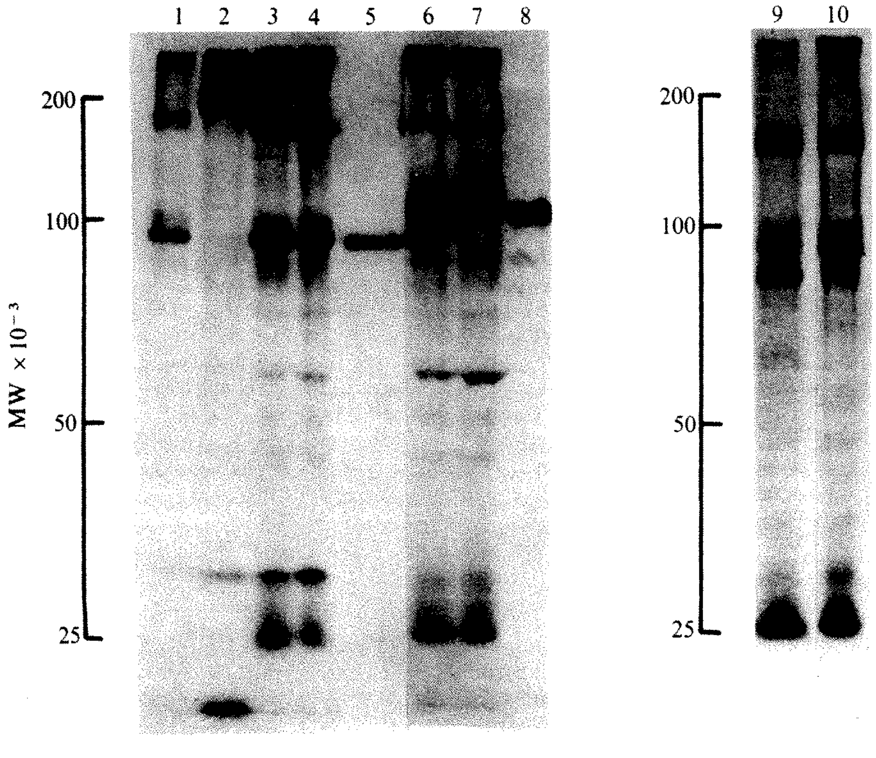

Fig. 1 SDS-PAGE of radiolabelled cell-surface glycoproteins. Tracks 1–5: glycoproteins labelled in sialic acid residues (see below). Track 1, from T lymphocytes; track 2, from B lymphocytes; track 3, from thymocytes; track 4, from thymocytes passed through a W3/13 antibody affinity column; track 5, W3/13 antigen eluted from affinity column. Tracks 6–8: glycoproteins labelled in galactose residues (see below). Track 6, from thymocytes; track 7, from thymocytes passed through a W3/13 antibody affinity column; track 8, W3/13 antigen eluted from affinity column. Track 9: thymocyte glycoproteins labelled in sialic acid from plasma membranes without inhibitors of proteolysis. Track 10: as for 9 plus inhibitors (see below). For tracks 1–8 thymocytes and T and B lymphocytes were prepared as in ref. 5 and labelled with NaB^{3}H$_4$ after oxidation with periodate[3] or galactose oxidase following neuraminidase digestion[4]. Extracts were prepared by resuspending the labelled cells at 3×10^8 ml^{-1} in 3% Brij 96 in Dulbecco's A and B buffer, 5 mM iodoacetamide and 5 mM DFP. After incubation for 15 min on ice nuclei were removed by centrifugation for 10 min at 2,000*g*. One vol of 3% sodium deoxycholate, 10 mM Tris-HCl, *p*H 8, was then added to 2 vol of the Brij 96 extract. For affinity chromatography the extract was passed through a column of W3/13 antibody and washed and eluted as in Table 1. The eluted material was brought to *p*H 8.6 with glycine and inhibitors of proteolysis were added. For tracks 9 and 10 plasma membrane was prepared from radiolabelled thymocytes using the Tween 40 method[6]. To minimize losses $\sim13.5\times10^8$ unlabelled thymocytes were added to 1.5×10^8 labelled thymocytes. For track 10 but not 9 inhibitors of proteolysis (as above) were added at each step. For all samples, glycoproteins were precipitated with 80% acetone at −20 °C overnight and the precipitate was recovered by centrifugation and suspended in 8 M urea, 5% SDS, 2% dithiothreitol. The samples were boiled for 5 min and run on 10% polyacrylamide gels[46]. The radioactive bands were visualized by fluorography[5].

molecule has a MW of 95,000, then that of the protein part is 38,000 (60% is carbohydrate, see below). From this, and the data in Table 1, it can be calculated that there should be 38,000 molecules of W3/13 antigen per thymocyte. At saturation, 35,000 molecules of the W3/13 monoclonal antibody bind per thymocyte[17] and this probably underestimates the number of antigenic sites by about 50% (ref. 20). Although both estimates of the amount of antigen suffer from some uncertainties, the data strongly suggest that the purified molecule is the W3/13 antigen.

The purified W3/13 antigen was analysed by SDS-PAGE followed by staining for protein with Coomassie blue (Fig. 2*a*) and carbohydrate with PAS stain (Fig. 2*b*). The purified glycoprotein stains very heavily with PAS stain and this is illustrated in Fig. 2 by comparing the staining of W3/13 antigen with that of rat brain Thy-1 antigen. With Coomassie blue stain 4 μg of protein gave roughly equal staining with both glycoproteins (Fig. 2*a*), whereas with PAS stain the W3/13 glycoprotein was stained much more intensely than Thy-1 (Fig. 2*b*). The purified W3/13 antigen showed more than one band with both Coomassie blue and PAS stain. Densitometry on the trace in Fig. 2*a* gave 70% of the stained material in the peak at 95,000 apparent MW, with other minor peaks at apparent MWs 86,000 and ~70,000. These are probably proteolytic products of W3/13 antigen as they stain heavily with PAS stain. This possibility was supported by an experiment in which the glycoprotein was run on SDS-PAGE followed by slicing the gel and assaying for W3/13 antigenic activity in material eluted from the gel. The results, which are considered to be semi-quantitative, are shown in Fig. 2*c* and antigenic activity is associated with the protein and carbohydrate bands shown in Fig. 2*a* and *b*. Small amounts of antigenic activity were also detected at an apparent MW of 58,000 where Coomassie blue staining bands cannot be seen. The overall conclusion from Fig. 2 is that the W3/13 antigen is sufficiently pure for determination of carbohydrate and amino acid compositions.

Table 2 Amino acid and carbohydrate composition of the W3/13, L-C and Thy-1 antigens and of human glycophorin A

Residue	W3/13	L-C	Thy-1	Glycophorin A
	Amino acids per 100 amino acid residues

The data for W3/13 and L-C antigens were determined as below; the data for rat thymocyte Thy-1 (L^+ form) and human glycophorin are from refs 18 and 19, respectively. (The glycophorin carbohydrate composition was calculated from that given for the chymotryptic 1 peptide, which contains all the carbohydrate structures.) Amino acids were quantified on a Durrum D500 after 24, 48 and 72 h of hydrolysis in 6 M HCl and 0.005 M phenol *in vacuo* at 110 °C. Ser and Thr were calculated by extrapolation to zero time. Cys and Met were determined after performic acid oxidation[41]. The data for W3/13 and L-C were for five and four preparations, respectively. Trp in L-C antigen was detected spectrophotometrically[42]. No Trp was detected in W3/13 by the method described in ref. 43. The s.e.m.s were less than 5% of the mean value except for Met, Tyr and His, which were less than 12% of the mean value. Hexoses and amino sugars were determined by gas–liquid chromatography after methanolysis and trimethylsilylation[44]. Sialic acid was also determined fluorometrically[45] with correction for interferences by hexoses and hexosamines. The carbohydrate analyses were from two to five separate preparations of W3/13 and L-C antigens. The s.e.m.s were less than 10% of the mean. The amino sugars were also analysed by ion exchange chromatography following hydrolysis in 3 M *p*-toluene sulphonic acid[43]. The values (not shown) were similar to those obtained by gas–liquid chromatography. Glucose was also found in fractions from the Sephacryl S300 column which did not contain W3/13 antigen and was therefore assumed to be a contaminant. The percentage by weight of carbohydrate of W3/13 and L-C glycoproteins was determined using the sialic acid values obtained by the fluorescence method, assuming it was *N*-acetylneuraminic acid. Amino sugars were assumed to be *N*-acetylated.

A final point regarding the purification is the relationship between the molecule which binds to the W3/13 antibody column and the whole of the 95,000 MW glycoprotein band. This glycoprotein appears homogeneous and the fact that all ^{3}H-labelled material shows the unusual behaviour after neuraminidase digestion (see Fig. 1) would suggest that the whole band is structurally similar. Despite this, it is clear that the W3/13 monoclonal antibody binds only a part of the glycoprotein. When solubilized membrane is passed through the affinity column, although all W3/13 antigenic activity is bound (Table 1) a part of the 95,000 apparent MW or the asialo 105,000 apparent MW glycoprotein band does not bind (Fig. 1, track 4 compared with 3, and track 7 compared with 6). Radioactivity counting in gel slices indicates that about 50% of the glycoproteins did not bind. This is not an artefact of glycoprotein radiolabelling because the same result was seen if material passing through the antibody column was analysed by PAS staining after SDS-PAGE (data not shown). It seems that the monoclonal antibody detects antigenic heterogeneity in glycoprotein molecules with an overall similarity of structure, a view supported by the fact that mouse antibodies raised against the purified W3/13 antigen can react with the 95,000 apparent MW band which has passed unretarded through the W3/13 antibody affinity column (W.R.A.B., unpublished observations).

Chemical composition of the W3/13 antigen and the L-C antigen from thymocytes

The pure W3/13 and L-C antigens, purified as previously described, were analysed for their carbohydrate and amino acid contents. The results are given in Table 2 where they are compared with the compositions of rat thymocyte Thy-1 antigen and human erythrocyte glycophorin A.

The W3/13 antigen has a carbohydrate composition quite unlike either of the other two heavily glycosylated molecules of the rat thymocyte membrane. Carbohydrate comprises 60% w/w of the molecule and consists solely of galactose, galactosamine and sialic acid. (Some glucose was also detected but this is probably due to contamination; see Table 2 legend.) No mannose or glucosamine was detected and thus the molecule lacks carbohydrate structures of the type which are *N*-linked to asparagine through *N*-acetylglucosamine and have a core of glucosamine and mannose residues[21]. The carbohydrate composition of W3/13 glycoprotein is what would be expected if the molecule contained structures of the type

$$\begin{tikzcd} \text{NANA} \arrow[r, "\alpha 2-3"] & \text{Gal} \arrow[r, "\beta 1-3"] & \text{GalNAc} \arrow[r] & \text{Ser/Thr} \\ & & \text{NANA} \arrow[u, "\alpha 2-6"'] & \end{tikzcd}$$

which are found attached to proteins by an *O*-glycosidic linkage to serine or threonine[21]. The absolute amount of galactosamine and galactose suggests that there are about 20 such structures per 100 amino acids and this is supported by the finding that Ser and Thr together constitute 27 mol % of the amino acids, an unusually high proportion.

The *O*-glycosidic linkage of carbohydrate to protein is alkali labpe whereas the *N*-glycosidic bond is not. Alkali effects a

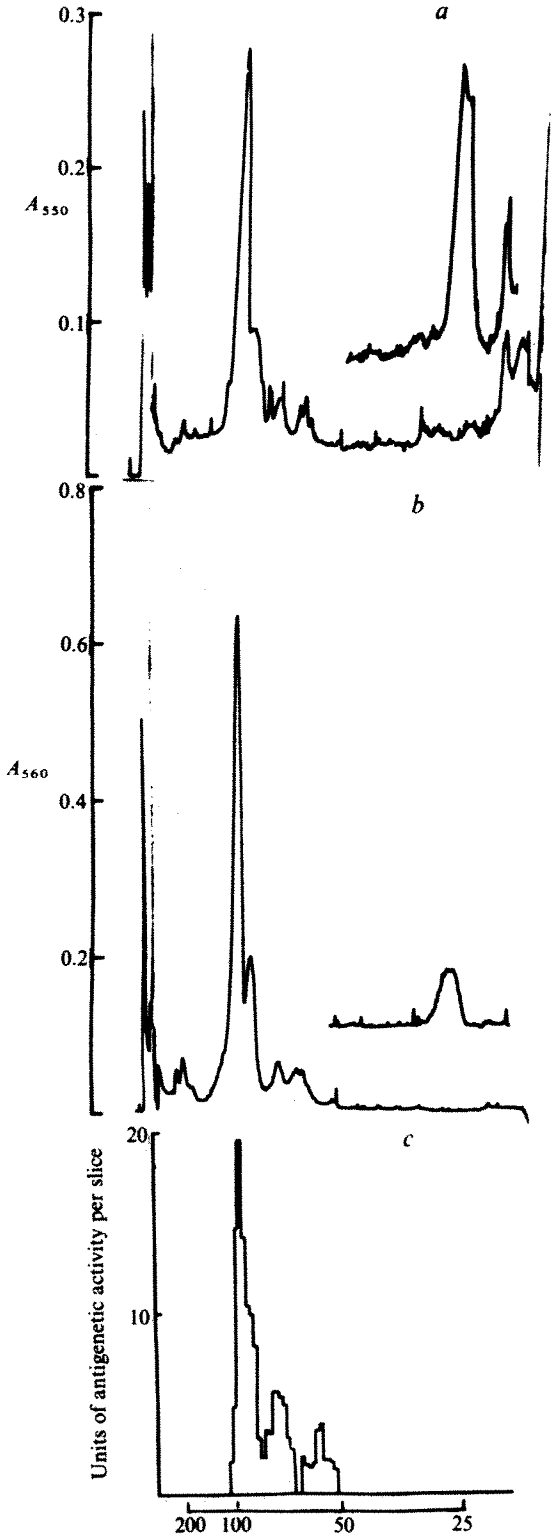

Fig. 2 SDS-PAGE of purified W3/13 antigen. W3/13 glycoprotein purified as in Table 1 was electrophoresed at 4 μg protein per sample on 11% polyacrylamide slab gels (3% stacking gel) and stained with Coomassie blue (*a*) and periodic acid Schiff stain (*b*) (methods as in ref. 6). The figure shows absorbance across the gel read by densitometry using a Gilford 2520 densitometer scanning at 550 nm for Coomassie blue and 560 nm for PAS stain. The insets show the traces from gels on which 4 μg protein of rat brain Thy-1 antigen was electrophoresed and stained with Coomassie blue (*a*) and PAS (*b*). *c* Shows the recovery of W3/13 antigenic activity after SDS-PAGE. A 3-μg protein sample of W3/13 glycoprotein was suspended in 0.1% SDS, 10% glycerol and electrophoresed as above. The gel was then sliced into 1-mm slices which were extracted overnight at 20 °C with 135 μl of 1% bovine serum albumin and 10 mM Tris-HCl, *p*H 8. The antigenic activity of the extracts was assayed by inhibition of an indirect binding assay for W3/13 antigen[17]. One unit of activity is the amount of antigen needed to give 50% inhibition of the standard assay. The total recovery of antigenic activity was 66% of that expected.

β-elimination of the carbohydrate attached to protein at serine or threonine residues. If this reaction is carried out in the presence of excess $NaBH_4$, the aldehyde at the reducing terminus of the eliminated oligosaccharide is reduced to an alcohol[22]. Thus, if the carbohydrate of W3/13 antigen is *O*-linked to Ser and Thr, it should be released in a low MW form by β-elimination in the presence of excess $NaBH_4$. This was examined using glycoprotein which had been labelled with tritium in its sialic acid or galactose residues (after removal of sialic acid). The results (Fig. 3) show that in both cases almost all the labelled carbohydrate was released by β-elimination into low MW forms which were retarded in gel filtration on a Bio-gel P-6 column. With asialo glycoprotein one low MW peak was obtained whereas alkali treatment of the sialylated glycoprotein gave two peaks. The latter two peaks presumably constitute structures containing one and two sialic residues. This is supported by the compositions (Table 2) which show that there is insufficient sialic acid for all structures to have two sialic acid residues as indicated in the structure above. The only unusual point about the results in Fig. 3 is that the ^3H-labelled oligosaccharides were retarded rather less than would be expected for their proposed MW in comparison with marker compounds chromatographed separately. The significance of this is unclear, but the data strongly suggest that all the sialic acid and galactose of the W3/13 antigen occurs in *O*-linked structures.

There is no similarity between the composition of the L-C antigen of rat thymocytes (glycoprotein MW 150,000) and W3/13 glycoprotein. Also, the amino acid content of L-C antigen shows no particular distinguishing features (Table 2); carbohydrate constitutes 25% w/w of the molecule, and the predominant saccharides present are mannose, galactose, *N*-acetylglucosamine and sialic acid. This suggests that the L-C antigen contains mainly *N*-linked carbohydrate, the low value for *N*-acetylgalactosamine arguing against a large number of *O*-linked structures. The compositions for L-C antigen are quite similar to those for Thy-1 antigen (Table 2). Brain Thy-1 antigen has three *N*-linked structures per polypeptide[10] (111 amino acids) and thymocyte Thy-1 may have the same attachment points but with structures differing in the extent of completion at the terminal branches[18]. The L-C antigen has about half as many mannose and *N*-acetylglucosamine residues per 100 amino acids as Thy-1 antigen. This suggests that there are roughly 1.5 *N*-linked carbohydrate structures per 100 amino acids, and thus about 15 *N*-linked structures per molecule, assuming a molecular weight of 150,000. The amino acid composition of Thy-1 antigen and L-C antigen are similar, but this is uninformative as the molecules differ markedly in size and do not have unusual amino acid compositions.

Discussion

We have shown here that one of the three major glycoproteins of rat thymocytes is unusual in having an *O*-linked carbohydrate structure attached to about one amino acid in five. This must have a major effect on the structure of the molecule. Presumably there would be little tertiary folding of the polypeptide and the molecule probably adopts an extended conformation in solution[23,24]. The expression of such a molecule at cell surfaces can be anticipated to have an important effect on the charge and topography of the outer surface. From the data in Tables 1 and 2 it can be calculated that on rat thymocytes 4×10^6 molecules of sialic acid are attached to the W3/13 antigen and probably twice this amount if all of the 95,000 MW glycoprotein is taken into account. This compares with $\sim 2 \times 10^6$ molecules of sialic acid per cell on Thy-1 antigen (two residues per molecule, 10^6 molecules per cell) and the same number on L-C antigen (30 residues per molecule and 70,000 molecules per cell). On both T lymphocytes and bone marrow neutrophils there is at least as much W3/13 antigen as on thymocytes[17]. An equivalent glycoprotein molecule can be identified on the cell surface of mouse thymocytes and T lymphocytes[3,4] and it seems possible that the major glycoprotein of 90,000 MW which has been identified on mouse neutrophils[25] is the equivalent of the rat W3/13 antigen.

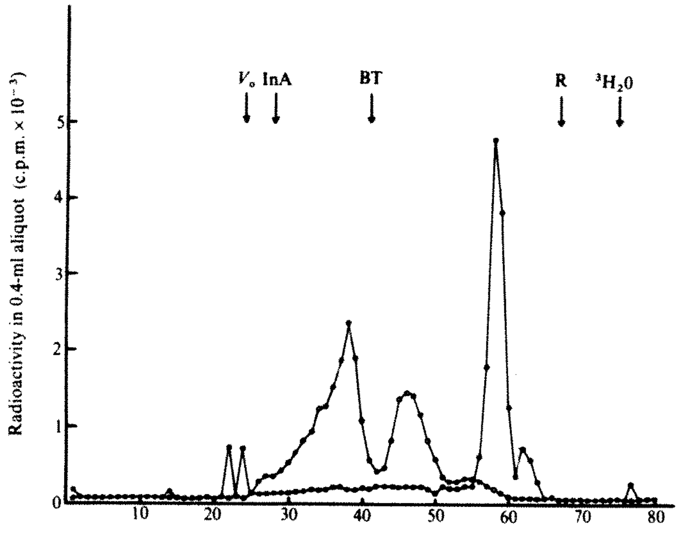

Fig. 3 Gel filtration of oligosaccharides derived by alkaline-borohydride degradation of ^{3}H-W3/13 antigen. ^{3}H-labelled W3/13 was prepared as described in Fig. 2 legend from thymocytes labelled with NaB^3H_4 after mild periodate oxidation (○) or after incubation with neuraminidase and galactose oxidase (●). The ^{3}H-labelled W3/13 was dialysed into distilled water and then subjected to alkaline borohydride degradation as described in ref. 22. After destruction of the excess $NaBH_4$ with acetic acid the mixture was fractionated on a Bio-gel P-6 column (102 × 1 cm) in 0.1 M NH_4HCO_3 at a flow rate of 4 ml h^{-1}. Fractions (1.1 ml) were collected of which 0.4-ml aliquots were scintillation counted in 3 ml Biofluor (NEN). The positions of elution of the following markers are shown. InA, insulin A, MW 2,360; BT, bacitracin, MW 1,460; R, raffinose, MW 504.

The expression of W3/13 antigen on T but not B lymphocytes may contribute to some of the differences between these cell types. Rodent T lymphocytes can be separated from B lymphocytes by electrophoresis because T cells are more acidic[26]. The presence of W3/13 antigen on T lymphocytes may be the reason for this difference in charge. Also, T lymphocytes are generally regarded as being less 'sticky' than B cells[27] and *in vivo* T cells recirculate more rapidly from blood to lymph[28]. Such differences could be mediated by an extended cell-surface molecule with a high concentration of negative charges which acts to impede surface contact.

Molecules with a high content of *O*-linked carbohydrate have been described from a variety of sources. A serum glycoprotein of this type is the anti-freeze protein of fishes which live at sub-zero temperatures[29]. A glycoprotein with similarities to the W3/13 antigen has also recently been purified from human serum[30]. Whether it might have originally derived from cell surfaces is not known. This molecule has an apparent MW of 140,000 on SDS-PAGE and contains 76% w/w carbohydrate, most of which is *O*-linked. Studies on this molecule suggest that it has a very extended conformation and little secondary structure[30]. Membrane or glycocalyx molecules with a high content of *O*-linked carbohydrates have also been described[21]. These include mucins which form a glycocalyx at epithelial cell surfaces and glycoproteins isolated from ascites tumour cells. These molecules seem to be much larger than the thymocyte glycoprotein described here and in the case of the tumour cell glycoproteins it has been suggested that the molecules mask other cell-surface structures[31,32].

The membrane molecule most like the W3/13 antigen is glycophorin, the major sialoglycoprotein of human erythrocytes. This molecule has 15 *O*-linked carbohydrate structures plus one *N*-linked structure attached to a sequence of 131 amino acids[19]. The amino acid and carbohydrate compositions for glycophorin are given in Table 2 and the similarities between this molecule and W3/13 glycoprotein are striking. Both molecules lack Cys and Trp and have low amounts of basic residues and high values for Ser, Thr and Pro. Significant differences are seen in the amounts of His, Ala, Gly, Tyr, Ile and Phe. In the carbohydrate compositions the *N*-linked structure of glycophorin is indicated by the presence of mannose and glucosamine. The similarities between the W3/13 glycoprotein and glycophorin suggest that these molecules may be evolutionarily related (alternatively, the similarities in amino acid composition could simply be a consequence of the unusual structure). There is more than one gene coding for the human erythrocyte glycophorins[33,34] and a family of genes, some members of which are expressed on other cells, could have evolved by gene duplication. The W3/13 antigen is not found on rat erythrocytes[17] but these cells are likely to express other glycophorin-like molecules[35].

The function of glycophorin is unknown and its importance has been questioned following identification of individuals who lack the molecule but show no defect in erythrocyte function[36,37]. This finding is difficult to evaluate because the expression of carbohydrate on other erythrocyte membrane molecules is altered in these individuals[36]. The finding of a glycophorin-like molecule as a major constituent of a number of other haematopoietic cell types (and possibly brain) strongly suggests that molecules of this type are functionally important. Their main role may be to alter the charge characteristics of the cell surface, particularly at a distance from the phospholipid bilayer. The expression of such molecules may affect the ease with which the membrane can align with that of another cell and thus be an important physical constraint in cell interactions.

We thank Mr W. Potts for assistance with carbohydrate analyses, Mr T. Gascoyne of the MRC Immunochemistry Unit, Oxford, for amino acid analysis and Mrs J. Kosak for typing the manuscript. W.R.A.B. was supported by an SRC research studentship.

The reactivation of developmentally inert 5S genes in somatic nuclei injected into *Xenopus* oocytes

Laurence Jay Korn & J. B. Gurdon

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

In the frog Xenopus, *the somatic-type 5S ribosomal RNA genes are active in all cells; the oocyte-type 5S genes are active in oocytes but not in somatic cells. A new method of native gel electrophoresis resolves the two types of 5S RNA which are of the same length but different sequence. When somatic nuclei were injected into oocytes, their inactive oocyte-type 5S genes often remained inactive, and had thus conserved their developmentally regulated condition. Other conditions, which include treatment with 0.35 M NaCl, reactivated the genes.*

THERE are two classes of 5S ribosomal RNA genes in the genome of *Xenopus* and other amphibians. One class, comprising the oocyte-type 5S genes, is expressed in oocytes, but not in somatic cells[1,2]. The other class, the somatic-type 5S genes, is expressed in both oocytes and somatic cells[2]. We are investigating the mechanism by which the oocyte-type 5S genes are inactivated in somatic cells, as this may elucidate the mechanism by which the cell type-specific expression of genes is achieved in development.

The transcription of cloned 5S genes has been studied extensively with purified DNA in injected oocytes[3-5] as well as in cell-free systems[6-13]. However, in none of these cases is the natural pattern of differential transcription between oocyte- and somatic-type genes reproduced; in injected oocytes and somatic cell extracts, both types of 5S gene are transcribed. As we believe that genes in an intact nucleus are more likely to exhibit regulated transcription, we have injected whole somatic nuclei into oocytes. Then, if the oocyte-type 5S genes are activated, we can investigate changes associated with activation; but, if these genes remain inactive after injection, we can determine which components of the nuclei must be removed to obtain reactivation.

Previous work encourages this approach. We found that somatic nuclei injected into *Xenopus* oocytes are transcriptionally active for many days[14]. In one series of experiments, a gene product made in HeLa cells continued to be synthesized by HeLa nuclei injected into oocytes[15]. In other experiments, genes characteristically inactive in somatic cells were activated after the injection of nuclei into oocytes[16].

We describe here different conditions in which the oocyte-type 5S genes in somatic nuclei can either be made to remain inactive or can be reactivated after their injection into oocytes. To assay for selective transcription of oocyte- or somatic-type 5S RNA, we have developed a generally useful procedure for distinguishing between different RNAs of identical length. Although we do not yet know what factors are responsible for the developmental regulation of 5S gene transcription, this new approach to studying the expression of specific genes as part of an intact nucleus can be used to yield information on the control of these genes.

Rapid resolution of different RNAs of the same length

The oocyte and somatic types of *Xenopus* 5S RNAs are the same length (120 nucleotides) and differ from each other in sequence by six nucleotides in both *Xenopus laevis* and *Xenopus borealis*[17,18]. All four RNAs co-migrate on a denaturing polyacrylamide gel (Fig. 1*a*). The four types can be distinguished by RNA fingerprinting[17], but this procedure is too laborious for use with numerous samples. We have developed a simple electrophoresis assay which distinguishes all four 5S RNAs, and which is suitable for the analysis of many samples simultaneously.

X. laevis and *X. borealis* oocyte- and somatic-type 5S RNAs are unambiguously resolved by electrophoresis through a non-denaturing 17% polyacrylamide gel prepared and run as described in Fig. 1 legend. The substantially different mobilities of these four RNAs probably reflect differences in conformation in these conditions. In modified conditions which favour less secondary structure (elevated temperature, urea), resolution is considerably decreased. For our purposes, the main value of this method is for the rapid determination of the relative synthesis of oocyte- and somatic-types of 5S RNA (Fig. 1*b*).

The resolving power of this gel system, however, is not limited to 5S RNAs. The yeast tyrosine tRNA SUP4 and a mutant tRNA U67 are both 78 nucleotides long, and differ only by a single base change at position 67 ($C \rightarrow U$)[19]. These tRNAs migrate with different mobilities on native gels (Fig. 1*c*), though they migrate together on denaturing gels[20]. Similar results have been obtained for other tRNAs.

5S genes are efficiently transcribed in injected nuclei

Cultured cell nuclei injected into living oocytes are transcriptionally active. Oocytes injected with as few as 100–200 nuclei synthesize many times more somatic-type 5S RNA than uninjected control oocytes (Fig. 2, lanes 1–9 compared with lanes

Table 1 Activation of oocyte-type 5S genes in erythrocyte nuclei injected into oocytes

	Oocytes injected with erythrocyte nuclei	Adult somatic cells		
		Liver	Tissue culture cells	Factor of activation
Oocyte-type 5S RNA	40	<0.05	<0.07	800
Somatic-type 5S RNA	1	1	1	

Erythrocyte nuclei prepared by lysolecithin treatment were injected into oocytes, aiming for the germinal vesicle. Four hours later 1 μCi [α-^{32}P]GTP was injected, and the oocytes labelled for 2 days. Subsequent analysis was as for Figs 1, 2. The relative intensities of oocyte- and somatic-type 5S RNA bands were measured by microdensitometry. Data presented are the average of seven samples from two experiments. To determine the relative synthesis of oocyte- and somatic-type 5S RNA in somatic cells, an adult *X. laevis* was injected with 5 mCi $^{32}PO_4$. After 4 days, the liver was removed and the RNA extracted[36]. The sample was electrophoresed with a 5S RNA marker on a 12% polyacrylamide 7 M urea gel, the 5S RNA region excised and the RNA eluted from the gel[37]. The RNA was then re-electrophoresed on a 17% polyacrylamide native gel as described in Fig. 1 legend. *Xenopus laevis* kidney tissue culture cells were labelled for 24 h and the RNA isolated and electrophoresed as described in Fig. 3 legend. The relative intensities of oocyte- and somatic-type 5S RNA bands were determined. The absence of oocyte-type 5S RNA in tissue culture cells may be due to rapid turnover of such transcripts. However, we also failed to detect any oocyte-type 5S RNA when cultured cells were labelled for only 4 h.

0028-0836/81/060461—05$01.00

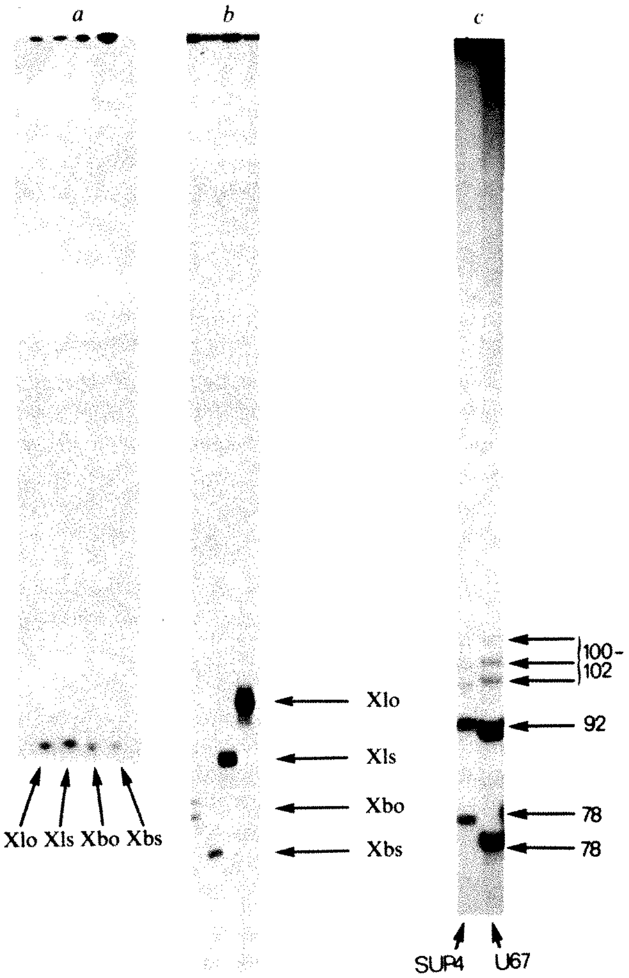

Fig. 1 Separation of RNA molecules by gel electrophoresis in non-denaturing conditions. *a*, Autoradiogram of a denaturing 12% polyacrylamide–7 M urea gel[38] of ^{32}P-RNA synthesized in *Xenopus* oocytes when [α-^{32}P]GTP and pXlo 8, pXls 11, pXbo 3, or pXbs 1 5S DNA were injected. pXlo 8 contains four *X. laevis* oocyte-type 5S genes[4]. pXbo 3 contains six *X. borealis* oocyte-type 5S genes[4,39]. pXls 11 and pXbs 1 contain one repeating unit each of *X. laevis* and *X. borealis* somatic-type 5S DNA, respectively[23]. About 5 ng DNA and 1 μCi [α-^{32}P]GTP were injected into the germinal vesicle of each oocyte. The oocytes were incubated at 20 °C for 24 h and the RNA extracted by the method of Brown and Littna[40]. The gel is 0.35 mm thick and contains 12% polyacrylamide, 7 M urea, 0.05 M Tris borate, *p*H 8.3, and 1 mM EDTA. For all gels, hypersensitized film was exposed at −70°C using a Dupont lightning plus intensifying screen. RNA transcripts from the cloned DNAs, following injection into oocytes, have been sequenced and identified as oocyte- or somatic-type 5S RNA from the respective *Xenopus* species[4,18,23]. *b*, Autoradiogram of a native 17% polyacrylamide gel of ^{32}P-RNA synthesized in *Xenopus* oocytes when [α-^{32}P]GTP and pXlo 8, pXls 11, pXbo 3, or pXbs 1 5S DNA were injected. DNA injections, and conditions for the synthesis and extraction of 5S RNA are as described for *a*. After ethanol precipitation and two 70% ethanol washes, the RNA sample was redissolved in 1–5 μl 10% glycerol, 1 mM EDTA, 0.05% xylene cyanol and 0.05% bromophenol blue. The 17% polyacrylamide (1:20 bisacrylamide/acrylamide), 0.35 mm-thick gel was prepared in 40 mM Tris, 20 mM Na acetate and 2 mM EDTA, to *p*H 7.8 with acetic acid. The electrode buffer was 50 mM Tris, 0.4 M glycine and 1 mM EDTA, *p*H 8.3. Electrophoresis was at constant current (9–11 mA) for 24 h. 5S RNA migrates through the gel at a rate of approximately 1 cm kV^{-1} h^{-1}. For maximum resolution, the gel should not be allowed to exceed 30°C. The pXbo 3 clone contains two types of Xbo gene (ref. 39, and L. J. K. and D. D. Brown, unpublished) the 5S RNA transcripts from these genes separate on the native gel. *c*, Autoradiogram of a native 17% polyacrylamide gel of ^{32}P-RNA synthesized in *Xenopus* oocytes when [α-^{32}P]GTP and pSUP4 or pU67 DNA were injected. pSUP4 contains the yeast Tyr tRNA SUP4 gene[41] and pU67 contains a single base change (C → U) at position 67 of the mature tRNA[19]. *Xenopus* oocytes transcribe and process these yeast tRNA genes[42]. The mature tRNAs are 78 nucleotides long. DNA injections, conditions for the synthesis and extraction of RNA and gel electrophoresis were as described above. tRNA precursor molecules of 92 and 100–102 nucleotides are indicated. Note that although the U67 mature tRNA migrates faster than SUP4, the 92- and 100–102-nucleotide precursor molecules do not. Therefore, the separation of the two 78-nucleotide molecules cannot be explained by the samples in one lane of the gel migrating faster than those in another.

10–12). The transcription of 5S genes in injected nuclei continues for at least 4 days (Fig. 2, lanes 7–9), and would probably continue for as long as the oocytes themselves remain synthetically active (sometimes for a few weeks). The rate of somatic-type 5S RNA synthesis has been estimated from the specific activity of the ^{32}P-GTP pool of oocytes (2.5 Ci mmol^{-1}), and from the number of ribosomes ($\sim 10^7$) synthesized per cell cycle in cultured cells. From these calculations, the rate of somatic-type 5S RNA synthesis in somatic nuclei injected into oocytes (500 transcripts per gene per h) seems to be at least as much as in the same nuclei when they were present in somatic cells (350 transcripts per gene per h). Thus this efficient transcription produces sufficient material from a single oocyte injected with nuclei to determine whether the 5S RNA synthesized is the oocyte or somatic type. As 5S transcription by injected nuclei is so much more than the endogenous level, the following results reflect the activity of 5S genes in the injected somatic nuclei and not that of the oocytes' own 5S genes.

The efficient transcription of nuclei injected into oocytes can be compared with that of isolated somatic nuclei incubated *in vitro*. Using two procedures optimized for transcription by RNA polymerase III (refs 6, 21), we found that 10^7 nuclei from *Xenopus* cultured cells incubated for 2 h synthesized only just enough 5S RNA to be detected (Fig. 2, TCN), or 0.025 transcripts per gene per h.

Activation or non-activation of oocyte-type 5S genes

Before assessing changes in 5S gene activity, we must establish the level of their activity before injection—in normal somatic cells and in oocytes. In somatic cells (see Table 1; Fig. 3, TCC; ref. 22) there are at least 20-fold more somatic-type 5S transcripts than oocyte-type 5S transcripts. This contrasts with the 5S gene copy number which in *X. laevis* favours the oocyte-type 5S genes by 50:1 (ref. 23). Thus, each somatic-type 5S gene is approximately 1,000 times more active in somatic cells than each oocyte-type gene. In the oocyte, on the other hand, the oocyte-type 5S transcripts predominate (oocyte/somatic 5S RNA ratio approximately 20:1) (ref. 2 and unpublished results). Note that, unlike the 18S and 28S ribosomal RNA genes, gene amplification is not responsible for this preferential expression of oocyte-type 5S genes in oocytes[24,25], the same number of these genes (20,000 per haploid chromosome set in *X. laevis*) being present in oocytes and in somatic cells.

As shown in Fig. 2, oocyte-type 5S genes of injected somatic nuclei can remain inactive after introduction into oocytes. Furthermore, this inactivity persists unaltered for at least 4 days. However, in several experiments we have observed the opposite result—an activation of oocyte-type 5S genes. Figure 3 shows the result of injecting samples of the same nuclear suspension into oocytes of two females. In the oocytes of one female,

Table 2 NaCl activation of oocyte-type 5S genes

No. activated/no. not activated	0.11	3.5	0.2	4.7
Effect of NaCl $\left(\frac{\text{ratio}+\text{NaCl}}{\text{ratio}-\text{NaCl}}\right)$	31x		24x	

An activated oocyte is one in which, following injection of somatic nuclei, the amount of oocyte-type 5S transcripts is greater than somatic-type 5S. No activation means somatic-type 5S transcripts exceed oocyte-type ones. Nuclei were prepared from *X. laevis* tissue culture cells by lysolecithin or Triton treatment[26]. Salt-washed nuclei were incubated for 15 min at 0 °C in 0.35 M NaCl at a concentration of 5×10^6 nuclei ml^{-1} before injection. Approximately 500 nuclei were injected into single oocytes from non-activating females, aiming for the germinal vesicle. Each assay is a single oocyte.

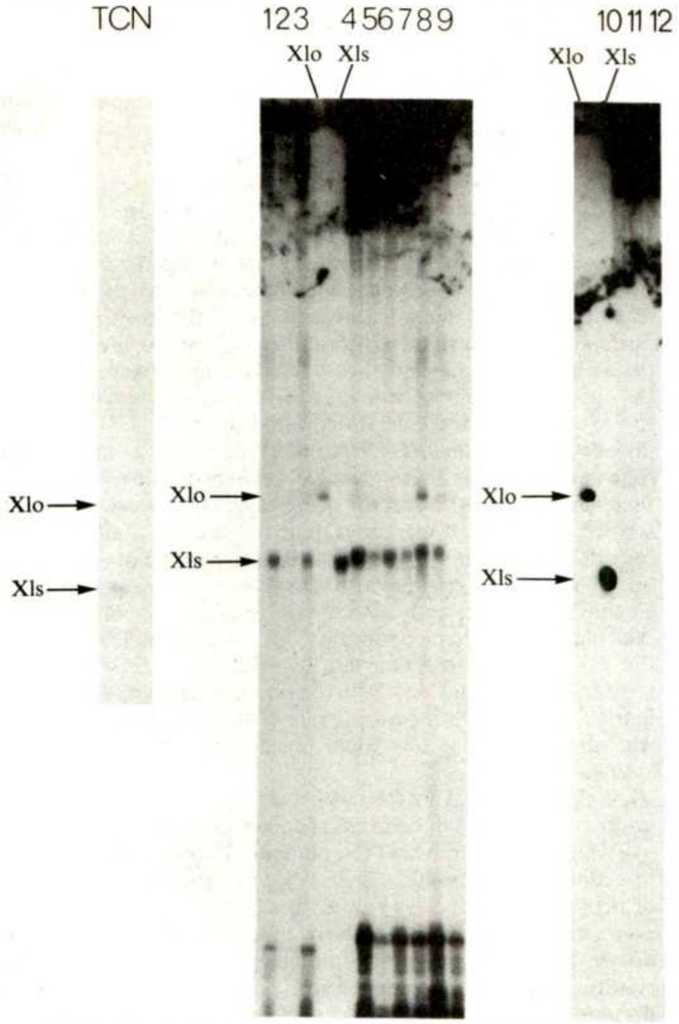

Fig. 2 5S gene transcription by somatic nuclei injected into oocytes. Tissue culture nuclei (TCN) were prepared by Triton treatment[26] from a line of *X. laevis* kidney cells growing in culture. 10^7 nuclei and 50 μCi [α-^{32}P]GTP were incubated for 2 h at 25°C as described by Crampton and Woodland[21]. The RNA was extracted and electrophoresed on a 12% polyacrylamide–7 M urea gel and the 5S RNA band was located by its co-migration with Xlo and Xls markers (see Fig. 1*a*). The 5S RNA band was excised and the RNA eluted[37]. The RNA was then electrophoresed on a 17% polyacrylamide native gel (track TCN). The positions of *X. laevis* oocyte-and somatic-type 5S RNAs which have been eluted from the denaturing gel and then electrophoresed on the native gel are indicated with arrows. Lanes 1–12, between 100 and 500 tissue culture cell nuclei prepared by lysolecithin treatment[26] were injected into individual oocytes, aiming for the germinal vesicle, followed by a second injection of 1 μCi [α-^{32}P]GTP at 4 h (lanes 1–3), 24 h (lanes 4–6) or 4 days (lanes 7–9) after the first injection. Tissue culture cells were removed from culture dishes by scraping rather than with trypsin because nuclei prepared from trypsin-treated cells were often toxic to oocytes. Control oocytes were injected with [α-^{32}P]GTP only (lanes 10–12). The endogenous oocyte transcription contributes to the high-molecular-weight RNA at the top of the gel. In this and all subsequent figures, the RNA was analysed as in Fig. 1 legend and half the RNA from individual oocytes electrophoresed in each lane of the native gel. tRNA molecules (bottom of gel) provide an internal control for the relative efficiency of labelling of RNA transcripts in different oocytes. Occasionally, a modest activation of oocyte-type 5S genes is observed (for example, lane 8); note, however, that Xlo 5S genes outnumber Xls genes by 50 : 1 (ref. 23).

Table 3 5S DNA-binding protein does not activate oocyte-type 5S genes

	Concentration (μg ml^{-1})	No. of oocytes with oocyte-type 5S genes Fully activated	Partially activated	Not activated
7S particle	1.5	0	0	7
7S particle	7.5	0	0	8
7S particle	60	0	2	5
Protein	0.8	0	0	8
Protein	3.8	0	0	8
Protein	30	0	0	8
None	—	0	1	7

Erythrocyte nuclei (about 200 per oocyte) were mixed with 7S particle or purified protein and injected into non-activating oocytes. The concentrations given are those of the material as injected. If the injected material was evenly dispersed throughout the oocyte, the intracellular concentration would have been about 10 times less (50 nl injected into 1 μl oocytes, of which about half the volume is solid yolk). The concentration of particle and protein used by Pelham and Brown[33] and in our experiments (purified as described in refs 32, 33) to give two- to six-fold stimulation of 5S DNA transcription ranged from <1 to >20 μg ml^{-1}. Injected ocytes are classified as partially activated when the ratio of labelled oocyte-type to labelled somatic-type 5S RNA was between 1 : 1 and 3 : 1, and as not activated when this ratio was 1 : 1 or less. Note that we never observed full activation (ratio $\geq$10 : 1). In a second experiment, in which again no evidence of activation was obtained by 7S particle or protein, full activation (oocyte-type/somatic-type 5S RNA ratio of $>$10 : 1) was observed when nuclei were treated with 0.35 M NaCl and Triton (as in Table 2 legend).

oocyte-type 5S genes were activated (Fig. 3, lanes 1–4); in the oocytes of the other they remained quiescent (lanes 5–8). Altogether we have tested oocytes from 50 females. Of these, 27 were activating, such that the amount of oocyte-type 5S RNA was between 5- and 40-fold greater than that of somatic-type 5S RNA. Sixteen females were non-activating, with an oocyte-type/somatic-type 5S RNA ratio of $<$1. Seven females had oocytes which gave intermediate values.

Note two aspects of these results. First, oocytes taken from the same female at intervals over a few months always (six females tested 2–4 times each) show the same activating or non-activating qualities as initially determined. Second, the pattern of somatic-type 5S transcription and tRNA synthesis in injected oocytes is approximately the same whether or not the oocyte-type 5S genes are activated (see, for example, Fig. 3). Somatic-type 5S RNA therefore provides an essential control, eliminating the possibility that the inactivity of oocyte-type 5S genes could be due to inviability of the injected nuclei in these oocytes. We conclude that the developmental inactivation of oocyte-type 5S genes takes place by a process that is readily reversed by components of the oocytes of some but not all females.

We have considered whether the oocyte-type 5S transcripts observed after the injection of somatic cell nuclei into activating oocytes could have resulted from a stimulation of transcription of the oocytes' endogenous 5S genes. This possibility has been eliminated by injecting *X. laevis* nuclei into oocytes from an activating *X. borealis* female. If the oocyte-type transcripts were coded for by the injected nuclei, they would be Xlo-type 5S RNA; however, if they were transcribed from the oocytes' own genes, they would be the Xbo type. The 5S RNA obtained co-migrates with Xlo, and not with Xbo (Fig. 3, lanes 9–11). Thus we conclude that the injected somatic nuclei are indeed activated to synthesize oocyte-type 5S RNA, and that the factor(s) responsible for this activation is not species specific.

5S gene activation in mature erythrocytes

Activation of 5S oocyte-type genes from cultured cell nuclei injected into oocytes might be due to the cell line becoming aberrant during many years of culture, as reported for a particular cultured line of *Xenopus* cells in which up to 15% of 5S transcripts are of the oocyte type[22]. We have therefore repeated our experiments with the nuclei of adult *Xenopus* erythrocytes to assess whether the inactivation of genes in a highly specialized, non-dividing, terminal cell type is also readily reversible.

Nuclei prepared by lysolecithin treatment[26] of mature erythrocytes of an adult frog were injected into oocytes of activating and non-activating females. Consistent with our results using nuclei from tissue culture cells, we find that erythrocyte nuclei injected into oocytes from non-activating females express somatic-, but not oocyte-type, 5S genes. In oocytes from activating females, on the other hand, the synthesis of oocyte-type 5S RNA was 40 times that of somatic 5S RNA (Table 1),

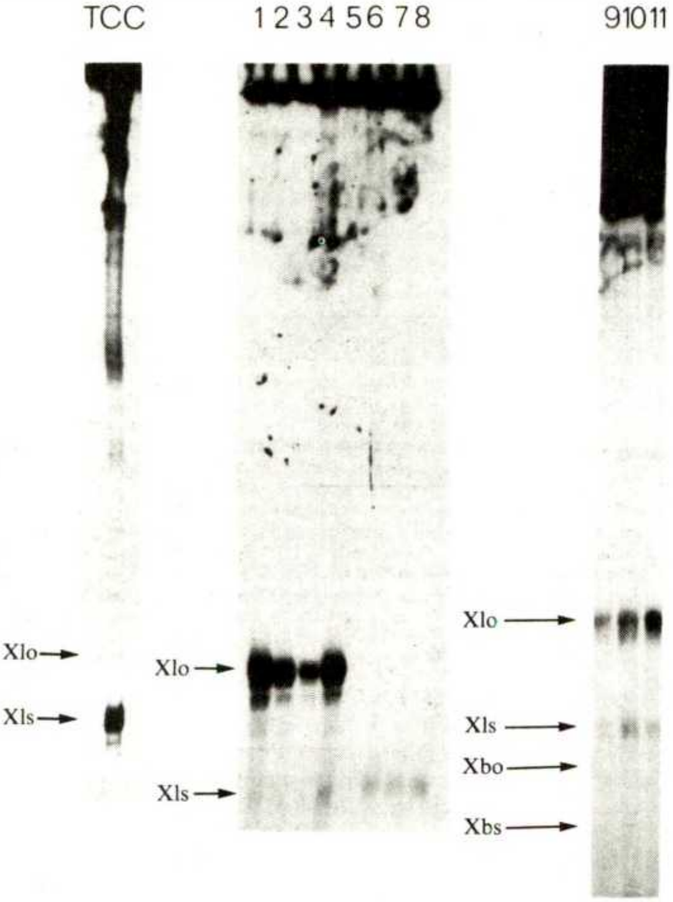

Fig. 3 Activating and non-activating oocytes. TCC, a 50% confluent flask of *X. laevis* kidney tissue culture cells (TCC) was incubated with 2 mCi ^{32}P inorganic phosphate for 24 h. Washed cells were lysed in isotonic buffer essentially as described by Kumar and Lindberg[43], except that the Nonidet P40 concentration was reduced to 0.2%. The RNA was electrophoresed on a 17% polyacrylamide native gel as described in Fig. 1 legend. Lanes 1–8, about 500 tissue culture cell nuclei prepared by lysolecithin treatment were injected with 1 μCi [α-^{32}P]GTP into individual oocytes from *X. laevis* female A (lanes 1–4) or female B (lanes 5–8), aiming for the germinal vesicle. Labelling was for 24 h. Lanes 9–11, approximately 300 *X. laevis* kidney TCC nuclei prepared by lysolecithin treatment were injected into individual *X. borealis* oocytes, aiming for the germinal vesicle, followed by a second injection of 1 μCi [α-^{32}P]GTP 4 h later. Labelling was for 40 h. The positions of *X. laevis* and *X. borealis* oocyte- and somatic-type 5S RNA, prepared as described in Fig. 1 legend, are indicated by arrows. tRNA synthesis, as seen at the bottom of the gel but not shown, was unaffected by the activated or non-activated state of the oocyte-type 5S genes.

just as was found in fully activated cultured cell nuclei. Similar results were obtained with a preparation of nuclei from immature blood cells taken from an adult *Xenopus* which had been rendered anaemic by the injection of phenylhydrazine 14 days earlier[27]. The 40-fold excess of oocyte over somatic 5S RNA represents a major activation of oocyte-type 5S genes, comparable with the endogenous ratio in oocytes (20–40 : 1). In somatic cells, as described above, the transcription of oocyte-type 5S RNA is typically less than 5% of that of the synthesis of somatic 5S RNA. We confirmed this by measuring the ratio of oocyte to somatic 5S RNA synthesis in liver, which is the erythropoietic organ of *Xenopus* adults (Table 1). Thus erythrocyte nuclei undergo at least an 800-fold activation of their oocyte-type 5S genes after injection into oocytes (see Table 1 legend for comments on this calculation). We conclude that the developmental inactivation of 5S genes is as easily reversed in a highly specialized, normal, adult cell type as it is in a cultured line of cells.

Oocyte components required for gene activation

The germinal vesicle is the site of 5S gene activation. To help identify the components responsible for inactivating oocyte-type 5S genes in somatic cells, we have investigated the intracellular location and general nature of the activity concerned. If the activity is localized in the oocyte's nucleus or germinal vesicle (GV), gene activation should occur only when nuclei are injected into the GV and not when injected into the cytoplasm. The site of injected nuclei has been determined by examination of stained oocyte sections, as well as by the co-injection of purified DNA known to be transcribed only in the GV[3,28]. In all the experiments reported above, injected nuclei were aimed at the oocyte's GV, and sections of oocytes revealed that in 90% of the cases, nuclei are indeed deposited there (Fig. 4). The co-injection of *X. borealis* DNA (Xbs) and whole nuclei was followed by analysis using native gel electrophoresis to distinguish Xb and Xl transcripts (Fig. 1*b*); Xbs DNA was transcribed in nearly all injections aimed at the GV, but never in injections aimed at the cytoplasm. The same type of analysis of nuclei injected together with DNA into activating oocytes established that the activation of oocyte-type 5S genes does not take place in the recipient oocytes' cytoplasm, though it did so in the GV of the same oocytes. Somatic-type 5S genes were transcribed by nuclei located in the cytoplasm as well as by those in the GV, although the overall rate of somatic 5S transcription was about 10 times less when nuclei were deposited in the cytoplasm.

Treatment with NaCl activates oocyte-type 5S genes. Another approach to the analysis of 5S gene activation by oocytes is to ask whether the removal of components of somatic nuclei before injection facilitates the effect. We have treated suspensions of nuclei in various ways before injecting them into oocytes of non-activating females, and have then assessed the extent of oocyte-type 5S activation by native gel electrophoresis. The results, which are summarized in Table 2, confirm that nuclei prepared by lysolecithin or Triton treatment alone only rarely synthesize more oocyte- than somatic-type 5S RNA. In contrast, 15 min incubation in 0.35 M NaCl at 0 °C, a procedure designed to remove most non-histone proteins[29], usually results in a pronounced activation of oocyte-type 5S genes (oocyte/somatic 5S ratio 10–30 : 1). In one experiment where nuclei were treated with 2 M NaCl and 0.5% Triton (Cook nucleoids)[30], a procedure which depletes almost all nuclear proteins, oocyte-type 5S genes were fully activated to give an oocyte/somatic 5S RNA ratio of over 30 : 1. Note that the 0.35 M NaCl treatment can activate the oocyte-type 5S genes to the same extent as in Cook nucleoids. Although the effect of removing materials from nuclei before injection is substantial, we have had occasional experiments in which NaCl treatment has little if any effect. We have not yet distinguished several possible explanations for the effect of NaCl.

The 5S DNA-binding protein does not cause activation. Engelke *et al.*[31] have isolated a protein from *Xenopus* ovaries that binds to the part of the coding region of 5S genes known as the control region[12,13], and which is required specifically for the transcription of both oocyte- and somatic-type 5S DNA *in vitro*. Recently, it has been shown that this same protein combines with 5S RNA to form a 7S particle characteristic of *Xenopus* ovaries[32,33]. These observations raise the possibility that this 5S DNA-binding protein may be responsible for 5S gene activation in oocytes.

We have tested this possibility by injecting oocytes of a non-activating female with somatic nuclei as well as with 5S DNA-binding protein or the 7S particle which contains this protein. We found no effect of either the protein or 7S particle on the reactivation of oocyte-type 5S genes in injected somatic nuclei (Table 3) or on total 5S transcription. We have tested the protein and particle on oocytes of two different non-reactivating females, and over several concentrations ranging from 1- to 25-fold the concentration required to give maximum stimula-

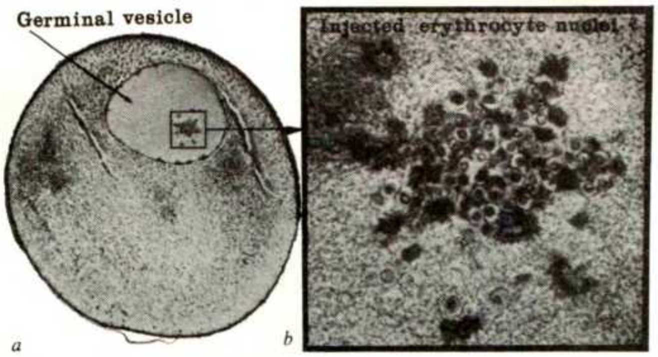

Fig. 4 Erythrocyte nuclei in injected oocytes. Oocytes were injected with a few hundred adult *Xenopus* erythrocyte nuclei prepared by the lysolecithin procedure[26], fixed after 1 day[26], sectioned and stained. *a*, The position of injected nuclei in the oocyte nucleus (germinal vesicle). *b* Shows an enlargement of the injected nuclei. Some of the nuclei appear to have formed dense-staining masses of chromatin, similar to those sometimes observed when HeLa nuclei are deposited in an oocyte germinal vesicle (see Fig. 3b of ref. 26). We do not know whether the 5S gene transcription which we observe comes from the chromatin masses or intact nuclei, both of which are seen in this oocyte section.

tion *in vitro*[33]. Pelham and Brown[33] showed that both protein and 7S particle independently stimulate transcription of 5S DNA *in vitro* by a factor of 2–6. As the preparations of protein and particle which we used also stimulated 5S DNA transcription when tested *in vitro*, we conclude that these substances are not sufficient for the reactivation of oocyte-type 5S genes in somatic nuclei.

Discussion

The rapid reactivation of the developmentally inert oocyte-type 5S genes in somatic nuclei, following their injection into oocytes, demonstrates the ready reversibility of gene expression in development, and is consistent with previous work involving the introduction of nuclei into *Xenopus* eggs or oocytes. The development of tadpoles from transplanted adult skin cell nuclei implies the reactivation of developmentally inert genes[34]. However, in this case, many cell divisions take place before reactivation is observed. More recently, two-dimensional gel analysis of proteins was used to demonstrate the synthesis of new proteins which are not expressed in a cultured line of *Xenopus* kidney cells, when nuclei from these cells were injected into oocytes[16]. The reactivation of gene expression is particularly clear in the case of the oocyte-type 5S genes, both because the primary transcripts derived from well characterized genes have been analysed, and the degree of developmental inactivation of these 5S genes is exceptionally strong. Nuclei injected into oocytes do not undergo division[26], and the activation therefore applies to the same actual genes or molecules of DNA as were previously inert. Our demonstration of 5S gene activation depends on the resolution of RNAs of identical size by gel electrophoresis in non-denaturing conditions, a method which is likely to be of considerable value in separating other groups of related RNAs such as low-molecular-weight nuclear RNAs[35].

The experiments reported here have shown that one can study the activity of genes in a regulated ('switched-off') condition. As far as we know, all cases in which purified genes as DNA have been tested for activity *in vitro* or *in vivo* result in the loss of the regulated state; for example both oocyte and somatic types of 5S DNA are fully active when injected into oocytes or added to somatic cell extracts[4,10,11]. This unique ability to observe regulated gene expression derives from the fact that in whole nuclei, as used in this study, genes are in their natural chromosomal environment. Thus the genes are still complexed with protein or other molecules with which they are naturally associated. The possibility that the developmental regulation of genes may require larger segments of DNA than are at present convenient to clone, or the cooperation of parts of the genome entirely unlinked to the genes being studied is easily accommodated by our system.

Our experiments give only indirect information about the nature of the activating effect of oocytes and hence about the developmental inactivation which is reversed. (1) Treatment with 0.35 M NaCl, which dissociates only a minority of chromosomal proteins[29], has nearly as much reactivating effect as 2 M NaCl and detergent which removes most of the molecules from DNA. This emphasizes again the lability of the developmental inactivation of 5S genes. We do not know whether NaCl activation involves the same mechanism as the effect of activating oocytes on untreated nuclei. (2) The 5S DNA-binding protein which promotes transcriptional activity *in vitro*[31,33] did not cause activation when tested by injection. Gene activation therefore seems unlikely to result from the mere presence of this protein in activating oocytes and its absence or low concentration in non-activating oocytes. This protein has not yet been shown to be able to discriminate between oocyte- and somatic-type 5S genes in its transcription-promoting effect.

The surprising existence of certain females which have non-activating oocytes, as well as others which have activating oocytes, was at first disturbing, but may eventually be providential; we can now prepare extracts of activating or non-activating oocytes and inject these with somatic nuclei into oocytes of the opposite type, with a view to fractionating the active extract.

We thank S. Whytock and R. Wells for assistance, Drs D. Brown, R. Roeder, K. Nishikura and E. De Robertis for communicating unpublished results, Dr J. Gottesfeld for providing *X. laevis* kidney tissue culture cells, and Drs D. Brown, R. Laskey, D. Melton, B. Meyer, G. Partington, J. Wells and M. Wickens for helpful discussions and comments on the manuscript. During part of this work, L.J.K. was a postdoctoral fellow of the Helen Hay Whitney Foundation.

Cruciform structures in supercoiled DNA

Nikos Panayotatos* & Robert D. Wells

Department of Biochemistry, College of Agricultural and Life Sciences, University of Wisconsin, Madison, Wisconsin 53706

Specific sites in supercoiled pVH51 and pBR322 DNAs are cleaved by single-strand specific nucleases. These sites are in the loops of potential cruciform structures.

CRUCIFORMS have been favourite hypothetical recognition sites on DNA since they were first postulated[1]. The observation that several regulatory sites contain varying lengths of inverted repeat sequences encouraged these speculations[2]. If a cruciform existed *in vivo*, even transiently, it could be stabilized by a suitable protein. In supercoiled DNA, however, the necessary free energy could be provided by supercoiling and relatively stable cruciform structures might exist. The thermodynamic properties of superhelical DNA and potential cruciform structures have been studied[3–5].

This article describes strong evidence supporting two naturally occurring cruciform structures in supercoiled DNA.

Cleavage of supercoiled DNA by single-strand specific endonucleases

Figure 1 shows the rates of cleavage of supercoiled pVH51 DNA by S_1 nuclease[6] (*a*) and the T_7 gene 3 product[7–9] (*b*). In both cases, the supercoiled DNA (form I) is converted to the nicked-circular DNA (form II), which is then converted into the linear form (form III). Further nicking events on form III eventually cause double-strand breaks and generate smaller molecules which appear as a smear on the gel. Figure 1*a* shows that when relatively high levels of S_1 nuclease were used, complete conversion of the supercoiled DNA to form II was observed after only a few seconds. After 8 min, almost all of the nicked DNA had been linearized and by 90 min most had been degraded to smaller pieces. When lower levels of the T_7 gene 3 product were used, the gradual conversion of the supercoiled DNA to form II was observed over 4 min. Using appropriate levels of enzymatic activity, each of the discrete steps of the reaction can be monitored. Overall, pVH51 DNA is cleaved by S_1 nuclease and the T_7 gene 3 product with similar rates for each step.

Although these data permit a kinetic evaluation of the conversion of supercoiled DNA to linearized segments, they cannot provide information on the position-specificity of the cleavage, as both forms II and III are obligatory intermediates in the reaction.

Mapping of cleavage sites on pVH51 DNA

To determine if the nucleolytic cuts in supercoiled pVH51 DNA were at specific or random loci, the DNA was treated with each single-strand specific endonuclease and then specifically cleaved with a restriction enzyme. If the cleavage was the result of nicking at random sites, identical restriction patterns would be obtained for the single-strand specific nuclease-treated and untreated DNA. On the other hand, if linearization occurred at specific sites, the restriction pattern of the single-strand specific nuclease-treated DNA would show the loss of one (or more) fragment(s) and the appearance of new fragments with the same total length.

The results of these experiments are shown in Fig. 2. pVH51 DNA was incubated with S_1 nuclease until approximately one-half of the DNA was linearized (Fig. 2*a*, lane 2). (The reaction was not carried further so as to prevent the degradation that accompanies extensive linearization (see below).) When the S_1-treated and untreated DNAs were digested with *Hae*III, the gel analysis showed the typical pattern expected from this digest (ref. 10 and refs therein) (Fig. 2*b*). However, as shown in lane 2, the intensity of the 610-base pair band of the DNA that had been treated with S_1 nuclease was reduced by approximately 50% relative to the undigested control and, in addition, two new bands appeared. The sizes of the two new fragments were 340 and 270 base pairs and their sum (610 base pairs) equalled the size of the fragment whose intensity was reduced. This indicated that S_1 nuclease cleaves pVH51 DNA very specifically at a position inside the 610-base pair *Hae*III fragment.

When pVH51 DNA was linearized with the T_7 endonuclease and then restricted with *Hae*III, the same two new bands appeared at 340 and 270 base pairs (Fig. 2*c*, lane 5), indicating that this enzyme also cleaves pVH51 DNA at the same specific position as the S_1 nuclease. Furthermore, when analysed by a double digest with *Hae*III and *Hin*dII, *Hin*dII cleaved the 610-base pair fragment to the 510- and 100-base pair products expected from the known restriction map. The 340-base pair fragment was also cleaved to two new fragments 240- and

The DNA sequences of pVH51 (ref. 11 and J. Tomizawa, personal communication), pBR322[16], G4[28], ΦX174[29], fd[30] and SV40[20] were searched by computer for perfect inverted repeat sequences (only A+T and G+C pairs with no interruptions in the stems) which contain a maximum of 16 nucleotides in the loop regions. As expected, the number of inverted repeats decreases sharply as the stem length increases. Many perfect inverted repeats were found for all DNAs but only those with the two longest stem lengths are listed. Approximately 75% (2,694 base pairs) of the pVH51 sequence was available for this search.

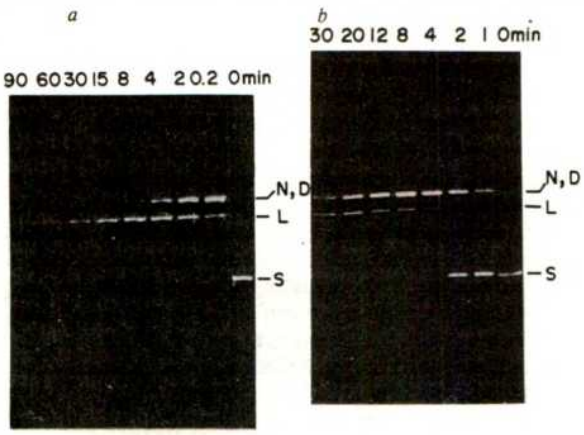

Fig. 1 Effect of single-strand specific endonucleases on supercoiled DNA. *a*, S_1 endonuclease; *b*, T_7 endonuclease. Reactions with S_1 nuclease were carried out in 40 mM sodium acetate buffer, *p*H 4.6, 0.05 M NaCl and 1.0 mM $ZnSO_4$. pVH51 DNA (5 μg) was reacted with 8 U of S_1 nuclease (specific activity 120,000 U per mg protein) in a final volume of 0.3 ml. The characterization of this preparation of S_1 nuclease has been described[21]. Reactions with T_7 endonuclease were carried out in a buffer containing 50 mM Tris-HCl, *p*H 7.6, 0.1 mM dithiothreitol, 10 mM $MgCl_2$ and 2.5 mM spermidine (hereafter called T_7 buffer). pVH51 (4 μg) was reacted with 6 U enzyme (specific activity 12,000 U per mg protein) in a final volume of 0.3 ml. T_7 endonuclease is the product of bacteriophage T_7 gene 3 (refs 7–9) and was purified from T_7-infected *E. coli* cells. The final preparation exhibited one major band, constituting at least 80% of the protein, on SDS-polyacrylamide gels (N.P. and R. D.W., unpublished results). One unit of activity is defined as the amount of enzyme necessary to convert 1 μg of supercoiled DNA into a mixture of nicked-circular and linear forms in 10 min in the conditions described above. All enzymatic reactions were carried out at 37 °C. Aliquots (30 μl) were removed, made 10 mM in EDTA at the indicated times and the mixtures were electrophoresed on 1% agarose gels and stained as described previously[22]. The positions of the supercoiled (S), linear (L), nicked (N) and dimer (D) DNA molecules are indicated. pVH51 DNA[23] was prepared as described previously[22].

100-base pairs long (Fig. 2*c*, lane 2). Thus, the unique linearization site must be located 240 ± 4 base pairs from the single *Hin*dII site of pVH51 DNA, which is inside the *Hae*III 610-base pair fragment.

The presence of a specific linearization site on pVH51 DNA was demonstrated with a nuclease-treated DNA preparation that contained approximately half form II and half linear molecules. At that ratio, nonspecific DNA degradation is minimal. However, if the nuclease reaction was allowed to proceed further to the point where all form II molecules were linearized, roughly 50% of the DNA was degraded to linear molecules of smaller than full-length size (Fig. 1*a*). On restriction of such a reaction mixture, the degraded molecules appeared on polyacrylamide gels as a background of numerous faint bands or even as a smear, depending on the progress of the reaction (data not shown). This indicates that, in addition to the highly specific linearization reaction, these single-strand specific nucleases are capable of degrading duplex DNA at a lower rate, by cleavage at less specific sites.

A 31-base pair inverted repeat sequence spans the linearization site

The discrete sizes of the 340-, 270- and 240-base pair fragments (Fig. 2) suggest that linearization results from nicks on the complementary strands at rather precise locations. If cleavage actually occurred at unique positions, it should be possible to end-label both strands at the cleavage sites and determine their nucleotide sequence. On the other hand, if linearization exposed more than one nucleotide at each end, labelling would not be specific and the sequencing gel would be impossible to read.

pVH51 DNA was linearized with S_1 nuclease, end-labelled and sequenced as described in Fig. 3 legend. Clear patterns were observed on the sequencing gel indicating that cleavage occurred at unique positions on each strand. Comparison of these sequences with the published sequence of pVH51 DNA (ref. 11, and J. Tomizawa, personal communication) revealed that the unique ends generated by S_1 nuclease were located exactly opposite each other on the two strands. Furthermore, the cleavage site was located 238 base pairs from the single *Hin*dII site of pVH51, in full agreement with the mapping data obtained with both the S_1 and T_7 nucleases.

Figure 3 shows the DNA sequence around the site of linearization. The remarkable feature of this sequence is an unusually long (13 base pairs) and perfect (no interruptions or G · T pairs) inverted repeat. The sequence can be shown in the form of a cruciform structure having double-stranded stems that are 13 base pairs long and single-stranded loops consisting of five nucleotides. The nicking site on each strand is located in the middle of each loop.

From these data, the following mechanism is proposed for the position-specific linearization of pVH51 DNA by the single-strand specific nucleases. The enzymes recognize a unique structural feature and cleave one strand, converting the supercoiled molecule into form II. Subsequently, the enzymes cleave the complementary strand exactly opposite the nick at a slower rate. At present, it is uncertain whether one of the complementary strands is cleaved first preferentially. Studies on the nonspecific nicking of PM2 DNA and ΦX174 RFI DNA by the

Fig. 3 pVH51 DNA sequence around the site cleaved by the single-strand specific endonucleases, drawn in cruciform structure. The positions of cleavage for each strand are indicated by arrows. pVH51 DNA was linearized with S_1 nuclease as described in Fig. 2 legend. Following treatment with bacterial alkaline phosphatase, the DNA was labelled with [γ-^{32}P]ATP, restricted with *Hae*III and fractionated on 5% polyacrylamide gels. Autoradiography revealed that 80–90% of the radioactivity was associated with the 340- and 270-base pair fragments. These fragments were eluted from the gel and sequenced as described[27] with some minor modifications[25]. Segments of both strands were sequenced and were in complete agreement with the published sequence[11].

Neurospora nuclease have shown that the first nick is not strand specific[5,12]. Likewise, it is uncertain whether one enzyme molecule cleaves both strands or whether the enzyme dissociates from the substrate after the first nicking event.

As described above, mapping studies on the site of cleavage with the T_7 gene 3 product demonstrated that both this enzyme and S_1 nuclease cleave at an identical (±4 base pairs) site. As the T_7 endonuclease was assayed at *p*H 7.6 in the presence of 10 mM $MgCl_2$, the possibility that the position-specific cleavage is induced by the unusual environment of the S_1 reactions (*p*H 4.6, 1 mM $ZnSO_4$) can be ruled out.

Supercoiling is necessary for site-specific cleavage

To determine the effect of supercoiling on the linearization rate, pVH51 DNA containing varying numbers of negative, superhelical turns was treated with the T_7 nuclease. The supercoil density and the appearance of linear molecules were monitored on agarose gels. Figure 4 shows that topoisomers within a higher density of supercoil turns are better substrates than the partially relaxed molecules. As the population of substrate DNAs with less supercoil turns increases (Fig. 4*b*), the amount of the linear molecules which are formed during the cleavage reaction decreases (Fig. 4*a*). In fact, the decrease in intensity of the band corresponding to linear molecules (Fig. 4*a*) closely parallels the decrease in intensity of the band of the most supercoiled molecules (Fig. 4*b*). In addition, partially relaxed molecules were much more resistant to the T_7 nuclease (Fig. 4*a*). To verify that the linear molecules observed in Fig. 4*a* resulted from site-specific cleavage, the DNA was restricted with *Hae*III and fractionated on polyacrylamide gels (Fig. 4*c*). The 340- and 270-base pair fragments were observed, as expected, and their intensities paralleled the intensity of the linear molecules observed in Fig. 4*a*.

Likewise, DNA restriction fragments, containing the sequence which is specifically cleaved in supercoiled DNA, are not cleaved in parallel conditions. Figure 2*c*, lane 4, shows that when pVH51 DNA was first restricted with *Hae*III and then treated with the T_7 nuclease, the 340- and 270-base pair fragments were not produced from the 610-base pair fragment. The same lack of specific cleavage was also observed when a mixture of restriction fragments including the 610-base pair fragment was incubated with the T_7 enzyme for prolonged times (Fig. 2*c*, lane 1). Hence, the DNA must be in a supercoiled, not relaxed or linear, conformation to be cleaved specifically by these single-strand specific nucleases.

Previous studies with the *Neurospora* endonuclease[5], mung bean nuclease[5], S_1 nuclease[13] and *Alteromonas espejiana* BAL 31 nuclease[14] have also shown that supercoiled DNA is a preferred substrate for the initial nick (conversion of form I to II). In contrast, the rate of nicking of PM2 DNA by pancreatic DNase I is independent of the degree of supercoiling[5].

Although a remarkably long, inverted repeat sequence exists around the cleavage site and the cuts are in the loops of the potential cruciforms, these data do not directly prove the presence of a cruciform structure. Two possible alternative recognition features (modified nucleotides and R-loops) have been considered and ruled out.

The presence of some types of modified nucleotides in pVH51 DNA specifically at the cleavage site could cause a partially disrupted DNA helix. To test this hypothesis, pVH51 DNA was grown in two different *Escherichia coli* host cells[10], M0 and

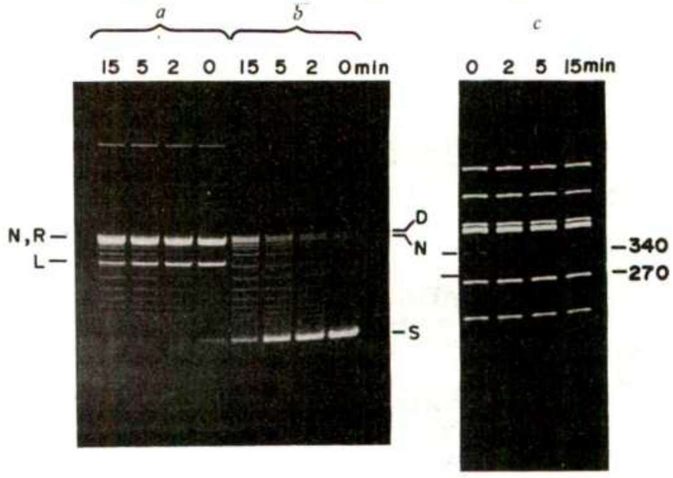

Fig. 4 Effect of supercoiling on the cleavage reaction. *b*, pVH51 DNA incubated with a nicking-closing enzyme for the indicated times; *a*, the partially relaxed DNA shown in *b* after incubation with T_7 endonuclease for 3 min; *c*, the partially relaxed and cleaved DNA shown in *a* after restriction with *Hae*III. pVH51 DNA (22 μg) was reacted at 37 °C with 4 μg wheat-germ topoisomerase in 60 μl T_7 buffer containing 30 mM NaCl. At the indicated times, each reaction mixture was placed at 72 °C for 10 min to inactive the enzyme and the solution was made 0.1 M with NaCl. Aliquots (10 μl) were then removed for electrophoresis on 1% agarose (*b*). T_7 endonuclease (1.2 U) was then added and the mixtures incubated at 45 °C for 3 min, followed by 10 min at 72 °C to inactivate the enzyme. Aliquots (10 μl) were removed for electrophoresis on 1% agarose gels (*a*). *Hae*III (2 U) was then added to each mixture and incubated for 3 h at 37 °C before electrophoresis on 5% polyacrylamide gels (*c*). The latter designations are as in Fig. 1 and R indicates the positions of relaxed, covalently closed, circular DNA. The wheat-germ DNA topoisomerase I was isolated and purified to approximately 60% purity by W. Dynan, J. Jendrisak, D. Hager and R. Burgess (unpublished method; gift of R. Burgess). This enzyme is free of nuclease activity and the products of a complete reaction are covalently closed, circular DNA without detectable amounts of nicked molecules. The faint bands on the top portion of *a* correspond to the form II-dimer and linear-dimer forms.

Fig. 5 pBR322 DNA sequence around the site cleaved by the single-strand specific endonucleases, drawn in a cruciform structure. The sequence is taken from ref. 16.

C600 SF8, the latter strain lacking a known modification system. Identical specific cleavages were found for both DNAs.

The second possibility is that an R-loop[15] might be present at the linearization site in the supercoiled DNA. This hypothesis was also eliminated when heat-denatured pVH51 DNA (which loses its R-loops[15]) produced the same results as native DNA.

Site-specific cleavage of supercoiled pBR322 DNA

If specific cleavage sites existed on supercoiled molecules other than pVH51 DNA, a comparison of their sequences might provide evidence as to the nature of the structural features necessary for recognition.

Supercoiled pBR322 DNA was linearized with the T_7 endonuclease and subsequently restricted in the manner described for pVH51. Two new bands appeared in the restriction patterns of the T_7 nuclease-treated DNA, indicating the presence of a specific cleavage site. The use of several restriction enzymes (*Hin*dII, *Hin*dIII, *Taq*I, *Hin*fI and *Hae*II) allowed rather precise mapping of the cleavage site at position 3,061 ± 5 base pairs of the published sequence of pBR322[16]. A *Taq*I digest of pBR322 DNA that had been treated with S_1 nuclease produced the same result.

Inspection of the DNA sequence revealed the presence of an inverted repeat around the cleavage site with a centre of symmetry at position 3,065. This repeat could be drawn into a cruciform configuration having double-stranded stems that are 11 base pairs long, and single-stranded loops consisting of three nucleotides (Fig. 5). The position of the loops corresponds to the position of cleavage, within experimental error. Therefore, as with pVH51, site-specific cleavage of pBR322 occurs at a position surrounded by an unusually long, inverted repeat sequence. Comparison of the DNA sequences around the cleavage sites in pVH51 and pBR322 revealed no significant homology that might constitute potential recognition sequences. Moreover, the requirement for superhelicity and the fact that two unrelated enzymes with no known sequence specificity cleave at the same site have already ruled out the possibility that the DNA sequence is recognized as a double-stranded helix. Instead, these results strongly support the notion that the supercoil pressure induces a tertiary (cruciform) structure which is maintained long enough for the single-strand specific nucleases to cleave at the single-stranded loops.

Absence of site-specific cleavage of other DNAs

Several other supercoiled DNAs were screened for position-specific cleavage. The replicative forms of G4, ΦX174, fd and M13 DNAs, as well as SV40 DNA, were linearized with the T_7 nuclease; S_1 nuclease linearization on SV40 and ΦX174 RFI DNAs was also studied. The nicking and linearization rates were comparable with the rates observed with pVH51 DNA (data not shown). Each DNA was then cleaved with at least two different restriction enzymes, in the manner described for pVH51 DNA, to ensure that the potential linearization site(s) did not overlap with a restriction site. In some cases, several bands were observed, indicating simultaneous linearization at many sites, but no unique bands that would allow unequivocal mapping of a cleavage site were found. Similar results have been published for the cleavage of ΦX174 RFI DNA by the *Neurospora* nuclease[12]. Therefore, G4, ΦX174, fd and M13 DNAs do not possess the unique structural features which, in the same conditions, lead to site-specific cleavage of pVH51 and pBR322 DNAs.

As the linearization sites on both pVH51 and pBR322 are in the middle of unusually long, inverted repeats, the lack of site-specific cleavage of G4, ΦX174, fd and M13 DNAs might be due to the absence of long, inverted repeats from the sequences of these molecules.

The published sequences of all six DNAs were searched by computer for inverted repeats and for A+T-rich regions.

Table 1 shows that pVH51 DNA contains the longest, perfect inverted repeat in the total of approximately 30,000 base pairs; this potential cruciform (Fig. 3) is the site of specific cleavage. The second longest repeat (13-base pair stem, one-base loop) was found in SV40 DNA. However, considering that a loop of less than three to four bases is sterically constrained[17], the maximum stem size for a cruciform of this repeat is 11 base pairs. The next longest repeat (11-base pair stem, three-base loop) was found in pBR322 DNA and this potential cruciform (Fig. 5) is the site of specific cleavage.

It may be necessary for the inverted repeat sequence to be within an A+T-rich segment of much larger size to form a relatively stable cruciform. The single cleavage site in pVH51 is located in a unique, easily denaturing and unusually A+T-rich region[18]. Likewise, the specific cleavage site in pBR322 DNA is located in one of the two most A+T-rich regions in that DNA. In contrast, SV40 DNA was not specifically cleaved. The experimental and theoretical denaturation maps of this DNA reveal that the region surrounding the largest inverted repeat is not particularly A+T-rich, whereas the molecule contains three other very distinct easily denaturing regions[19].

Supercoiling is known to generate locally single-stranded regions in double-stranded DNA molecules. These regions are easily denaturing stretches of DNA, due to their high A+T content[2]. Our data suggest that cruciforms which exist in A+T-rich regions are the most stable. It is possible that the non-paired nucleotides in the A+T-rich region, which are in dynamic equilibrium with the duplex form, might facilitate the formation of a cruciform. Alternatively, if an inverted repeat is within a larger G+C-rich region, the duplex form of the DNA may be the most stable. According to this model, specific nucleases would cleave supercoiled DNA at specific sites if (at least transiently) stable cruciform structures could be formed within the most easily denaturing region. Inverted repeats present outside the most A+T-rich region would not readily form cruciforms and, therefore, would not be the first sites to be cleaved. On the other hand, if the most A+T-rich region did not contain inverted repeats, cleavage might still occur at random sites inside this region due to its single-stranded nature.

Accordingly, this model would predict that linearization of SV40 DNA by S_1 and T_7 nuclease would probably occur not at the inverted repeat but, instead, at the most easily denaturing regions. Previous studies have shown that S_1 nuclease cleaves supercoiled SV40 DNA at a preferred region, which is located at 0.45–0.55 map units and coincides with an easily denaturing region[13]. We observed that linearization of SV40 DNA by S_1 and T_7 nucleases was not reproducibly found at a specific site in the relatively low-temperature conditions which lead to position-specific cleavage of pVH51 DNA. In contrast, at high temperatures (72 °C), specific linearization was observed at position 4,540 ± 50 base pairs of the published sequence[20]. This position corresponds to 0.55 map units, in the middle of one of the three most A+T-rich regions. Thus, these results are consistent with the above predictions.

In a special case, Gellert *et al.* (reviewed in ref. 2) constructed a completely inverted repeat DNA by recombinant techniques and showed that it could assume a cruciform structure.

Conclusions

We report here the first evidence supporting the existence of cruciform structures in naturally occurring DNA sequences. The supercoiled forms of two different DNAs (pVH51 and pBR322) contain specific cleavage sites for two endonucleases (S_1 and the T_7 gene 3 product) which are specific for single-stranded regions. Both sites are in the centre of unusually long, inverted repeats and coincide with the single-stranded loops of potential cruciform structures. Five other DNA molecules (G4, ΦX174, fd, M13 and SV40), which lack long inverted repeats, are not cleaved specifically. The DNAs must be in a supercoiled form to be cleaved specifically; topoisomers with a larger number of supercoiled turns are cleaved more rapidly than those which are partially or totally relaxed. R-loop structures and one nucleotide modification system were eliminated as possible explanations. These results indicate that superhelicity induces tertiary (cruciform) structures which expose specific bases in single-stranded conformations.

This work was supported by NIH and NSF grants CA 20279 and PCM77-15033, respectively. We acknowledge the gifts of SV40 DNA by J. Mertz, the replicative forms of ΦX174, G4, fd and M13 DNA by G. Horn, and pBR322 DNA by W. Hillen. The computer programs used to search for inverted repeats and A+T-rich regions were developed by G. Horn and R. Littlewood, respectively.

Galactic γ and radio synchrotron radiation

C. G. T. Haslam*, S. Kearsey†, J. L. Osborne†, S. Phillipps† & H. Stoffel*

* Max-Planck Institute for Radio Astronomy, Auf dem Hügel 69, Bonn, FRG
† Department of Physics, University of Durham, South Road, Durham DH1 3LE, UK

The galactic γ-radiation and radio synchrotron radiation contains information on the distribution of cosmic-ray particles, magnetic field and gas throughout the Galaxy. We report here a new all-sky survey of 408-MHz radio continuum which has been used to compare the distributions of radio and γ-ray emission, with the former convolved to the response function of the COS B γ-ray detector. The overall similarity of the longitude profiles suggests that the bulk of the γ-ray emission is from the interstellar medium rather than discrete sources. On a large scale in the galactic plane the two emissivities seem to be similarly distributed, although in detail the γ-ray emission is more clumpy.

γ rays with energies in the region of interest (~100 MeV) are produced by bremsstrahlung of cosmic-ray electrons of a few 100 MeV on the interstellar gas and from the decay of neutral pions, produced in the interactions with the gas of cosmic-ray nuclei with energies of a few GeV. (The inverse Compton interactions of cosmic-ray electrons are expected to give a much smaller contribution than these two processes except, perhaps, at high galactic latitudes.) If the cosmic-ray proton to electron ratio is constant, the interstellar γ-ray emissivity is then proportional to the product of cosmic-ray intensity and total gas density. There is, of course, independent information on the distribution of interstellar gas in the Galaxy so that, in principle, the distribution of cosmic rays can be obtained (the work of the past decade on this problem is reviewed in ref. 1). In practice, there are large uncertainties because the important molecular hydrogen component of the gas has to be inferred from the distribution of CO, which is itself only known in certain regions. Also, mainly because of the rather poor angular resolution of the γ-ray detectors, there is uncertainty concerning the contribution of unresolved discrete sources to the apparently diffuse γ-ray emission along the galactic plane. Additional information may therefore be usefully sought from a comparison of the γ-ray distribution with that of radio synchrotron radiation. In the frequency range from 100 MHz to 1 GHz, where there is the best combination of good angular resolution and low contamination by thermal continuum radiation, the synchrotron radiation is produced by cosmic ray electrons of a few GeV. The synchrotron emissivity is proportional to the product of the cosmic-ray electron density and approximately the square of the magnetic field intensity (B^2). The large scale distribution of B^2 may in turn possibly be related to the distribution of interstellar gas. If, for example, the γ-ray and synchrotron emissivities were in a constant ratio then B^2 would be proportional to gas density irrespective of the variation of cosmic-ray density.

Comparisons between the γ rays and synchrotron radiation have been made by several authors (see refs 2–4). They have mainly considered γ-ray data, having rather low statistical accuracy, from the SAS 2 detector (8,000 γ rays) and the synchrotron radiation data were in a form which did not make the necessary convolution easy. We now use the new all-sky survey at 408 MHz of Haslam *et al.*[5,6]. This is from observations at Effelsberg, Jodrell Bank and Parkes. The data, smoothed to a

0028-0836/81/060470—04$01.00

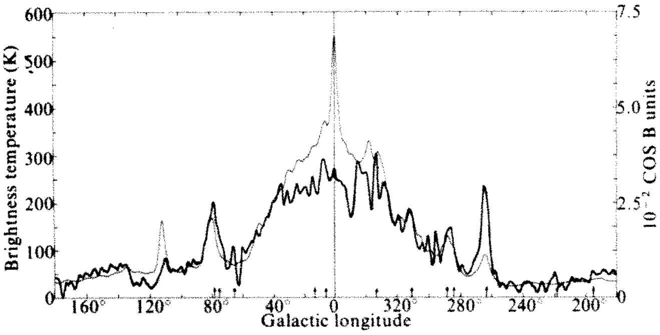

Fig. 1 Galactic plane profiles. Thick line and right-hand scale: distribution of 70 MeV to 5 GeV γ rays obtained by the COS B detector. The arrows show the longitudes of features corresponding to γ-ray 'sources'. Thin line and left-hand scale: distribution of 408 MHz continuum radiation convolved to the HPBW of the COS B detector.

common resolution of 51 arc min, are in the form of brightness temperatures at 20 arc min intervals of galactic latitude and longitude. It has been convolved and averaged appropriately for comparison with the COS B γ-ray distributions of Mayer-Hasselwander *et al.*[7] based on 64,000 photons. We present here the comparisons with latitude and longitude distributions of γ rays with energy 70 MeV $<E<5$ GeV. Comparison with the longitude distributions of γ-rays after division into three energy bands in this range leads to similar conclusions although the effects of statistical fluctuations are naturally greater.

Figure 1 shows the longitude distributions. The γ-ray intensities are given in units of 'on-axis' counts s^{-1} sr^{-1} for the COS B detector (henceforth referred to as COS B units). The thick line shows the cut along the galactic plane ($b = 0°$) of the contour map derived using the smoothing procedure detailed in ref. 7. This removes features smaller than the half-power beam width (HPBW) of the detector but not all the remaining features are necessarily statistically significant. For comparison, the 408 MHz data must be convolved to the beam profile appropriate to the γ-ray detector. Such a profile was constructed taking into account the energy dependence of the HPBW (from 7° at 70 MeV to 2° at 5 GeV) and the relative numbers of γ rays of a given energy in the COS B data: it has a HPBW of 3.5° and a longer tail than a gaussian distribution. The result of the convolution is given as the thin line curve in Fig. 1. We have chosen the cut at $b = 0°$ for the comparison rather than the longitudinal variation of the average γ-ray intensity for $|b| < 5°$, which is also given in ref. 7, because the former is affected less by the differing latitude distributions of the γ and synchrotron radiation. An indication of the statistical significance of the features in the γ-ray cut at $b = 0°$ can be obtained from the quoted statistical errors on these average intensities. We deduce that, over one beam area, statistical fluctuations of about 0.15×10^{-2} and 0.2×10^{-2} COS B units are to be expected for the outer and inner halves of the galactic plane respectively. Thus, while many of the features in the outer half of the plane can be discounted most of those in the inner half are real.

The latitude distributions are shown in Fig. 2. The points are the intensities at 1° intervals in latitude averaged over the longitude intervals indicated. The lines are the 408 MHz brightness temperatures convolved and averaged appropriately. As the object is to compare the galactic radio and γ-ray emission the isotropic extragalactic contributions have to be removed. From the 408-MHz data a 6 K isotropic component has been subtracted. The COS B intensities are those above a background. This is the sum of an instrumental background, an extragalactic component, and the estimated galactic radiation at $b = 90°$. Strictly this last component should be added back in. From the SAS 2 experiment[8] for $E > 70$ MeV this is $\sim 2.2 \times 10^{-5}$ cm^{-2} s^{-1} which seems to correspond to about 0.6×10^{-3} COS B units. For the longitudinal profile this is negligible. For the latitude profiles the addition would be just large enough to make all of the plotted points positive. Although the 408 MHz continuum radiation is predominantly non-thermal there is some thermal contribution. In the plane of the Galaxy ~20% of the extended emission is thermal. The scale height of the thermal emissivity is smaller than that of the non-thermal radiation by a factor of between 5 and 10, so that after convolution the contribution at $b = 0°$ is no more than a few per cent. The broad peak in emission underlying the sources in the Cyg X region ($l \approx 80°$) is predominantly thermal, however.

Let us now consider the latitude and longitude profiles. In Figs 1 and 2 the radio γ-ray intensities are plotted with the same arbitrary normalization ($100\,K \equiv 1.25 \times 10^{-2}$ COS B units). This makes the longitudinal profiles generally coincide (to within ~35° of the galactic centre). The most obvious difference between the profiles is that there is no strong γ-ray source at the galactic centre corresponding to the radio source Sag A. This gives a contribution of 150 K to the convolved radio profile at $l = 0°$ but has no effect on the profile for $4° < l < 356°$. Two other features must be discounted. The peak in the radio at $l = 112°$ is due to the supernova remnant Cas A ($l = 111.7°$ $b = -2.1°$); this is not a detectable source of γ rays. The peak in the γ rays at $l = 263.5°$ is essentially all pulsed emission from the Vela pulsar while the corresponding peak in the radio is unpulsed radiation from the Vela supernova remnant.

On the south side of the Galaxy the steps at 285°, 310° and 330°, usually regarded as evidence of spiral structure, are reproduced on both distributions while on the north side there are no steps in either distribution between 40° and 60° where one might expect the spiral arms to reappear. Both the distributions have a broad minimum at $l = 240°$. The rather close resemblance of the two profiles (the discrepancy within 35° of the galactic centre is discussed below) supports the proposition that the γ-ray emission, like the synchrotron radiation, is predominantly produced in the interstellar medium rather than being due to discrete sources. It is possible, of course, that such a distribution of emission could be produced by discrete sources but their number density would have to follow rather closely the variation of the product of cosmic-ray density and the square of the galactic magnetic field strength. There does, however, seem to be more structure in the γ radiation than in the radio smoothed to the same HPBW even after statistical fluctuations are taken into account. To investigate the clumpiness of the γ-ray emissivity further more detailed data than that currently published are required. Not only the maxima but also the minima in the γ-ray distribution are of interest in this context. It is possible to account for the minimum at $l = 62°$ in terms of interstellar production. This dip is almost certainly real although its sharpness may be the result of fluctuation. In this direction there is the longest line of sight to the nearest spiral arm in the whole galalctic plane. When the Perseus arm is eventually reached at a distance of 10 kpc the scale height of the gas subtends an angle much less than the beam size and its contribution to the γ-ray intensity is much reduced. The effect will be less marked for the synchrotron radiation which has a considerably larger scale height.

Catalogues of γ-ray sources have been produced from the COS B data. A source is defined as a significant excess of counts compatible with the instrument point spread function so that a feature extending to ~1° is not distinguished from a point source. The second COS B catalogue[10] contains 22 sources at low galactic latitudes. The longitudes of the 12 which contribute to features on the longitudinal profile are indicated by arrows on Fig. 1. Apart from the Vela pulsar there is no certain identification of any of these with a radio source but five features are coincident in position with radio sources strong enough to give features on the convolved radio profile. 2CG075+00 and 2CG078+00 are in the Cyg−X region. 2CG284−00 and 2CG288−00 are in the Carina spiral arm. In both regions there are various radio sources with which they might be identified including supernova remnants–OB associations (SNOBs)[11]. The fifth source 2CG006−00 is perhaps the prime candidate for a

SNOB, being positionally coincident with the bright supernova remnant W28 and the HII region RCW146 both of which appear to be at a distance of 1.6 kpc from the Sun. In the direction of increasing longitude from the peak due to this source the next four γ-ray peaks all have corresponding features in the radio profile. The completely different behaviour of the profiles on the other side of the galactic centre suggests, however, that this is a chance effect.

Comparison of the latitude profiles in Fig. 2 shows that the synchrotron emission is much broader in extent than the γ radiation. This is true for all longitude ranges except $145° < l < 175°$. In the inner part of the Galaxy, as would be expected for production in the interstellar gas, the true latitude distribution of the γ radiation is masked by the HPBW of the detector. Taking the profiles in turn one sees that in Fig. 2*b* the North Polar Spur enhances the synchrotron emission at positive latitudes but not the γ radiation. In Fig. 2*c* the blackened area shows the contribution from the bright radiogalaxy Cyg A, which is not a γ-ray source. The contribution of Cas is shown similarly in Fig. 2*d*. The γ-ray peak in Fig. 2*f* is due to the bright source 2CG195+04. There is no significant radio emission associated with it. In Fig. 2*k* the peak in the γ-ray profile is due to the Crab pulsar. The γ rays are pulsed while the radio emission (shaded) is from the supernova remnant.

The latitude profiles show that the γ-ray emissivity is not proportional to the synchrotron emissivity in three dimensions. There could still be, however, an overall proportionality between the two emissivities in the galactic plane. The deficit in the γ-ray profile within 35° of the galactic centre does not preclude this as there are two geometrical effects that must be considered. The first is a manifestation of the differing scale heights of the γ and synchrotron radiation. The reduction in the recorded intensity due to the angular width of the emissivity being much less than the beam size of the detector is larger for the narrower γ-ray emission and increases with distance. The second is the effect of a regular component of the galactic magnetic field. In the neighbourhood of the Sun a regular component of the magnetic field is observed lying in the direction of galactic rotation and of the same order of magnitude as the fluctuating component. If this azimuthal field extends throughout the Galaxy there is an enhancement in the synchrotron radiation due to its being viewed perpendicularly as the line of sight approaches $l = 0$. The distribution of synchrotron emissivity in the galactic plane derived from the full resolution synchrotron profile by an unfolding technique in which the ratio of regular to irregular field is treated as a free parameter is to be reported elsewhere[12]. A good fit is obtained for a ratio of unity and for an emissivity that peaks at a distance of 3.6 kpc from the

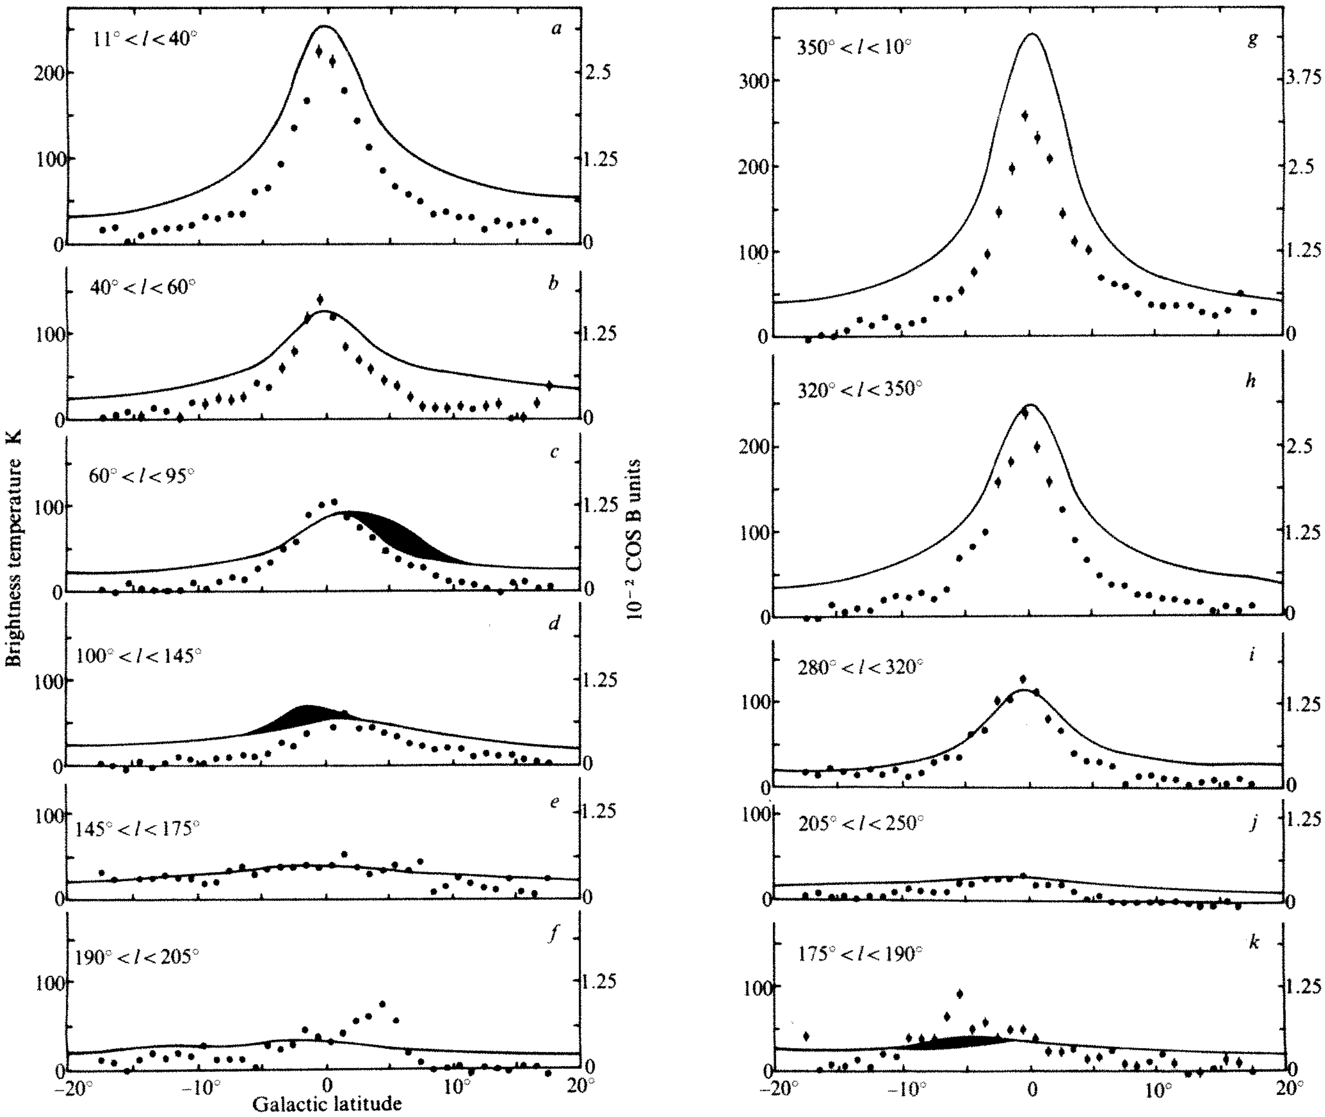

Fig. 2 Galactic latitude distributions. ●, γ-ray intensities averaged over the indicated longitude ranges. Statistical errors are shown when larger than the points. Lines, 408 MHz intensities correspondingly convolved and averaged.

galactic centre and is low within this distance. If we predict the γ-ray profile assuming that the emissivity in the plane mirrors this synchrotron emissivity but that its scale height is that of the gas, a reasonable fit to the observations is obtained. If the two emissivities are in constant ratio the implication is that B^2 is proportional to gas density on some suitably large scale in the plane of the Galaxy. Developing instabilities would extend the magnetic field out of the plane and destroy the proportionality there.

Laser-radar measurements in southern England of aerosols from Mount St Helens

L. Thomas, C. P. Chaloner & S. K. Bhattacharyya

SRC Rutherford and Appleton Laboratories, Ditton Park,
Slough, Berks SL3 9JX, UK

Material from the eruption of Mount St Helens (46°N, 122°W) has been detected at lower stratospheric heights using a laser-radar system at Winkfield (51°N, 1°W). The observation of a distinct layer of ~1 km thickness near 15.5 km altitude for several days in early June is consistent with the west-east transport of material from above the eruption site expected at this height and also indicates a significant northward spread of the material. In late July less pronounced layers were observed at 17-18 km and 22 km at which level the direction of motion is less certain.

The laser incorporated in the radar system operated near a wavelength of 0.6 μm and produced 1 μs pulses at a repetition frequency of $1\,s^{-1}$. The receiver included a 0.8-m diameter newtonian telescope and operated in a photon-counting mode, the return signals being recorded in channels corresponding to 1 km height intervals. The inclusion of a neutral density filter in the receiver and the restriction of the laser energy to a very low value (< 20 mJ) ensured that the photomultiplier was not overloaded by returns from low altitudes.

The results obtained near the end of May and during June are presented in Fig. 1. These show the variations with height of the range-corrected backscattered signal and standard error for ~1 h of observations on each of four nights. In each case the corresponding height variation expected for the Rayleigh-scattered signal is shown, as derived from molecular densities obtained from radiosonde data for Crawley (51°N, 0°W) provided by the Meteorological Office, Bracknell, and fitted to the observations at the lower heights. The tropopause heights indicated were from the same data. The deviations from the Rayleigh scattering results on 27 May are consistent with other measurements at Winkfield before the eruption[1]. Note the strong scattering from heights of ~15.5 km during the nights of 6 and 7 June; this feature was observed consistently between 4 and 9 June, adverse weather conditions interfering with measurements on either side of these nights. In addition, small enhancements are shown over the height range 16–24 km on the 7 June. Balloon-borne observations[2] of scattered sunlight in southern France on 5 June also showed the presence of an enhanced aerosol layer at a height near 15.5 km. The presence in the eastern US on 22 May of layers of material between 12 and 16 km from the Mount St Helens eruption was recorded with the NASA Langley airborne laser radar system[3]. Furthermore, the absence of anomalous scattering at Winkfield on 27 May was consistent with the location of the 14–16 km material at ~30°W, as observed[3] with the satellite-borne Stratospheric Aerosol and Gas Experiment (SAGE). As indicated in Fig. 1, no major scattering was observed at Winkfield during the second half of June.

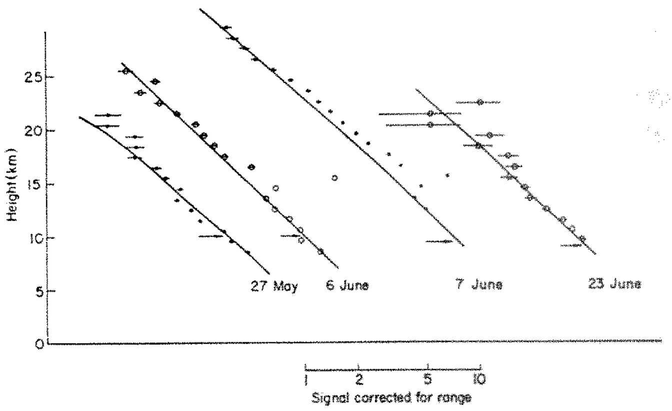

Fig. 1 Variations with height of the range-corrected signals from soundings at vertical incidence during four nights. The smooth curves represent the corresponding variations expected for Rayleigh scattering as computed for molecular densities derived from radiosonde measurements which also provided the tropopause heights denoted by arrows.

The approximate arrival date, relatively short duration and the location near 15.5 km of the layer observed at Winkfield are consistent with the transport of the layers observed previously in the eastern US by the west-east winds expected at these levels during May and June[4]. From an examination of the mean wind for the 100 mbar level, as derived by the Meteorological Office from radiosonde data, it is considered that a significant spread of the material towards the north must also have occurred. Unusual twilight effects following previous volcanic eruptions[5,6] showed that the dust injected can spread over very large areas within about 2 months of the events. Furthermore, balloonsonde[7] and laser-radar observations[8,9] revealed that the maximum enhancements of material extended over a considerable part of the 15–20 km altitude range, and continued for many months after the eruptions. Small enhancements in scattering have been observed from levels near 18 and 22 km during nights in the period 21–25 July, the only observable nights during that month.

We thank the Meteorological Office, Bracknell, for radiosonde data and information on winds at the 100 mbar level.

Similarities in amorphous and crystalline transition metal–metalloid alloy structures

P. H. Gaskell

University of Cambridge, Cavendish Laboratory, Madingley Road, Cambridge CB3 0HE, UK

In many amorphous and glassy systems the local structure seems to be essentially the same in amorphous and crystalline phases. It thus becomes possible to define a 'local structural unit', such as the SiO_4 group in silicates. Determination of the structure then reduces to the problem of describing how the local units are connected and packed in the medium-range structure. There is mounting evidence that alloys of transition metals with metalloids are more adequately described by arrangements of stereochemically-defined structural units than by alternative descriptions in terms of random packing of atoms. There are three phases, Fe_3C, Ti_3P and Fe_3P, which may serve as models of local structural units. These lattices differ to a small degree in the symmetry of the metalloid nearest-neighbour shell but there are major differences in the arrangement of local structural units. Although the experimental evidence is limited, it seems that the distinctive features of the local and medium-range topologies of the crystalline phases are represented in the structures of each of the corresponding glasses.

Models for transition metal–metalloid (T–M) glasses have been constructed[1,2] by randomly connecting local structural units—trigonal prisms consisting of six T atoms centred on M atoms, Fig. 1, using the edge-sharing arrangement found in the cementite Fe_3C lattice. Crystalline alloys with small metalloid radius ratios, such as Pd–Si, Ni–B and Co–B, have this structure. Calculations based on the model agree well with high resolution measurements of neutron scattering from amorphous Pd–Si alloys[3,4], giving a quality of fit at least equal to that of any other model. Moreover the model provides a good representation of the partial pair correlation functions for this alloy. Whether this type of model adequately describes other transition metal–metalloid glasses is particularly relevant for systems such as Ni–P or Fe–B in which crystalline T_3M phases are isostructural with Fe_3P or Ti_3P lattices respectively.

A relatively broad distribution of T–M bond lengths in Fe_3C structures, Fig. 2, reflects the distinction between distances from M to vertex or capping T atoms. This is particularly noticeable when M is small and T large, for example, in Pd_3B, where the trigonal prism is almost undistorted. The metalloid radius ratio is generally larger in Fe_3P and Ti_3P lattices causing extensive dilatation of the trigonal prism and distances to the nine first neighbours become almost identical (Fig. 2).

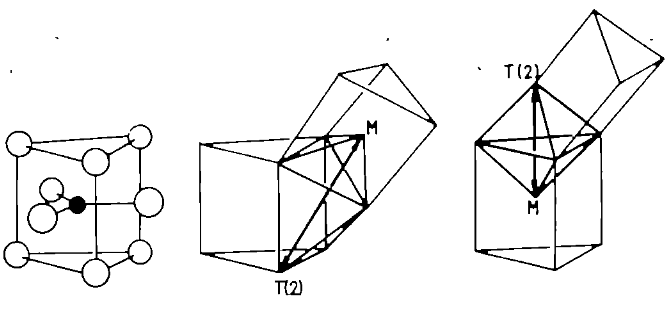

Fig. 1 Trigonal prismatic packing of transition metal atoms (large circles) around a metalloid atom observed in many crystalline alloys, together with the edge-sharing arrangement of trigonal prisms found in the Fe_3C structure (centre) and in Fe_3P (right). (Some atoms are omitted for clarity.) The two arrangements may be distinguished by distances from metalloids to second-neighbour transition metal atoms (M–T(2)). These can be visualized as the separation between two vertices of a tetrahedron sharing a face with a half octahedron (Fe_3C) and the distance between vertices of two tetrahedra (Fe_3P), the latter generally being shorter as shown.

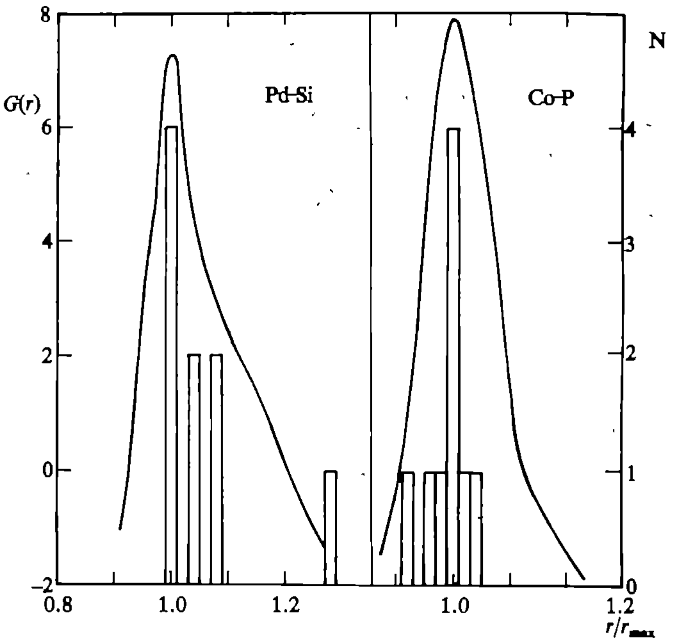

Fig. 2 Comparison of the profiles of the first-neighbour metalloid–transition metal distributions in crystalline and amorphous alloys. Bar charts represent the distribution of first neighbours (right-hand ordinate) in crystalline $Pd_3Si(Fe_3C)$ and Fe_3P lattices, as a function of reduced interatomic distance, r/r_{max}, where r_{max} is the value corresponding to the maximum of the distribution. Curves represent Si–Pd and P–Co partial pair distribution functions (left-hand ordinate) for glassy $Pd_{84}Si_{16}$ and $Co_{81}P_{19}$ alloys[5,6].

Extraction of T–M partial pair distribution functions for amorphous alloys requires an analysis of three essentially independent scattering measurements (for example, using X-ray and polarized neutrons) and this is rarely possible. Two good examples exist: $Pd_{84}Si_{16}$ (ref. 5) and $Co_{81}P_{19}$ (ref. 6). The former is potentially a 'Fe_3C glass' and the latter arguably related to Fe_3P on the basis of its radius ratio and crystallization products in Co–P–B ternary alloys. The marked differences between the profiles of the first Si–Pd and P–Co peaks is shown in Fig. 2. Furthermore, the T–M distribution for each glass is clearly similar to the bar chart for the corresponding crystalline phase. This strongly suggests that the environment of the non-metallic atoms is not random but is predominantly trigonal prismatic as in crystals. Moreover, distortions of the trigonal prisms resulting from the central metalloid atoms seem to be essentially identical in each type of amorphous and crystalline compound, suggesting a degree of stability for this type of coordination.

The disposition of trigonal prisms in the three crystalline lattices may be characterized as packing of trigonal prisms around half octahedra in Fe_3C or around tetrahedra in Ti_3P or Fe_3P lattices (Fig. 1) and it is possible to distinguish each type of packing through differences in the distances from a metalloid to second neighbour metal atoms. Second neighbour M–T(2) distances are shown in Fig. 1 and correspond to the vertex–vertex separation of a distorted tetrahedron sharing a triangular face with a half octahedron (Fe_3C) and the distance between vertices of two tetrahedra sharing a triangular face (Ti_3P and Fe_3P).

Second neighbour distances can be calculated for each pair of polyhedra as a function of the metalloid radius ratio, $p = r_M/r_T$. For the bi-tetrahedral configuration:

$$r_{M-T(2)} = (p^2+2p-\tfrac{1}{3})^{1/2}+(8/3)^{1/2}$$

and for the tetrahedral–octahedral configuration:

$$r_{M-T(2)} = [p^2+2p+5-4(p^2+2p)^{1/2}\cos\beta]^{1/2}$$

0028-0836/81/060474—03$01 00

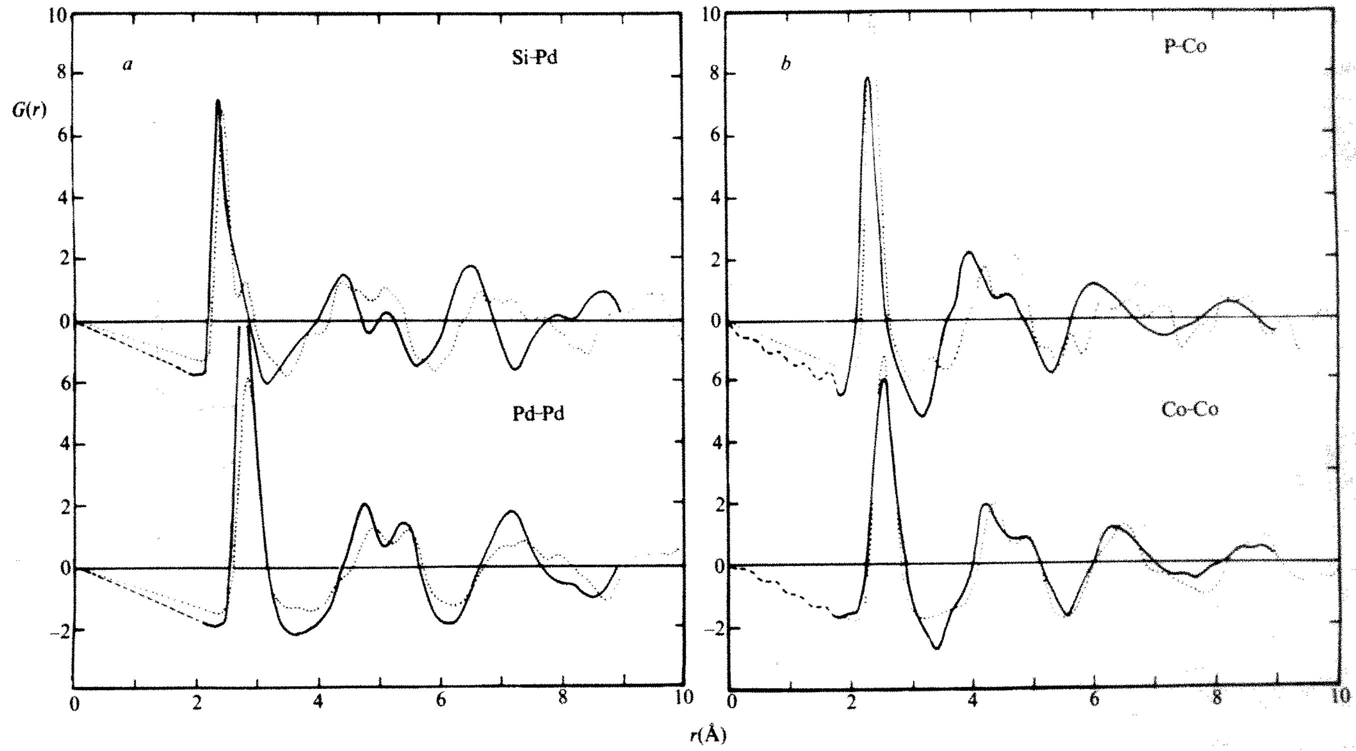

Fig. 3 Experimental (solid lines) and calculated (dotted lines) partial pair distribution functions for an amorphous Pd–Si alloy (*a*) and a Co–P alloy (*b*). Experimental data from Sadoc and Dixmier[5,6]. Si–Pd correlation functions have been derived from two experimental measurements only: an approximation which should be adequate because Si–Si correlations are very weak and the form of this distribution can be assumed with sufficient accuracy.

where $\beta = \psi_1 + \psi_2$. The angles ψ_1 and ψ_2 are dihedral angles for a half octahedron and a distorted tetrahedron,

$$\psi_1 = \cos^{-1}(3^{-1/2}), \quad \psi_2 = \cos^{-1}[(3p^2+6p)^{-1/2}]$$

The radius ratio for Co–P is 0.83 (using Sadoc and Dixmier's values[5]) suggesting a second neighbour distance, $r_{\text{M-T(2)}} =$ 3.87 Å for the bi-tetrahedral model which agrees well with the experimental value, 3.95 Å. The corresponding tetrahedral–octahedral distance is 4.14 Å. Conversely, for $Pd_{84}Si_{16}$ ($p =$ 0.74) the best fit to experiment, $r_{\text{M-T(2)}} = 4.40$ Å, is given by the tetrahedral–octahedral model, 4.35 Å compared with 4.05 Å for the bi-tetrahedral arrangment. It seems, therefore, that the medium-range structure in these two amorphous alloys is essentially different and that there may be some equivalence of the medium-range topologies of crystalline and amorphous lattices.

This calculation may be confirmed by computer-simulation. The aperiodic model constructed with medium-range topology equivalent to Fe_3C (refs 1, 2) gives good agreement with the total neutron structure factor of amorphous Pd_4Si and the total radial distribution function. As Fig. 3*a* shows, this model also gives an excellent representation of the Pd–Pd and Si–Pd partial correlation functions obtained by Sadoc and Dixmier[5]. A split peak in the computed Si–Pd distribution is introduced by setting values for the equilibrium Si–Pd (vertex) distance of 2.4 Å, and 2.8 Å for the distance to capping atoms. This is a crude model of the nearest-neighbour arrangement shown in Figs 1 and 2. Both components of the second neighbour peak Si–Pd at 4.4 and 5.1 Å are satisfactorily reproduced, although the position of the first and the intensity of the second are somewhat inaccurate.

The model has been rescaled for Co–P without making any essential alterations to the topology, that is trigonal prisms and Fe_3C-type interconnections persist. Changes in nearest neighbour geometry have been introduced in an attempt to represent the local structure in Fe_3P-type alloys, specifically, the distinction between distances to vertex and capping atom mentioned above has been withdrawn. Computed Co–Co and P–Co pair correlation functions are shown in Fig. 3, together with measurements of Sadoc and Dixmier[6]. Co–Co distances are again reproduced adequately to ~8 Å so that the total radial distribution function and structure factor, which are weighted by the Co–Co distribution, agree well with experiment[7]. The profile of the first P–Co peak and the position of the second component of the second neighbour peak at ~4.9 Å agrees with experiment, but the first component at 3.95 Å is inadequately represented by a peak at 4.17 Å in the computed data. Several attempts have been made, by altering values of the cohesive energy, changing equilibrium interatomic distances, to reduce this discrepancy and at the same time preserve a good fit to the rest of the data, but none has been successful. This difference, although small, seems to be significant and represents a closest P–Co(2) distance in an essentially tetrahedral–octahedral arrangement. Although a full model, built on packing principles exhibited by Fe_3P lattices, is required to prove the point, it seems that the bi-tetrahedral arrangement shown in Fig. 1 will be necessary to model successfully scattering data for cobalt phosphorus alloys.

Further experimental investigations of the partial correlation function of other amorphous alloys corresponding to Fe_3C and Fe_3P crystalline phases are needed and while the data, for which the errors have not been established, are sparse, current information suggests two conclusions. First, amorphous T–M glasses seem to contain a common local structural unit in which the detailed arrangement is basically determined by properties, such as the radius ratio, of the two elements. The local structure, therefore, is essentially identical to that of a compositionally-related crystalline phase. Second, medium-range structures for different combinations of elements are determined by rules, which are as yet incompletely deciphered, although the radius ratio again seems to be a dominant parameter. The result is that Fe_3C- and Fe_3P-type amorphous alloys (and crystals) possess essentially dissimilar medium-range topologies. This seems to be the first example of detectable medium-range structural differences in amorphous alloys.

Although there is little direct evidence, the composition-dependence of some magnetic properties of crystalline and amorphous Fe–(P, B) alloys[8,9] indirectly supports the idea of differences in medium-range structures. For alloys with B : P ratio of ≤ 0.5 the stable crystalline form is Fe_3P, otherwise Ti_3P

(except for compositions close to Fe_3B where Ti_3P is metastable). The composition-dependence of the Curie temperature of both crystalline and amorphous alloys shows breaks corresponding to the transition between crystalline forms. These measurements have been interpreted in terms of changes in short-range order but the local structure is almost identical in the two crystalline forms. Therefore, even if changes of magnetic properties are directly related to local structure, these are probably accompanied and perhaps driven by changes in the mode of packing of prismatic units.

Recently, evidence from NMR measurements[10] of the similarity in local structure in crystalline and amorphous alloys and of the dependence of local structure on composition has been reported. The environment of boron in glassy $Ni_{78}P_{14}B_8$ is found to be similar to that of Ni_3B which has the Fe_3C structure. In $Mo_{48}Ru_{32}B_{20}$, boron has cylindrical local symmetry which could reflect an essential similarity between boron coordination in the glass and in crystalline Mo_2B in which the atom is surrounded by eight Mo atoms at the corners of a square antiprism. However, as crystalline Fe_3P is also tetragonal, the NMR results are consistent with this type of structure also (Durand, personal communication).

Finally, local and medium-range topologies and the question of microcrystallinity are essentially distinct facets of any structural description of amorphous solids. The information presented here seems to be inconsistent with simple hard-sphere packing models for amorphous alloys; equally it is unnecessary to invoke any form of periodicity.

This work has been carried out during the tenure of an SRC Senior Fellowship. I thank the SRC and Pilkington Brothers Ltd for their support.

Formation and behaviour of coal free radicals in pyrolysis and liquefaction conditions

L. Petrakis & D. W. Grandy

Gulf Research and Development Company, PO Drawer 2038,
Pittsburgh, Pennsylvania 15230

In the past several years there has been a renewed interest in fundamental studies of coals and coal conversion. This interest is due to the expectation that an understanding of the structure of coal and of the fundamental processes during coal conversion would aid the development of technology for the utilization of coal on cost-effective and environmentally acceptable terms. In this context, electron spin resonance (ESR) is a promising technique, for it can be used to study paramagnetic centres in coal, including reactive free radicals which are generally assumed to have a key role in conversion processes. The ESR measurements of coals reported to date have all been measurements of pre-existing free radicals or free radicals remaining after some treatment. We report here the fabrication and utilization of a uniquely designed high-pressure–high-temperature ESR cavity and the first *in situ* observation of free radicals in coals.

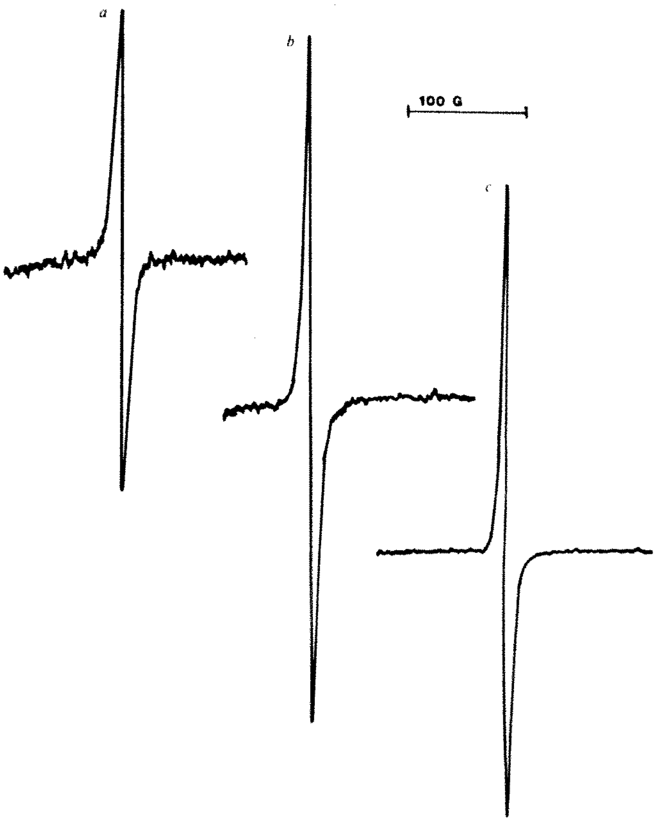

Fig. 1 ESR spectrum of Powhatan no. 5 bituminous coal under 10.335 MPa of hydrogen. Sample temperatures: *a*, 20 °C before heating; *b*, 450 °C; and *c*, 20 °C after 450 °C heating. Relative spectrometer gain factors are 8, 2.5 and 1, respectively.

This development makes it possible to perform a wide range of experiments such as coal conversion studies in process-relevant conditions, coke formation and various catalytic reactions. Findings from the *in situ* monitoring of the formation and behaviour of coal free radicals include: residual free radical concentrations following pyrolysis are similar to concentrations at reaction temperatures; manipulation of typical process variables effect a 12-fold increase in radical concentration, while the experimental error is much smaller (±40%); the determination that the most important process variable is temperature; process-derived solvents behave quite differently from single-component hydro-aromatic solvents such as tetralin.

Naturally occurring free radicals in coals were first reported in 1954. Subsequent studies have shown that the characteristics of pre-existing free radicals depend on the quality of the coals[3], that they offer the possibility of probing the structure of coal[3–5], and that additional free radicals may be generated on various thermal treatments[2,5–8]. This latter observation is particularly interesting, as it is generally assumed that stabilization of the free radicals through hydrogen abstraction from hydrogen-

Table 1 Comparison of yields in conversion of Powhatan no. 5 in ESR experiments

SRC-II*	27–36	2–6
Tetralin*	32–58	12–40

* 460 °C, low residence time.

0028-0836/81/060476—02$01.00

donating solvents may be an important aspect of coal liquefaction[9]. Alternatively, recombination of free radicals at high temperatures could result in undesirable, high-molecular-weight species that cause reactor problems. Thus, it would be useful to be able to study the formation and/or reactions of free radicals *in situ*, that is in high-temperature and high-pressure conditions. The detailed design and operation of our ESR cavity that allows such measurements are discussed elsewhere[10]. A different high-pressure ESR application has also been described recently[11].

Figure 1 shows spectra that have been obtained from a Powhatan no. 5 HVA bituminous coal. This coal is one that has been used in pilot plant studies for the Solvent Refined Coal-II (SRC-II) process. Figure 1*a* is the first-derivative spectrum of the free radicals of natural coal at room temperature and 10.335 MPa pressure of hydrogen. Figure 1*b* is the signal obtained while the same sample is held at 450°C and the pressure of hydrogen in the sample is at 10.335 MPa. Finally, Fig. 1*c* shows the same sample after termination of the treatment and re-establishment of room temperature at hydrogen pressure of 10.335 MPa. By recording reference spectra, spin concentration and *g*-values can be readily determined, as well as how they may change with various treatments and time. On thermal treatment (450 °C), the free radical concentration of Powhatan coal increases several-fold from 8.6 ± 1.0 to $59 \pm 5.0 \times 10^{18}$ spins per gramme. The observed increase is expected and it may be even greater for other types of coals and coal components[5]. On returning to room temperature, the observed residual free radical concentration is about the same ($53 \pm 5.0 \times 10^{18}$ per g) as had been observed at the high temperature.

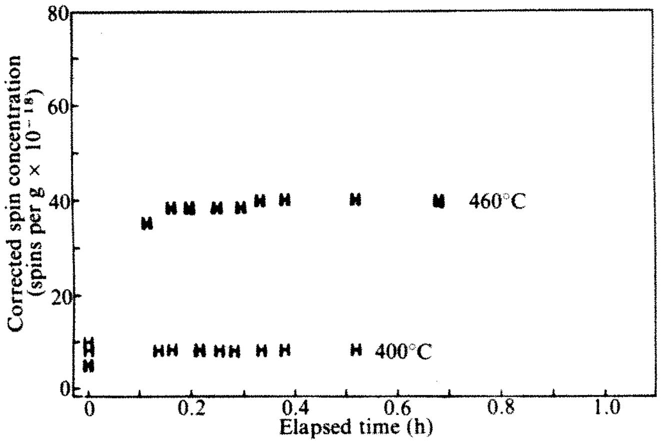

Fig. 2 Spin concentration plotted against elapsed time for Powhatan no. 5 and Tetralin. 1,200 p.s.i. H_2; HT = 3.

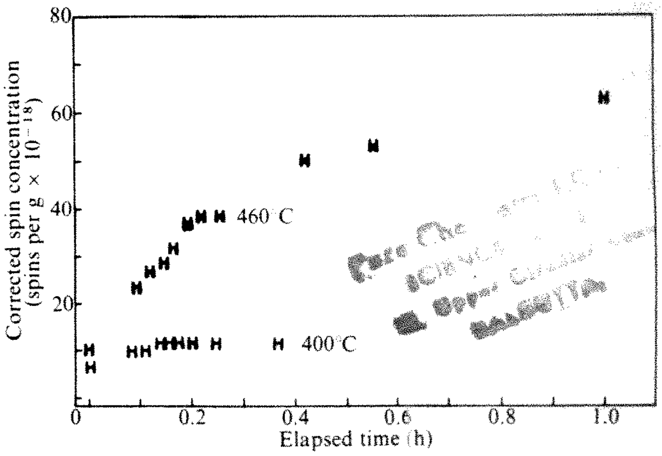

Fig. 3 Spin concentration plotted against elapsed time for Powhatan no. 5 and SRC-II HD. 1,200 p.s.i. H_2; HT = 3.

In addition to these pyrolysis experiments, more than 60 experiments, including a partially replicated 2^5 factorial design, have been carried out to assess: (1) the role of liquefaction-process variables, such as solvent, temperature, gas, pressure and heating rate, on the formation of free radicals; and (2) how the degree of conversion and quality of product are correlated with the measured free radical parameters. ESR spectra can be obtained continually starting 3 min after the initiation of the heating cycle. Figures 2 and 3 show the variation of the free radical concentration as a function of residence time. These results allow the effects of temperature (400 and 460 °C) to be assessed with two different solvents (tetralin and the heavy distillate of the SRC-II process-derived solvent from the Powhatan no. 5 coal). All other experimental conditions are identical in the four experiments shown (that is H_2 gas at 8.37 MPa and 3-min heating time to achieve reaction temperature). With tetralin as a solvent (Fig. 2), the free radical concentration remains constant at 400 °C as a function of residence time, while at 460 °C it reaches its maximum value within 6 min. With SRC-II heavy distillate as solvent (Fig. 3) there is a small increase in free radical concentration at 400 °C, while at 460 °C the free radical concentration continues to increase even after 1 h of reaction time. The free radical concentration with tetralin as the solvent is lower than with the SRC-II heavy distillate. This is not unexpected, as tetralin is considered a good hydrogen donor and, therefore, can quench efficiently the coal free radicals.

We have also attempted to obtain data on the degree of conversion and quality of the product obtained. Such data are necessary to establish whether free radical chemistry determines the reaction paths in the liquefaction of coal[9]. The preliminary data available indicate that the overall tetrahydrofuran soluble conversion is lower when SRC-II distillate is the solvent (27–36% conversion) compared with the corresponding tetralin experiments (32–58%). For the same ESR experiments, the oil yields (pentane solubles) with SRC-II heavy distillate solvent are considerably lower (2–6%) compared with the corresponding tetralin runs (12–40%) (Table 1). These different degrees of conversion as well as the differences in the time-dependent spectra (Figs 2, 3) clearly indicate that some significantly different chemistry is taking place in the SRC-II process solvent experiments relative to the tetralin experiments. This is especially true in the first half-hour of the liquefaction reaction. The results also indicate very strongly the importance of both individual and combination effects of the process variables on the formation and behaviour of free radicals. Finally, the results shown here indicate the potential of using *in situ* measurements for understanding coal conversion processes on a molecular level, and thereby controlling the quality of the liquefaction product through the manipulation of the free radical chemistry by the various process variables.

Determination of geomagnetic archaeomagnitudes from clay pipes

K. P. Games & M. E. Baker*

Department of Geophysics, Oliver Lodge Laboratory,
The University of Liverpool, Oxford Street,
Liverpool L69 3BX, UK

Archaeomagnitude determinations of a selection of clay pipes dateable to AD 1645±10 as well as studies of pottery samples from the same site and of the same age have been made. Values of the magnitude of the ancient magnetic field ($\mathbf{B}_{\mathrm{anc}}$), were obtained from two pottery sherds, two pipe bowls and three pipe stems. The values from the sherds and bowls agree within 2% and compare well with the average value of the magnitude of the magnetic field for the seventeenth century as determined by other archaeomagnetic studies. However, the pipe stems give values of $\mathbf{B}_{\mathrm{anc}}$ which are significantly less than those from the bowls and pottery. We have not yet been able to explain this and thus we suggest that reliable archaeomagnitude determinations can be made from the bowls of clay pipes but not from the stems. Nevertheless, this result provides a new source of material for investigating variations in the geomagnetic field strength over the past 400 yr. Clay pipes have been manufactured in England since the end of the sixteenth century. In the firing process some pipes were broken and disposed of without ever having been smoked. One such collection, discovered at Rainford, Lancashire, in 1978, consisted of a series of discrete dumps including pipes, kiln debris and a small collection of contemporary used earthenware sherds. The internal consideration of the dumps suggested a very short period of activity and archaeologists (P. Davey, personal communication) ascribe all the material to the period 1645±10 yr. With such well-dated material, we set out to check whether or not reliable archaeomagnitudes could be obtained from the pipes.

The samples were all analysed using Shaw's[1] ARM technique. The maximum size of the samples used was determined by the sample holder which was designed to hold 1-inch diameter cylindrical cores. Figure 1 shows the graphs obtained for one of the pipe bowls. The points labelled R are rejected because they do not lie on a straight line of gradient = 1.00 on the plot of ARM 1 against ARM 2. The value of $\mathbf{B}_{\mathrm{anc}}$ is determined from the slope of the normal remanent magnetism (NRM) against thermoremanent magnetism (TRM) graph using the equation

$$\frac{\mathrm{NRM}}{\mathrm{TRM}}=\frac{\mathbf{B}_{\mathrm{anc}}}{\mathbf{B}_{\mathrm{lab}}}$$

where $\mathbf{B}_{\mathrm{lab}}$ is the laboratory magnetic field in which the TRM was acquired, in this case 50μT.

All the samples were given their TRMs over a period of 7 h to reproduce as closely as possible the original slow cooling rate. This minimizes the error introduced by different cooling rates for the NRM and TRM as described by Fox and Aitken[2]. All the TRMs were installed using a field in the direction of the NRM to produce a TRM in the same direction as the original NRM within about 5°. This was to avoid the possible source of error caused by anisotropy[3]. This was very important as some of the samples were very anisotropic (see Table 1).

The results obtained for the pottery, bowl and stem samples are given in Table 1. To ascertain how close these results were to the actual value of the magnetic field at that time we averaged all of the known archaeomagnitude determinations for the seventeenth century as published by the Academy of Sciences (USSR)[4]. Seventy-two results for this period have an average value for $\mathbf{B}_{\mathrm{anc}}/\mathbf{B}_0$ of 1.12 ± 0.13 where $\mathbf{B}_0$ represents the present day field value at the place where the sample came from, and where the error is the r.m.s. deviation from the mean. For Rainford, therefore, we would expect the value of the ancient magnetic field strength to be 53.8 ± 6.2 μT. Table 1 shows that the values of $\mathbf{B}_{\mathrm{anc}}$ from the pottery and bowl samples agree very well with each other and with the expected value. Averaging both sets of results we get 51.0 ± 2.0 μT for the bowls and 52.0 ± 1.0 μT for the pottery. However, the three pipe stems studied give widely ranging values which are all less than the expected value. Two of these stems, R7810 and R7813, give values which are of the order of 30% and 15% too low compared with the pottery and bowls, while the third stem, R7814, gives a value which is about 5% too low.

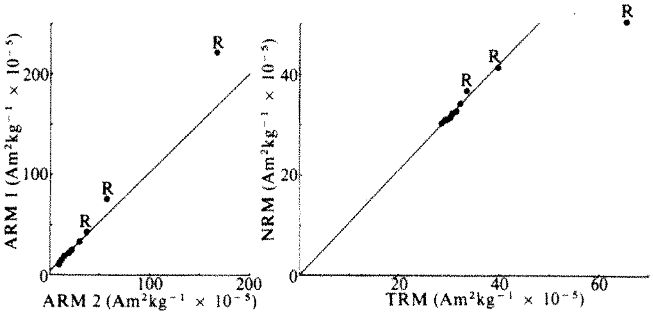

Fig. 1 Results for bowl sample R 7822. The graphs show all of the data for the NRM and TRM and ARM 1 versus ARM 2 plots. The points labelled R are rejected because they do not lie on the straight line of gradient = 1.00 drawn on the plot of ARM 1 versus ARM 2.

We have not yet succeeded in finding the reason for these low values from the stems, but we determined the degree of TRM anisotropy present in all of our samples, and these values are given in Table 1. Although two of the stems show the greatest degree of anisotropy, this in itself should not affect the value of $\mathbf{B}_{\mathrm{anc}}$ as the TRM was always installed along the same direction as the NRM. Moreover, the third stem actually has quite a small degree of anisotropy.

These pipes were possibly placed in a radial pattern around a central pillar inside a cylindrical oven, with the bowls on the outside and the stems towards the centre. The lengths of the

pipes may have been longer than the radius of the ovens, and so there would be a certain amount of stacking and overlapping of pipe stems in the central region. We calculated the effect of the distortion of the field produced by the overlapping stems, and concluded that it was too small to account for the low values of the field which we have obtained.

Another way in which the pipes could have been arranged was with the bowls at the outside of the oven, with the stems pointing radially inwards but also raised vertically so that the ends of the pipe stems met at some common point. As the inclination of the magnetic field is quite steep in England, this configuration would mean that the direction of the NRM in the pipe stems would in some cases be nearly parallel to the length of the stem and in other cases it would be transverse to the stem, whereas in the previously described configuration there is no obvious way that the NRM can be acquired along the length of the stem. When we analysed the NRM directions in the stems, we found that the direction of the NRM varied from angles of 10° to 85° with respect to the axis along the length of the stem (see Table 1). Furthermore, there was a correlation between this angle and the value of $\mathbf{B}_{\text{anc}}$, but we cannot find any explanation for this.

We conclude, therefore, that the bowls of clay pipes may be used to determine archaeomagnitudes. As one of the major problems in archaeomagnetism is the availability of well-dated suitable material, any new source material such as these clay pipes is of great interest. Also, once the changes in the strength of the geomagnetic field over the past 400 yr have been satisfactorily determined, we may be able to date pipes of unknown age by this technique.

We thank P. Davey for samples and for his interest and help. K.P.G. is supported by NERC grant no. GR3/2396.

Thermoluminescence dating of late Devensian loesses in southern England

A. G. Wintle

The Godwin Laboratory, Sub-department of Quaternary Research,
Free School Lane, Cambridge CB2 3RS, UK

Scattered across southern England are many isolated deposits of loess-like material[1]. A few, such as that at Pegwell Bay in Kent, are highly calcareous and unweathered but most have been reworked by fluvial or colluvial processes. There is good stratigraphical evidence for a few pre-Devensian loesses, also in Kent, but dating of more recent loess has so far been based on indirect evidence. Much work has been done on the Pegwell Bay loess as it is the most extensive, truly aeolian loessic deposit in Britain. Kerney[2] compared the late Devensian deposits in the Isle of Thanet and at Pegwell Bay with similar deposits in Holland and Belgium where radiocarbon dates have been obtained for interstadial deposits. Correlation of the East Kent deposits with these in Northern Europe indicates that the loesses in Kent were formed between 30,000 and 14,000 yr ago. I report here dates for six of the more recent deposits in southern Britain from the Scilly Isles to Kent. The dates have been obtained on the loess itself, using a recently developed thermoluminescence (TL) dating technique[3,4], and confirm the ages as being late Devensian.

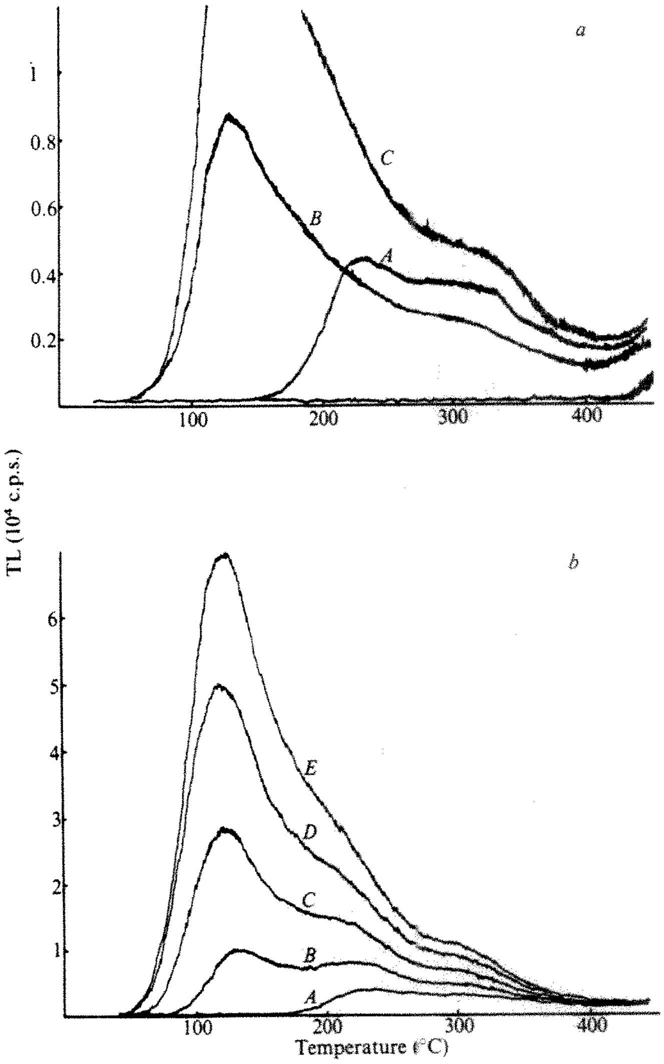

Fig. 1 TL glow curves for late Devensian loess. *a*: *A*, natural TL; *B* and *C*, TL due to 6.7 and 13.4 krad after heating. *b*: *A*, natural TL; *B–E* natural + 8.9, 13.4 and 17.9 krad respectively.

The TL dating of any sedimentary deposit, whether marine or terrestrial, is based on the assumption that exposure to sunlight during the weathering and transport of the detrital grains is sufficient to remove most of their previously acquired TL signal. The TL signal in a mineral is due to the untrapping of electrical charges in the crystal when it is heated, the trapped charges having been produced by ionization due to the decay of natural radioactive elements in the sediment. The most common TL-sensitive minerals are quartz and feldspar and these are the dominant minerals present in loess. In southern England the peak grain size of the deposits decreases from ~45 μm in Kent to 25 μm in the south-west[1] suggesting that the loesses, if contemporary, have been derived from a source in the North Sea. In this study polymineral grains in the range 4–11 μm were used, 0.5-mg samples being deposited onto 1-cm diameter aluminium disks for TL measurements. The disk is heated in an oxygen-free atmosphere from room temperature to 450 °C at 2 °C s^{-1} and the resulting TL output recorded as a function of temperature known as a glow curve. The glow curves for all six samples are very similar to each other and to those obtained for detrital grains from ocean sediments[3].

Only the Pegwell Bay sample 1a could be described as pure aeolian loess. The St Agnes sample 1d looked pure but did not

† Repeat measurements on three subsamples of 1a gave the same age within errors.

break up when placed in water. The other Scilly Isles sample, from St Mary's, (1f) had a similar texture but had large brown stains running through it. The sample from Barton in the New Forest area was also uniform but contained fine roots. Sample 1b from Sturt Pond in the New Forest area and 1e from the Lizard Peninsula, Cornwall, also contained roots and many small pockets of darker soil which are likely to have been washed in from above. The last two samples were initially considered to be unsuitable for TL dating because of likely contamination but were included for completeness.

Figure 1*a* shows typical glow curves for the Barton sample, showing natural TL and response to subsequent laboratory irradiations. To obtain the age of the sediment since its last exposure to sunlight, the natural TL signal needs to be compared with that induced in it by a known radiation dose. A $^{90}Sr/^{90}Y$ β source was used with method (c) of Wintle and Huntley[4] to separate the TL due to radiation exposure since burial from that which was not bleached by the original sunlight exposure (termed the residual component). Figure 1*b* shows the effect of additional doses of radiation on top of the natural TL for the same sample (on a different vertical scale): the lower temperature peaks are the more sensitive. Above 350 °C the residual component is responsible for >50% of the natural TL and this, combined with the low TL sensitivity in this region, makes it impossible to obtain the equivalent radiation dose (ED) in this region. The values of the ED obtained in the glow curve temperature region 260–320 °C are given in Table 1. In this region the value of the ED obtained does not vary with glow curve temperature. Integrating over this temperature range, the residual signal is equivalent to 40% of the total natural TL for samples 1b to 1f and 50% for 1a; ignoring it would have added about 3.5 krad to the ED of each sample. This is typical of residual signal obtained by the same technique for polymineral samples of ocean sediments having EDs in the range 3–26 krad (ref. 3). The TL signal from samples which have been irradiated after heating indicates that the TL at lower doses is not perfectly linear and an intercept correction (I) is made as in the case of the quartz inclusion TL dating method for pottery[5]. The error in the determination of the past radiation dose ($ED+I$) is $\sim\pm 7\%$ and is due mainly to the subtraction of the residual signal.

To obtain the age of the sediment, the radiation dose obtained from the TL measurements must be combined with the annual dose rate obtained from radioactivity analyses. The contribution from ^{40}K is calculated from the total K_2O content measured by atomic absorption spectrometry and for these samples the ionization due to ^{40}K is responsible for about a third of the natural TL. Apart from a 14 mrad yr^{-1} contribution due to cosmic radiation, the remaining radiation is due to the α, β and γ radiation from the decay of ^{238}U and ^{232}Th chains present in the sediment. Their activity is measured by a ZnS α scintillation counting technique[6]. Table 1 shows that the total α count rate is very similar for the four cleanest samples. The two which were observed to contain small pockets of darker soil had larger α counts, perhaps indicating recent contamination. (Sub-sampling of these specimens also gave a scatter of 10% whereas the cleaner samples were reproducible to within 5%. Clean water was dripped continuously through samples 1a and 1b for 10 days after measurement and on recounting no change was observed for 1a but a loss of 25% in total α count was observed for 1b.) If the U and Th decay chain contributions had been the same as for the other samples, the ages for 1b and 1e would have been 17,200 and 18,200 yr respectively.

The α efficiency factor, a, was measured for each sample and the annual dose rate calculated using the energy conversion factors of Bell[7] and assuming a mean water content of 20%. The saturation water content was measured for each sample in the laboratory. However, except for the two samples from the Scilly Isles, 1d and 1f, the samples formed a slurry and it was thought incorrect to try and estimate a mean annual water content from these values. The 20% value was found to be the mean *in situ* value for British brick-earth deposits. The water content is important because of the absorption of energy by the water which would otherwise be absorbed in the minerals to produce a higher TL signal. The age calculated is directly dependent on the per cent water content and this is the greatest source of error in dating these samples. Anomalous fading tests were carried out and no losses within the experimental reproducibility limit of ±4% were found in the 260–320 °C temperature range.

This is the first application of TL dating to late Devensian loess, although apparently successful TL dating of the quartz fraction of older loess has been reported in the Soviet Union[8]. The uncertainty in estimating the water content and the residual signal are the two major sources of error in the age and an overall error of ±20% should be applied to these dates; this makes it impossible to separate the six samples studied here but they are easily distinguished from older loesses which I am studying. TL dating can thus resolve the controversy concerning the presence of late and/or early Devensian loess in Britain.

I thank Dr J. A. Catt for samples and for stimulating discussion, Mrs M. Miller for potassium analyses and Dr M. J. Aitken for use of a ^{242}Cm α source. Financial support was provided by a NERC grant to Dr N. J. Shackleton.

Bermuda sea level during the last interglacial

Bermuda is a stable, mid-oceanic carbonate platform for which a particularly complete record of sea level fluctuation during the period ~135–70 kyr has been reconstructed from $^{230}\mathrm{Th}/^{234}\mathrm{U}$ dating of corals and speleothems, amino acid racemization dating of molluscs, and a reinterpretation of geological field relations. During the past 5 yr Bermuda has been the focus of an extensive geochronological programme which has included a detailed re-examination of the geology (to be reported elsewhere[1–3]). Here we focus only on the latest interglacial sequence. We use the stratigraphic nomenclature of Land *et al.*[4], but will present new age data and interpretations of geological relationships. This information, as it relates to the last interglacial period, is given in Tables 1 and 2 and summarized in Fig. 1. We show that during the last interglacial period, sea level was only above its present level for a few thousand years at about 125 kyr when it stood at +4 to +6m. At ~105 and ~85 kyr, sea level rose to between −15 and −20 m as constrained by ages for submerged speleothems and eolianites. At ~95 kyr sea level in Bermuda was at least −15 m below present level.

The Bermudas are a group of tectonically stable, Pleistocene-age islands in the mid-Atlantic (35°N, 65°W) consisting of intercalated and interfingering shallow-water marine calcarenites, eolianites and terra-rose palaeosols deposited on a stable volcanic pedestal. At least four complex, superimposed suites of marine and eolian carbonates occur in a general pattern of seaward accretion with the younger units lying closer to the coast. Within each suite there is an alternation of carbonate facies, with successive suites generally separated by palaeosol horizons. Caves formed by groundwater solution and collapse are common within the older, more lithified carbonate units and often extend below present sea level and are partially or totally filled with seawater. Extensive deposition of calcium carbonate speleothems (stalactites, stalagmites and flowstones) at elevations above and below present sea level is characteristic of the older caves.

Bretz[5] and Land *et al.*[4] established the conceptual framework within which Bermudian geology must be considered. They recognized that the carbonate formations are not simple stratigraphic units arranged in layer-cake fashion which can be separated solely on the basis of lithological or palaeontological criteria, and pointed out that an understanding of depositional mechanism is critical to the interpretation of Bermudian geology. Eolianites comprise over 90% of the exposed carbonate rock in Bermuda and represent lithified, transverse-lobate dune ridges[6]. These can be observed in some cases to merge laterally into marine carbonates and therefore must have been deposited during times of interglacial high sea stand. Thus, preserved littoral marine carbonates and patch reefs must have formed during interglacial periods at times when sea level was at or above its present level and eolianites can only have formed when the Bermuda platform (−20 m) was submerged to provide a source of sand for eolian shoreline dunes, but with sea level not necessarily as high as at present. During intervening glacial periods of depressed sea level, the Bermuda platform was subaerially exposed, and accumulation of terra-rose or regolith palaeosols and deposition of speleothems in caves at elevations below present sea level occurred coincident with vadose carbonate diagenesis. Thus, because the Bermuda platform is in an area of the world not significantly affected by either the effects of vertical displacement due to tectonic uplift or isostatic deformation through ice or water loading[7,8], Bermudian geology represents an approximate palaeosea level gauge, presumably recording absolute eustatic fluctuation of late Pleistocene sea level.

The last interglacial period in the marine record from ~135,000 to 75,000 yr BP is commonly assigned to Stage 5 of the marine oxygen isotopic record[9,10]. As Fig. 1 shows, the Bermuda platform was probably submerged for most of this time. Before Stage 5, during Shore Hills time, sea level was below the edge of the Bermuda platform, then rose rapidly, passing −13 m at ~134 kyr, to the Devonshire +4 to +6 m high stand at 125 kyr. Here it produced a wave-cut notch in the older Belmont Formation, deposited the Devonshire marine calcarenites and flooded what are at present the air-filled portions of many caves resulting in the development of aragonitic surface coatings on actively forming stalagmites and stalactites up to elevations of +3 to +4 m. Sixteen $^{230}\mathrm{Th}/^{234}\mathrm{U}$ dates on Devonshire corals from sites around Bermuda where stratigraphic relationships are clear range from 134 ± 8 to 118 ± 6 kyr with a mean of 125 ± 4 kyr (Table 2), thus correlating the Devonshire Formation with the Rendezvous Hill terrace in Barbados[11,12], reef complex VII in New Guinea[13] and the Wiamanalo shoreline in Hawaii[14]. Sea level stood at this level for only a short period before quickly falling off the Bermuda platform as indicated by initiation of speleothem deposition at elevations below present sea level by ~120 kyr. This regression is reflected in the geological record by the development of the Harrington Formation which gives both U-series and amino acid racemization ages of ~120 kyr (Table 2).

The remainder of Stage 5 time in Bermuda is a long and complex episode of dune building and soil deposition resulting from periodic submergence and exposure of the Bermuda platform but with sea levels always below present level. The amino acid racemization ages of ~105 and ~86 kyr for two post-Devonshire eolianites (Table 2) record the timing of these transgressions. The dates correlate well with isotope Stages 5c

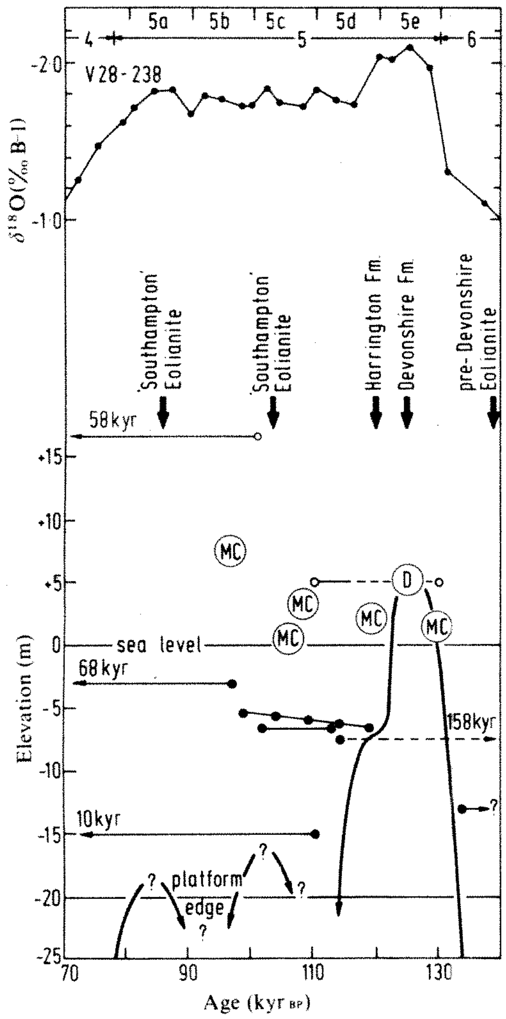

Fig. 1 Palaeosea level curve for Bermuda during the last interglacial. ^{230}Th/^{234}U age determinations: ●, submerged speleothems; ○, aerially exposed speleothems. Solid lines connecting speleothem age determinations indicate continuous deposition over the indicated interval; dashed lines signify interrupted growth. Horizontal arrows denote speleothem deposition outside the 70–140 kyr period of interest here. The circle labelled 'D' indicates the Devonshire last interglacial maximum high sea stand; those labelled 'MC' indicate time–elevation relationships for south-shore storm deposits (conglomerates). Vertical arrows show amino acid racemization ages for molluscs from the stratigraphic units indicated calibrated to D. The sea-level curve is based entirely on Bermudian geology and chronology. Correlation between the Bermuda sea level and the marine oxygen isotope record[10] is based on absolute dating. The isotope stages are numbered after Emiliani[9].

and 5a (ref. 10), as well as the Ventnor and Worthing terraces in Barbados[11,12] and reef complexes VI and V in New Guinea[13]. This is the first time to our knowledge that these events have been documented in a tectonically stable area. The deposition of stalagmites at elevations down to −15 m indicates that sea level was below this level from ~110 kyr to the end of Stage 5. This is consistent with the fact that no Pembroke or Southampton marine facies or strandlines have been observed, as they must be below present sea level.

The two most persistent problems of Bermudian geology have been the patchy marine conglomerates which occur along the south shore at elevations between sea level and +11 m, and a complex of evenly bedded, seaward-dipping sands which are present along the north shore at elevations up to about +20 m. Land *et al.*[4] assigned the conglomerates to one lithological unit, the Spencer's Point Formation, which they interpreted to be a single post-Pembroke marine transgression. These conglomerates and the north-shore sands were then correlated because the latter were considered marine in character near sea level and can be traced inland tomverlap what was considered to be Pembroke eolianite. However, ^{230}Th/^{234}U dating of corals from seven of these conglomerates (Table 2) has yielded ages correlative with each transgressive phase of Stage 5, plus one modern age. Close examination of these conglomerates in the field reveals each to be an isolated, chaotic deposit emplaced as a plaster or cliff pocket infilling. Thus, we reinterpret them to be deposits thrown up along the dynamic south-shore coastline from storms during times of platform submergence. This result has two important consequences. First, it emphasizes that lithological units as mapped in the field (that is rock-stratigraphic units) are not necessarily time-stratigraphic units. Second, it removes the correlation between the south-shore conglomerates and north-shore sands.

The north-shore sands we now assign to the Devonshire Formation on the basis of amino acid racemization ages which are the first absolute age data for these deposits. The sea stand responsible for the deposition of the north-shore sands, 'perhaps as high as 20 m (Blackwatch Pass)'[4], has always been based on interpretation of depositional environment of the uniform seaward-dipping section. Some geologists might claim that all the units are marine, others have argued that they are all eolian

Table 2 Stratigraphic column for the last interglacial sequence of Bermuda[*]

Southampton Formation
  Poorly consolidated dunes with unconsolidated zones rich in land snails. Age >30 kyr by radiocarbon[*][†] and ~86 and ~105 kyr for molluscs from two different outcrops by amino[‡] acid racemization.

St George's Soil
  Red residual soil of moderate development and only rare palmetto stump casts.

Spencer's Point Formation
  Discontinuous patches of marine conglomerate along the south shore and harbour islands plastered in cliff pockets and recesses or on large breakdown blocks at elevations of between +1 to +11 m; previously correlated with seaward-dipping sands along the north shore[4]. Age: corals from various conglomerates have given ^{230}Th/^{234}U ages of 131±7, 124±8; 121±6, 118±6, 118±11, 108±6, 105±6, 97±6[‡], 85±6, 83±5, and <2 kyr.

Pembroke Formation
  Extensive, island-wide eolianites with landward-dipping foreset beds which commonly extend down to and below present sea level.

Harrington Formation
  A yellowish to reddish unconsolidated layer on the Devonshire or Belmont Formations which contains abundant land snails near the top and grades downwards into coarse marine beds near the base. Age: ~120 kyr by amino acid racemization for molluscs, and 121±9 by ^{230}Th/^{234}U.

Devonshire Formation
  Intertidal marine conglomerates and calcarenites at +2 to +6 m which contain abundant Belmont clasts and a characteristic fauna. Age: corals from this unit have given ^{230}Th/^{234}U ages of 118±6[‡], 124±6[‡], 124±8[‡], 124±6[‡], 124±12, 124±12, 125±6, 127±9, 127±9, 127±6, and 134±8 kyr.

'Unnamed Eolianite'
  Seaward-dipping eolianite underlying the Devonshire marine beds on the north and south shores. Age: ~140 kyr by amino acid racemization for molluses.

Shore Hills Soil
  Well developed red palaeosol of island-wide extent with abundant palmetto stump casts.

* For core V28-238 assuming $-0.1‰$ change in $\delta^{18}O$ of foraminifera calcite per 10 m rise in sea level.

backset beds[3]. We have found no definite evidence but have recognized apparent beach cusps as high as +3 m above present sea level, and conclude that higher beds must be due to reworking during storms (hurricanes) during Devonshire time. The underlying eolianites, which give an amino acid age of ~140 kyr, thus represent an early phase of the Devonshire transgression, during which time the extensive North Lagoon could have supplied sand and stone[5].

Because the Bermudian palaeosea level record for the last interglacial presented here (Fig. 1) is particularly complete, it has important implications for the idea of glacial surge. Hollin[15] has recently argued that a catastrophic surge of the East Antarctic ice sheet caused a rise in worldwide sea level to about +16 m at ~95 kyr. Although such an event should have left some evidence of its occurrence in the geological record of island and coastal areas, it can be argued that it might not be reflected in either the marine oxygen isotope or tectonic island sea level records because both of these are relatively low-resolution measures of global ice volume integrated over a time scale of a few thousand years. Hollin[15] recognized that his hypothesis must be tested in an area where a highly resolved sea level record for the last interglacial is preserved. Bermuda is one such locality, and thus the palaeosea level record presented here is a crucial test for such an ice surge.

Although Bermuda is cited by Hollin[15] to support a +16-m high sea stand at ~95 kyr, the reappraisal of geological relationships resulting from our chronological and field studies has revised the tenuous correlation on which a possible +20 m post-Devonshire high sea stand was based. Figure 1 shows that sea level in Bermuda was only once above its present level during Stage 5; that is during Devonshire time at 125 kyr when it stood at +4 to +6 m. Otherwise, from ~135 to 70 kyr sea level was below ~-15 m. There is no geological evidence to the contrary. There is no indication of a former freshwater table at elevations above present sea level, except the +2 m feature relating to the penultimate high sea stand which deposited the Belmont Formation between ~230 and 200 kyr (ref. 1). Neither have we observed any overgrowths nor surface coatings of marine aragonite and serpulid worm shells on any speleothems above +3 to +4 m in the more than 20 caves investigated nor found any interior aragonite layers in speleothems younger than 120 kyr. Such features are present to some extent on the surface of all speleothems presently submerged in seawater.

In Crystal Cave, stalactites at +2 to +4 m above sea level typically contain one interior layer of such marine deposition which can be easily observed because the lower portions of these speleothems have been broken by human activity to reveal a cross-section through these deposits. For one such stalactite previously studied, the aragonitic layer only extended upwards inside the stalactite to an elevation of +3 to +4 m, above which calcite crystal growth was continuous across the axis of the entire stalactite. $^{230}\mathrm{Th}/^{234}\mathrm{U}$ dating gave an age of 130±10 kyr for the calcite layer just inside the marine layer and 110±14 kyr for the outer calcite layer thus independently documenting the absolute elevation of the Devonshire high sea stand at 125 kyr (Fig. 1) (ref. 16). Certainly one would expect to observe two such sediment layers in these stalactites and marine overgrowths and surface coatings on subaerial travertines and flowstones as well as evidence for an elevated freshwater table between +4 and +16 m if there had been a post-Devonshire sea level rise to +16 m. Also, neither the extensive Devonshire marine calcarenites and relatively unlithified Pembroke or Southampton eolianites, nor the wholly unconsolidated, Harrington Formation have been reworked to any extent. All these units are exposed along the south shore of Bermuda at or near sea level, not more than 1–2 km from the platform edge, at present a very dynamic, high-energy environment. It, therefore, seems most unlikely that a +16 m rise in sea level over only a few hundred or thousand years, as required by the surge hypothesis[15], could have happened without some reworking, eroding, and re-depositing of these units. The discontinuous marine conglomerates cannot be surge-derived unless the coincidence of their ages with the well recognized isotope Stage 5e, 5c and 5a high sea stands is fortuitous, with surge events occurring within each of these transgressions, and demonstration that deposition of stalagmites below present sea level could have been interrupted by a marine transgression and then resumed without leaving behind physical or petrographical evidence to this effect.

Finally, the Bermuda palaeosea level record presented here is in basic agreement with both the marine oxygen isotope[10] as well as the New Guinea[13] and Barbados[11,12] sea level records (Table 3). Although there are some internal inconsistencies among these various ice-volume records which reflect both geological and chronological uncertainties, the overall agreement is striking. However, although casting serious doubt on Hollin's[15] postulated surge of the East Antarctic ice sheet at 95 kyr, these results do not question either the theory or reality of the general concept as discussed by Aharon *et al.*[17]. The Devonshire high sea stand may in fact represent a surge event at 125 kyr superimposed on the general submergence of the Bermuda platform during the last interglacial period.

The $^{230}\mathrm{Th}/^{234}\mathrm{U}$ coral and speleothem dating programme and palaeosea level work in Bermuda has been supported by a grant from the NSF (EAR 77-23026) and a Wilkinson Fellowship from the Bermuda Biological Station. The manuscript was typed by Miss J. McLean and illustrations drawn by J. Bennett.

Low $^{15}N/^{14}N$ in hydrothermal vent animals: ecological implications

Greg H. Rau

Institute of Geophysics and Planetary Physics,
University of California, Los Angeles, California 90024

Low-trophic-level animal biomass from the Galápagos and 21 °N hydrothermal vents was found to have $^{15}N/^{14}N$ ratios which are lower than those previously reported for organic nitrogen[1–6], ammonium[1,2,5], and nitrate[1,2,7,8] in deep Pacific Ocean water. These nitrogen isotope ratios of vent animals are, however, near those of deep-oceanic N_2 (refs 1, 2, 7, 9) and resemble those of marine biota associated with N_2 fixation[2,10]. These observations suggest that organic nitrogen of nutritional importance to vent animals is initially synthesized within the vent environment and this synthesis may be preceded by N_2 fixation.

It has been argued[11–19] that local bacterial chemo-autotrophy is the primary source of biomass and energy for the dense invertebrate communities found at Pacific Ocean hydrothermal vents. Part of the evidence for vent primary production is the difference between the $^{13}C/^{12}C$ of vent animals and the $^{13}C/^{12}C$ of animals in the overlying pelagic environment[13,19]. It was reasoned that measurement of vent animal $^{15}N/^{14}N$ would provide further clues as to the base and the structure of these vent food webs.

A variety of animal tissues from hydrothermal vents were analysed including: trophosome and vestimentum from *Riftia pachyptila* Jones (a vestimentiferan worm), mantle tissue from *Calyptogena magnifica* Boss and Turner (vesicomyid clams), and crab muscle from *Bythograea thermydron* Williams (brachyuran crabs). These animals had been originally taken from either the Galápagos or the 21° N hydrothermal vent sites through the submersible Alvin, as indicated in Fig. 1. These tissues were dried at 60 °C and ground, and the nitrogen present in 5–10-mg replicate subsamples of these tissues was completely converted to N_2 using methods described by Stump and Frazer[20]. The $^{15}N/^{14}N$ relative to air (Fig. 1 legend) of these N_2 gas samples was determined by David Winter using a Varian MAT 250 ratio mass spectrometer.

Figure 1 shows vent animal $\delta^{15}N$ ranges from +1.8 to +9.8‰, with the values generally increasing as a function of the animal's assumed trophic level. This animal $\delta^{15}N$ increase with trophic status corroborates observations[2,4,10,21–25] that food chain/heterotrophic processes tend to increase ^{15}N relative abundance in the resultant animal biomass. Consequently, if vent animals were utilizing sedimentary organic nitrogen that had been produced and biologically processed on its journey through the more than 2 km of water overlying the vents, one would expect the $\delta^{15}N$ of vent animals: first, to exceed the $\delta^{15}N$ of plankton encountered in the surface layers of the Pacific Ocean, commonly 5–10‰ (refs 1, 2, 5, 10, 26), and second, to equal, if not exceed, the $\delta^{15}N$ of deep-ocean sedimentary organic nitrogen, 5–13‰ (refs 1–6). The relatively low $\delta^{15}N$ of assumed primary producer–consumer tissues from the vents, 1.8–4.9‰ (Fig. 1), however, suggests that the organic nitrogen present in these tissues has undergone relatively little biological cycling and is, therefore, of local, rather than pelagic–sedimentary origin.

Additionally, the striking similarity between the $\delta^{15}N$ of low-trophic level vent animal tissues and the $\delta^{15}N$ of marine organisms associated with N_2 fixation (Fig. 1) suggests that the production of the organic nitrogen found in vent animals is preceded by N_2 fixation. Both the concentration and the low $\delta^{15}N$ of dissolved N_2 are relatively constant throughout the ocean[1,7,9], and little nitrogen isotopic fractionation is known to occur during fixation of N_2 and subsequent organic nitrogen synthesis[2,10,27–31]. The yet-to-be measured $\delta^{15}N$ of the NH_4^+ and the NO_3^- present[32] in the vicinity of the vents may, however, prove these ions as likely as N_2 to be precursors to vent animal nitrogen. Large nitrogen isotope fractionations incurred during nitrate or ammonium assimilation and biomass production by some microbes and by some autotrophs in certain conditions[2,28,31,33–35] may also be factors causing vent organisms to be relatively depleted in ^{15}N.

Whatever the synthesis pathways and their inorganic starting compounds, the existing isotopic evidence indicates that the organic nitrogen as well as the organic carbon[13,19] found in vent animal biomass are largely produced by non-pelagic and non-photosynthetic processes.

This research was made possible through the generosity of Mr Bud Smithey and Drs Robert Hessler, George Somero, Horst Felbeck, James Childress and Ian Kaplan. Support was provided in part by a joint US Bureau of Land Management/Department of Energy contract No. EY-76-3-03-0034

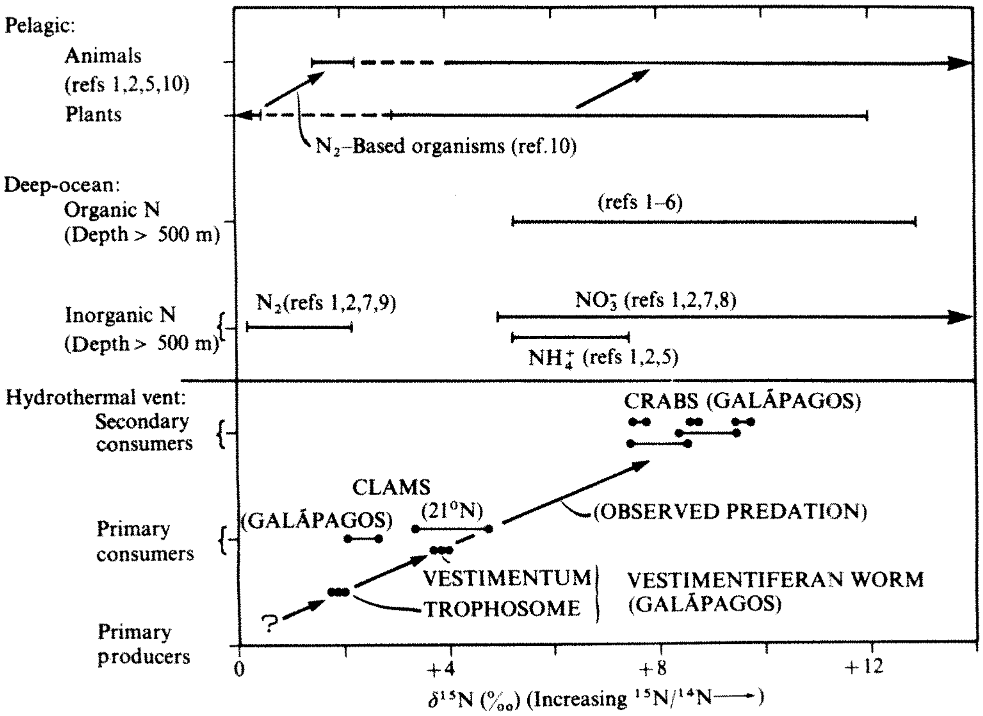

Fig. 1 The $\delta^{15}N$ of various Pacific Ocean nitrogen pools where:

$$\delta^{15}N = \left\{\left[\frac{(^{15}N/^{14}N)_{sample}}{(^{15}N/^{14}N)_{air}}\right] - 1\right\} \times 10^3‰$$

The vent sites, Galápagos (0.8° N, 86.1° W) and 21° N (20.9° N, 109.1° W), are located at ocean depths of 2.5 and 2.6 km, respectively. The assumed trophic levels and transfers (diagonal arrows) of hydrothermal vent animals/tissues are based on knowledge of related species, and on observations by Drs R. R. Hessler, G. N. Somero, H. Felbeck and J. J. Childress. The trophosome of the vestimentiferan worm is at least partly, if not largely, composed of autotrophic tissues[16–18]. Replicate analyses of a single individual's tissue are connected by a horizontal line.

Fourier analysis of test shape of planktonic foraminifera

Nancy Healy-Williams & Douglas F. Williams

Belle W. Baruch Institute for Marine Biology and Coastal Research
and Department of Geology, University of South Carolina,
Columbia, South Carolina 29208

The exact characterization of test shape is important in morphological studies of foraminifera and other marine microfossils. Most biometric studies of microfossils, however, have only measured test diameter or other linear components[1]. The tests of planktonic foraminifera exhibit a wide range of morphological traits, some of which are related to environmental conditions and others to the phylogenetic history of the taxon[1,2]. Mean test size or linear measurements of chambers and/or whole tests of fossil foraminifera can be used for palaeoecological interpretations from the morphological variations[3–10]. We report here that Fourier shape analysis could be an objective and unambiguous biometric method for determining the components which comprise the shape of foraminifera. Fourier shape analysis has been successfully applied to fossil ostracods[11,12], fossil bryozoans[13,14] and miospores[15]. In the present study, Fourier series shape analysis was performed on the planktonic foraminifera, *Globorotalia truncatulinoides*, from the southern Indian Ocean, to differentiate palaeoenvironmentally significant trends in the test shape of this species. Kennett[16] and Takayanagi *et al.*[17] have used linear test measurements to describe latitudinal gradients in the test morphology of *G. truncatulinoides*. Highly conical forms dominate in tropical waters, whereas more compressed, biconvex forms dominate in cool water.

Table 1 Core top locations used in the Fourier analysis of *Globorotalia truncatulinoides*

Core	Lat (°S)	Long (°E)
V20–175	22° 18′	68° 00′
RC11–145	25° 29′	110° 01′
E48–11A	29° 40′	97° 32′
E48–46A	31° 09′	83° 46′
E48–32A	32° 48′	83° 52′
E48–31A	34° 49′	84° 08′
E48–18	35° 26′	91° 53′

E48–23	39° 31′	83° 43′
E48–03	41° 01′	100° 00′
E50–03	42° 01′	100° 00′
E49–46A	44° 04′	100° 01′
E45–79	45° 03′	114° 22′
E45–77A	46° 26′	114° 25′
E49–42A	47° 20′	100° 00′

Closed-form Fourier series analysis is a mathematical expression of cosines used to describe any shape or any two-dimensional shape outline to a specified accuracy[18]. Fourier series both provides exact characterization of shape and separates the components of the whole form, enabling us to see how each component (harmonic) affects the total shape. Each harmonic is an independent and uncorrelated measure of a specific geometric contribution to the total shape[14,19]. The shape of each specimen is represented by a series of harmonics of the form: $Rn \cos(n\theta - \phi n)$, where Rn represents the amplitude of the nth harmonic, and the remainder concerns the phase angle of that harmonic. The set of harmonic amplitudes constitutes the 'harmonic amplitude spectrum' (Fig. 1*a*). The Fourier series is estimated for each planktonic foraminiferal projection from analysis of the coordinates of peripheral points with the origin at the centre of gravity of the foraminifera (see ref. 18). Each harmonic amplitude represents the relative contribution to the empirical shape of a characteristic shape component. For example, the amplitude of the second harmonic represents the contribution to the empirical shape of a 'figure eight' and is thus a measure of elongation. The third harmonic represents a trefoil, the fourth a quadrefoil, and so on. In general, the nth harmonic amplitude represents the shape contribution of an n-leaved clover[18]. The observed shape is thus partitioned into a series where gross shape (for example, elongation, and triangularity) is measured by the harmonic amplitudes of the lower harmonic orders, and increasingly fine-scaled surface sculpture is measured at higher orders.

Fourier analysis in closed form, given enough terms, has enough information to describe any shape completely. This is demonstrated in Fig. 2 by computing the Fourier series of amplitudes and phase angles for a given shape, and then using only the information contained in the Fourier series to reconstruct the shape. For example, in Fig. 2, composite shapes are formed for a specimen of *G. truncatulinoides* by the successive addition of the first 20 terms in the computed Fourier series until the original shape is accurately reproduced.

Table 3 Correlation coefficients from linear regression analyses

	Harmonic 2 (elongation)	Harmonic 3 (conical shape)	Surface temperature (°C)	Coiling % sinistral	Lat
Harmonic 2	1.00	−0.46	−0.70	0.87	0.76
Harmonic 3	−0.46	1.00	0.77	−0.42	−0.73
Temperature (°C)	−0.70	0.77	1.00	−0.76	−0.99
Coiling	0.87	−0.42	−0.76	1.00	0.81
Lat	0.76	−0.73	−0.99	0.81	1.00

Values are results from Fourier shape analysis of *G. truncatulinoides*.

The specimens of *G. truncatulinoides* used in this Fourier biometric study were removed from the surface sediment of 11 trigger cores and four piston cores from the southern Indian Ocean (lat 22–47° S) (Table 1). The principal oceanographic features of the surface waters in this region are the subtropical convergence (38–40° S) separating the subtropical and sub-Antarctic waters, and the polar front (48–50° S) separating sub-Antarctic and Antarctic waters. Both fronts are defined by strong salinity and temperature gradients[20]. Only samples which contained well preserved Recent or late Holocene foraminifera were chosen[21,22]. An aliquot was removed from each sample using an FB Dial microsplitter and ~35 foraminiferal specimens were selected from the 300–450 μm size fraction. A separate experiment was performed to monitor the effects of size on test shape[23]. The coiling direction of the assemblages varied from 100 to 6% sinistrally coiled. Fourier analysis was performed on the side view of all specimens. A normalization process in the Fourier series means that differences in size do not affect shape comparisons. The periphery of each foraminifera specimen was digitized as 48 equiangular coordinates and then converted to a Fourier series containing 20 harmonics. As seen in Fig. 2, the first few harmonics describe the gross shape while the higher-order harmonics refine the overall test shape. The result is a harmonic amplitude spectrum for each foraminiferal specimen with changes in shape reflected by changes in amplitude values. The amplitude spectrum for a sample comprises the primary data used for analysis (Fig. 1*a*). Each foraminifera in a sample contributes an amplitude value for every term of the series, that is the 20 terms calculated produce an $n \times 20$ matrix (n = number of foraminifera). Thus, for each term of the series, histograms (Fig. 3) can be constructed by plotting amplitude values (Fig. 1*a*) as a function of frequency of occurrence. The histograms are called shape frequency distributions. Each foraminifera can be described by 20 harmonic amplitude values, so each sample can be described by 20 shape frequency distributions (Fig. 3).

Thus, with the *G. truncatulinoides* data in this form, samples can be statistically compared and the specific harmonics responsible for shape differences can be determined. A χ^2 table was constructed for the first 10 harmonics as these harmonics capture the significant components of overall shape in this species (Fig. 1*b*, Table 2). According to Benzecri[24], χ^2 values can be used as indicators of dissimilarity. Plots of χ^2 values indicate that the 2nd, 3rd, 4th and 6th harmonics are statistically significant in describing the shape of this species (Fig. 1*b*). Because the harmonic amplitude spectra indicated that harmonics 2 and 3 contain the highest degrees of shape information (Fig. 1*a*), these are used in the following analysis.

Shape frequency diagrams for harmonics 2 (elongation) and harmonic 3 (triangularity or conical shape) show the amplitude distributions in all 15 samples ranked according to latitude (Fig. 3). The conical shape of *G. truncatulinoides* (harmonic 3) increases from the subpolar to subtropical water masses, in agreement with earlier biometric studies of this species[16,17]. The frequency distributions of harmonic 2 (elongation), however, do not show a clear relationship with latitude. Instead, elongation seems related to the coiling direction of the populations (Fig. 3). In populations dominated by sinistrally coiled individuals (80–100% sinistral) south of 31° S, the mean amplitude values do not change systematically and show no variation in the elongation of *G. truncatulinoides*. In populations with significant numbers of dextrally coiled individuals (42–94% dextral) (30–22° S), *G. truncatulinoides* becomes less elongated. This relationship has never before been observed in this species.

Linear regression analyses were performed on harmonics 2 and 3 in relation to coiling ratio and various environmental parameters (Table 3). Harmonic 2 is strongly correlated with coiling direction ($r = +0.87$). Elongation is also correlated with latitude and surface-water temperature but not at the level of significance as with coiling-direction preference. Harmonic 3, on the other hand, has its highest correlation with surface-water temperature ($r = 0.77$) and a poor correlation with coiling ($r = 0.42$). We interpret the correlation between triangularity and water temperature to be indicative of ecophenotypic variation, that is, environmental-induced variation. The elongation (harmonic 2) of *G. truncatulinoides* may reflect more phenotypic

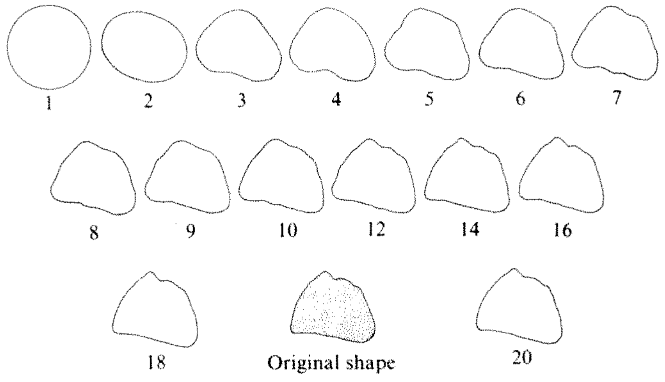

Fig. 2 Reproduction of the shape of *G. truncatulinoides* (from V20–175) by addition of successive harmonics. The original shape is reproduced using the first 20 harmonics.

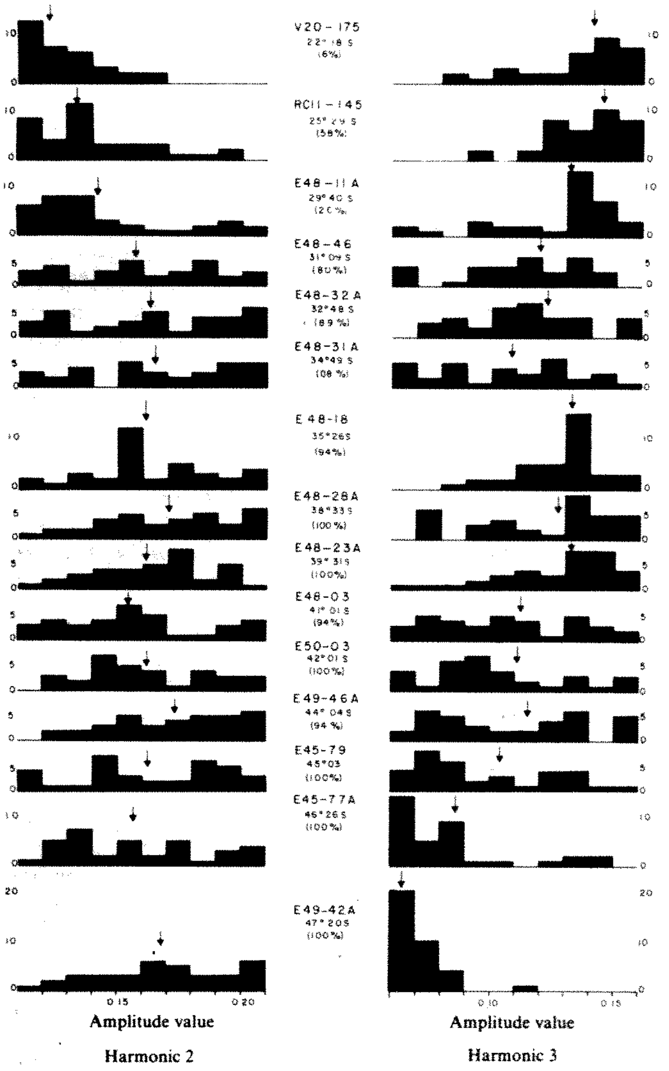

Fig. 3 Histogram plots of harmonic amplitude values for harmonic 2 (elongation) and harmonic 3 (triangularity/conical shape) in *G. truncatulinoides*. The histograms are ranked according to latitude and the per cent sinistrally coiled specimens in each sample is also shown. Arrows indicate the mean harmonic amplitude values in each sample.

variation (that is genetic and environmental influence) than ecophenotypic variation if we assume that coiling direction is genetically controlled. The factors governing coiling in foraminifera are not well understood[2]. However, the coiling of *G. truncatulinoides* in the southern Indian Ocean may reflect more of a clinal relationship rather than a strict environmental relationship, because this species remains dominantly sinistrally coiled across such an important oceanographical and biogeographical boundary as the subtropical convergence.

This study clearly illustrates that the conical shape of *G. truncatulinoides* varies as a function of water temperature and, as such, can be used as a palaeoceanographical index of water temperature in this region of the southern Indian Ocean. Current work uses the conicalness/ water temperature correlation to estimate water mass changes in the southern Indian Ocean sediments during the late Quaternary. The significance of the relationship between test elongation and coiling direction can only be resolved by studies of living plankton and laboratory-cultured specimens. We have demonstrated, however, that Fourier shape analysis is an accurate and quantitative method for rapid determination of the components of test shape in foraminifera. Because test shape may vary as a function of phylogenetic (evolutionary) affinities, environmental stress and ecophenotypic variation, we believe that Fourier shape analysis could be a powerful tool in morphometric studies of Cenozoic and late Mesozoic foraminifera.

We thank James P. Kennett for helpful criticism, Robert Ehrlich for helpful discussions, Cary Fico for his assistance with the Fourier software and Duane Eppler for use of his Drawshape program. Parental investment in male and female offspring in polygynous mammals

T. H. Clutton-Brock, S. D. Albon & F. E. Guinness

King's College Research Centre, Cambridge CB2 1ST, UK*

Two evolutionary theories predict how mammalian parents would be expected to allocate the resources at their disposal to their male and female progeny. Where reproductive success varies more widely among males than females and variation in success among adults is influenced by parental investment[1], parents would maximize their reproductive success by allocating a greater proportion of their resources to individual sons than to individual daughters[2–5]. However, because the benefits of producing offspring of one sex are inversely related to the total investment allocated to them, parents should, on average, divide their total investment equally between their male and female progeny, rearing fewer of whichever sex is individually more expensive to produce[6–10]. Here we examine the extent to which parental investment in red deer (*Cervus elaphus*) and other polygynous mammals matches these predictions. We conclude that, in several mammals, mothers invest more heavily in individual sons than daughters but that, contrary to prediction, there is no indication that fewer male offspring are reared in these species.

In most polygynous mammals, lifetime reproductive success probably varies more widely among males than females and is affected by maternal investment[1]. For example, in the red deer of the Isle of Rhum (Scotland), where hinds live for 12–14 yr, mating in October, giving birth in June and weaning their calves

Table 1 Birth sex ratios of calves born between 1970 and 1979 to different categories of red deer hinds

Age of mother (yr)	3	4	5–6	7–8	9–10	11–12	13+
% Males	52.6	59.7	56.0	58.3	53.8	58.8	69.0
n	38	67	109	84	65	57	29

Reproductive status in previous year	Failed to produce calf	Calf died within month of birth	Calf reared through first winter
% Males	59.3	60.3	56.4
n	59	68	218

Quality of home range	Superior	Inferior
% Males	56.0	57.1
n	168	98

For details of data collection and allocation see ref. 13.

approximately 6 months later[11–13], individual mothers rear from 0 to 12 calves surviving to 1 yr old during their lifetime[14]. In contrast, stags, which hold large harems of hinds during the mating season, father from 0 to >25 calves surviving to 1 yr during their lifetime[14,15]. In both sexes, reproductive success is probably affected by maternal investment during the growth period, but the relationship is particularly close among stags, where growth during the first year of life is related to adult body size and fighting ability[14].

In precisely these circumstances, mothers should maximize their reproductive success by investing more heavily in individual sons than daughters. Do they do so? One way they might achieve this would be to vary the sex ratio of their progeny according to their own body condition, producing relatively more male offspring when they were in good condition (and could afford to invest heavily) and relatively fewer males when in poor condition, perhaps by selectively aborting or resorbing male fetuses[2]. However, there is little evidence that factors which affect maternal condition in red deer have an important influence on birth sex ratios, which do not differ significantly between mothers of different ages, between those that have suffered the energetic strains of rearing a calf through the previous winter and those that have not done so, or between those occupying superior compared with inferior home ranges, although sample sizes are admittedly small (Table 1). Moreover, despite claims to the contrary[2], evidence for an association between maternal condition and birth sex ratio in other mammals is ambiguous[16,17]: some studies have found a tendency for females in good condition to produce relatively more males[18–23], while others have found the reverse[24–27].

An alternative possibility is that the sex ratio of progeny does not vary with maternal condition but that mothers transfer a greater proportion of their body reserves to sons than to daughters[3–5]. Several lines of evidence suggest that this is the case in red deer: compared with females, male calves have significantly longer gestation lengths (236.1 days versus 234.2 days, $P < 0.05$), heavier birth weights (6.72 kg versus 6.23 kg, $P < 0.002$) and, by analogy with other studies of dimorphic deer[28–31], probably gain weight faster. Observations show that male calves suck from their mothers more frequently (5.1 ($n = 17$) versus 2.6 ($n = 10$) daily suckling bouts: $P < 0.05$) and there is a trend for the duration of suckling bouts involving male calves to be longer than those involving females (Fig. 1). Evidence that the costs of rearing male calves exceed those of rearing females are provided by comparisons of the subsequent reproductive performance of mothers: between 1971 and 1980, hinds that had reared a male calf through the previous winter were less likely to produce a calf than those which had reared a female (Wilcoxon matched pairs signed ranks test across years, $T = 11$, P (one-tailed) $= 0.05$). In addition, hinds calved on average 11 days later following winters when they had supported a male calf compared with those when they had supported a female (Wilcoxon matched pairs signed ranks test across individual hinds, $z = 2.66$, $n = 32$, $P < 0.01$). As calving date is known to be related to body condition in red deer[32,33] and late calving increases the chances that calves will die during their first winter[34], this provides additional evidence of the increased costs of rearing male calves.

Similar data for other species are uncommon. However, detailed studies of maternal investment in elephant seals (*Mirounga angustirostris*) have found that male pups are weaned later than females[3] and, age for age, tend to be larger, while in a variety of other polygynous mammals, males commonly show longer gestation lengths, heavier birth weights, faster growth rates and greater food requirements than females[4,35–42]. There is also some evidence that the energetic costs of producing and rearing males may exceed those of producing and rearing females: in sheep, lambs born co-twin with males are lighter than those born co-twin with females[43] and, in Indian cattle, two studies have found a (non-significant) tendency for the next conception to be delayed longer after a bull calf has been produced[44,45]. However, a contrasting situation is found in colonies of macaques, where dominant females who have produced daughters are significantly less likely to produce another offspring in the next season than those that have reared sons[46]. One possible explanation is that, in this case, parental investment may have a greater effect on the breeding success of daughters and less on that of the sons because daughters generally inherit their mother's dominance rank while male body size may have little effect on competitive success[47].

In species where sons cost more to produce and rear than daughters, the sex ratio of progeny should be biased against males by the age at which parental investment is terminated[8]. However, sex ratios at weaning (as well as at birth) are often male-biased in polygynous species[47]. In particular, slightly male-biased weaning ratios occur in both species for which there is good evidence of increased investment in males before weaning (Table 2).

There are at least two ways in which these results could be reconciled with current theory: (1) Parental investment in daughters (but not sons) continues after weaning, balancing heavier pre-weaning investment in sons. This may be the case in a number of species where daughters adopt territories or home ranges overlapping those of their mothers while sons disperse[4,49]: if the presence of resident daughters reduces the amount of food available to the mother and her subsequent offspring, maternal tolerance of mature offspring should be regarded as a continuation of parental investment. However, this argument is unlikely to explain the existence of male-biased weaning ratios in either red deer or elephant seals. In the latter, both sexes of offspring are abandoned by their mothers on the breeding beaches and there is no evidence of social bonds between mothers and their weaned offspring[3,48]. In the former, toleration of mature daughters is unlikely to represent an important form of investment since unrelated hinds occupy overlapping home ranges, so that if a mother were to exclude her daughters from her range, this would have little effect on the resources available to her. (2) Alternatively, the primary sex

Table 2 Sex ratios at birth and after weaning in two polygynous mammals

	Sex ratio at:	
	Birth	12 months (~6 months post-weaning)
Red deer[14] (*Cervus elaphus*)		
% males	57.0	53.3
n	423	296
	Birth	1 month (shortly after weaning)

ratio may be fixed at unity. In this case, selection for increased investment in individual sons could prefer parents that allocated a greater proportion of their total investment to male progeny[5]. However, evidence that sex ratios can be modified argues against this theory[47].

Thus, the available data suggest that polygynous mammals commonly invest more in individual sons than daughters and that this tendency may be associated with a greater total investment in male than female progeny. Why total investment is not equalized between males and females remains an anomaly.

Photon-like signals following weak rhodopsin bleaches

J. F. Ashmore* & G. Falk

Department of Biophysics, University College London,
Gower Street, London WC1E 6BT, UK

The rod visual system in its dark-adapted state behaves as a near-ideal light detector[1]. Psychophysical studies on the reliability of light detection in man[2,3], analysis of the dark noise in rod bipolar cells[4] and observation of photon-like events in rods[5] in the dark suggest that the visual pigment, rhodopsin, is very stable against spontaneous isomerization. When a light which bleaches a small fraction of the rhodopsin is extinguished, the visual threshold may be increased by several orders of magnitude. The eye is then 'light-adapted' and the process (or processes) by which the sensitivity returns constitutes dark adaptation. We report here that bleaching of a small fraction of the rhodopsin produces a prolonged increase in the noise observed in the dark in rod bipolar cells of the dogfish retina. The associated noise events are similar to those produced by the absorption of light quanta and presumably have their origin in the rods which transmit their signals to the bipolar cells. This increased noise after bleaching would decrease the reliability of detection of light quanta and contribute to the elevation of visual threshold.

Responses to light were recorded intracellularly in rod bipolar cells in the initially dark-adapted, hemisected eyecup of the dogfish, *Scyliorhinus canicula*. The bipolar cells studied here were those which in the dark-adapted state depolarized in response to light delivered as full-field illumination. The methods of recording, identification of cells and estimation of irradiance and bleaching have been described previously[6,7]. Because of the high voltage gain in signal transmission from rods to bipolar cells[7], we could study responses to light and changes in voltage noise during and following light which bleached fractions of between 10^{-9} and 10^{-3} of the rhodopsin.

Figure 1*a* shows the noise increase during dim light, bleaching, on average, about one rhodopsin molecule per rod in 50 s. The noise at higher gain and faster sweep during the period indicated by arrows is shown as the middle record of Fig. 2*a*. Power-spectral analysis of this noise suggests that most of the noise arises from random absorption of light quanta by the rods within the receptive field of the bipolar cell ('photon noise')[4]. When the dim light was switched off, there was no detectable change in the dark noise.

Figure 1*b* shows the response of the same cell to light 4,000 times brighter, during which time the dark noise was suppressed

0028-0836/81/060489—03$01.00

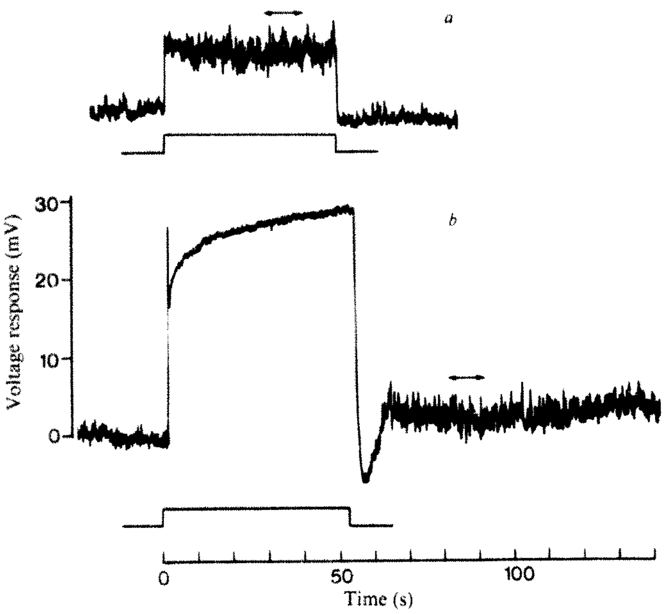

Fig. 1 Voltage responses of a rod bipolar cell to steps of light, accompanied by an increase of noise during very dim illumination (*a*) and a prolonged increase of noise following a bleach (*b*); both records are from the same cell. The duration of the light stimulus is indicated under each record, which in all experiments was delivered as full-field illumination. *a*, The total bleach during the step was 1.1 Rh**, at a rate of 0.022 Rh** s^{-1}, where Rh** signifies a rhodopsin molecule bleached per rod[7]. The voltage noise variance in the dark (corrected for noise due to the electrode determined with the electrode in the cell in a bright light) was 0.20 mV^2; the noise variance during illumination was 0.95 mV^2. *b*, The response to a step of light with a total bleach of 4,300 Rh** at a rate of 79 Rh** s^{-1}. Assuming 3×10^8 rhodopsin molecules per rod (ref. 4), this corresponds to a 0.0014% bleach. Note that the noise increased with a delay following the light step. The noise variance following the bleach (during the period indicated by arrows) was 1.0 mV^2. Potential of the cell in the dark, −56 mV; maximum response to a bright flash, 30 mV; flash sensitivity 1,860 mV per Rh** (ref. 7); step sensitivity, 645 mV s per Rh** (ref. 7). Temperature, 17.5 °C. An increase in noise was observed in 7 out of 10 cells following light steps producing bleaches of 10^{-6}–10^{-5} of the rhodopsin. Low sensitivity and noise in the recording system may have obscured the effect in some cells.

and then increased with a delay of about 10 s when the light was switched off. Several features of Fig. 1*b* require comment. The non-steady depolarization during light may be due to a bipolar cell membrane non-linearity, while the slow, upward creep of the depolarization during steady light may indicate a slow inactivation of potassium conductance. Although this membrane non-linearity may contribute to a decrease in noise during light which produced response saturation, the decrease in noise can be shown to be due mainly to the non-linear relation between light intensity and depolarization. Only in the linear region of response does photon noise variance increase in proportion to the mean depolarization. As saturation of the response is approached, the noise variance declines to zero. In Fig. 1*b*, the light bleached 4,300 rhodopsin molecules per rod or about 0.0014%. When it was turned off, there was a transient hyperpolarization followed by a prolonged after-depolarization, accompanied by an increase in noise variance. The after-depolarization reached its peak value of 5 mV and the noise variance increased to six times its dark value 10 s after the light was turned off. The noise variance returned to its initial dark value in about 3 min. The post-bleach noise during the interval indicated by arrows in Fig. 1*b* is shown at an expanded sweep and amplification in Fig. 2*a* (bottom record). Clearly, the character of the post-bleach noise is similar to that during dim light and this similarity to photon noise was confirmed by their power spectra.

The effect of light bleaching 0.17% rhodopsin is illustrated in Fig. 3, recorded in another cell. As in the cell of Fig. 1, the noise increased after a delay and the increased noise was associated with a depolarization lasting about 10 min. The noise recorded about 4.5 min after the light was switched off is shown at an expanded sweep and higher gain as the bottom record of Fig. 2*b*. The post-bleach noise had characteristics similar to the noise recorded during dim light in the same cell (the middle record of Fig. 2*b*). The power spectra of the noise recorded at different times during the period following the bleaching were all indistinguishable (except for a power-scale factor) and were the same as during dim light. Because the events giving rise to the increased noise are like photon events, we presume that they arise in the rods. Recently, Lamb has observed increased fluctuations in single rods, resembling light quantal events, which are induced by bleaching[8].

We can estimate the equivalent rate of photon-like events in the rod in the following way. For a linear shot process model for

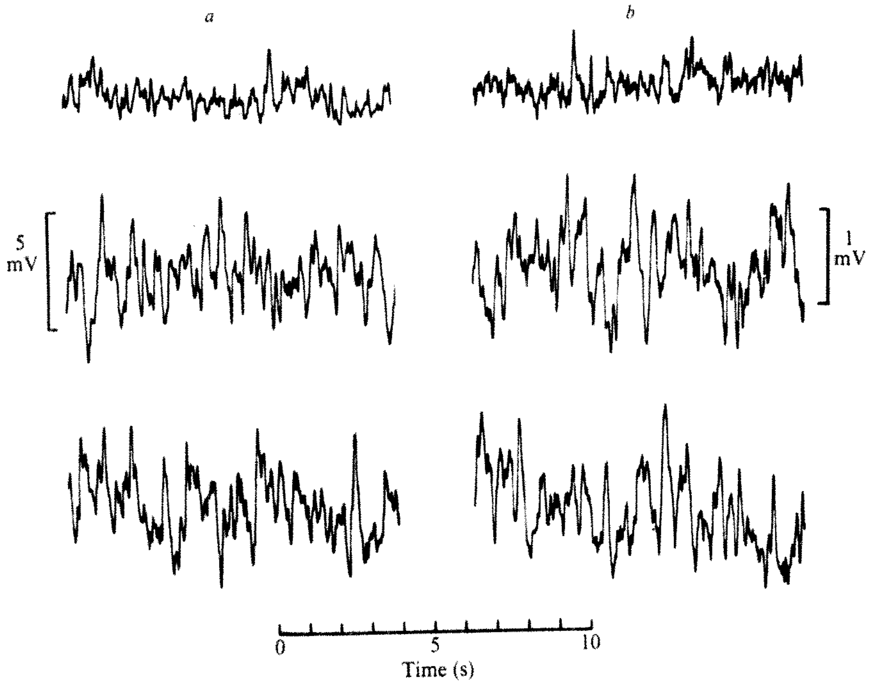

Fig. 2 Voltage noise in bipolar cells in darknesss (upper row), during dim illumination (middle row) and following bleaches (bottom row), at higher gain and sweep speeds. *a*, Records from the cell illustrated in Fig. 1. The middle and lower records are from the intervals indicated by the arrows in Fig. 1*a* and Fig. 1*b*, respectively. *b*, Records from the cell illustrated in Fig. 3. The middle record shows the noise during dim illumination at an intensity of 0.026 Rh** s^{-1} (~1 molecules bleached per 40 rods per s), which depolarized the cell by 2.7 mV. The bottom record shows the noise following a 0.17% bleach, corresponding to the interval arrowed in Fig. 3.

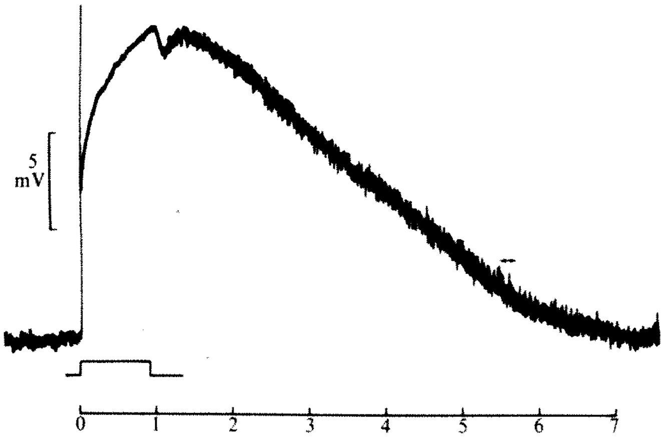

Fig. 3 Prolonged increase of noise in a rod bipolar cell following a pigment bleach of 0.17%. The rate of bleaching was 9.4×10^3 Rh** s^{-1} so that the total bleach was 5.2×10^5 Rh**. The noise variance in the dark (corrected for electrode noise) was 0.01 mV^2. Approximately 4.5 min after the bleaching light was turned off, the noise variance was 0.074 mV^2. The cell was held for 15 min following the bleach during which time the potential and noise returned to their pre-bleach values. Potential of the cell in the dark, −29 mV; maximum response to light, 17 mV; flash sensitivity, 320 mV per Rh**; step sensitivity, 120 mV s per Rh**. Temperature, 17 °C.

events seen in the bipolar cell, the equivalent rate per rod would be

$$\lambda = V/(aN\tau)$$

where V is the mean depolarization, a is the amplitude of the shot event in the bipolar cell, N is the number of rods in its pool and τ is the integration time. (If, like the effect of light, the relation between mean depolarization and the rate of events is a rectangular hyperbola, λ would need to be corrected by a factor, $\{1-(V/V_{\max})\}^{-1}$, where $V_{\max}$ is the maximum response.) The product, $aN\tau$, is the step sensitivity and was determined in the well dark-adapted state as the slope of the relation between steady-state depolarization and light intensity in the linear range of response[7]. For the cell of Fig. 1, the peak rate of events, following a bleach of 0.0014% giving a 5-mV depolarization, was 0.01 per s per rod. This was 10.3 times the initial dark-adapted rate of equivalent events, determined in the way described by Ashmore and Falk[4]. Another bleaching exposure in the same experiment, bleaching 1/15th of that illustrated in Fig. 1*b*, resulted in an increased post-bleach noise variance of 70% greater than that of the initial well dark-adapted state. For the bleach of 0.17% illustrated in Fig. 3, the peak post-bleach rate (corrected for non-linear summation) amounted to 1.8 events per s per rod, which was 1,500 times the initial dark-adapted rate. These results suggest that the peak extra rate of noise events induced by bleaching is proportional to the amount of rhodopsin bleached, at least for small bleaches. Quantitatively,

$$\frac{\lambda_B}{\lambda_D} = \alpha R$$

where λ_B is the peak rate of additional events induced by bleaching, λ_D is the dark-adapted rate of equivalent events, R is the number of rhodopsin molecules bleached per rod and α the constant of proportionality amounting to $2\text{–}3\times 10^{-3}$ per Rh**, where Rh** denotes one rhodopsin molecule bleached per rod.

These relatively weak bleaches give rise to an increased rate of spontaneous events lasting many minutes and the question arises of how the total number of extra events is related to the number of rhodopsin molecules bleached. Integration of the increased rate over time indicates that bleaching of a rhodopsin molecule has only a small probability, less than 0.001, of inducing an event. It is unlikely that this low probability is the result of regeneration of rhodopsin which in the elasmobranch eye[9] is very much slower than the rate of recovery of the noise to its dark-adapted value.

The present results confirm Rushton's[10] and Barlow's[11] conjecture that bleaching of rhodopsin in rods induces signals which constitute a background of 'dark light' or noise which would raise the threshold for detection of a light stimulus. Rushton[10] found that the equivalent background light increased exponentially with the fraction of rhodopsin in the bleached state. Extrapolated to weak bleaches, the exponential relationship becomes one of linearity. However, note that the value of α reported here for weak bleaches is several orders of magnitude greater than that inferred from the psychophysical measurements[10,11] with strong bleaches. Likewise, the rise in visual threshold in man following weak bleaches[12,13] is also greater than that predicted from near-total bleaching.

An increase in the rate of occurrence of discrete events following bleaching may be general among photoreceptors for it has been reported to occur in the photoreceptors of invertebrates[14,15]. We cannot decide yet whether the increased rate of spontaneous events in rods following absorption of light quanta is due to an increased rate of thermal isomerization of rhodopsin or to a link with some reaction involved in phototransduction.

The work was supported by an MRC project grant.

Isolation of the phagocytosis-inducing IgG-binding antigen on senescent somatic cells

Marguerite M. B. Kay

Laboratory of Molecular and Clinical Immunology, Geriatric Research, Education and Clinical Center, Veterans Association Wadsworth Medical Center, and the Department of Medicine, University of California, Los Angeles, California 90073

To remove senescent red blood cells (RBCs) from the circulation, macrophages must distinguish them from mature RBCs. That is achieved by a specific recognition system[1,2]. An antigen that develops on the surface of a senescing RBC is recognized and bound by the Fab region[1] of an IgG autoantibody in the serum[2]. Subsequently the Fc region of the autoantibody is recognized and bound by a macrophage[3], which proceeds to phagocytose the RBC. The antigenic molecule can be extracted from senescent but not young RBCs with Triton X-100 (ref. 4), although 10–30% as much antigen can be extracted from middle-aged as from senescent RBCs[4]. I have now used IgG autoantibodies eluted from senescent RBCs to isolate and purify the IgG-binding antigen on senescent RBCs, and to detect the antigen on other somatic cells. The antigen is a ≃62,000-M_r protein which is present on stored platelets, lymphocytes and neutrophils, and on cultured human adult liver and embryonic kidney cells, as well as senescent RBCs.

0028-0836/81/060491—04$01.00

IgG was eluted from human senescent RBCs[5], by the method of Kochwa and Rosenfield[6] (for details see Fig. 1). The IgG-containing eluates of senescent RBCs from 50 l of blood were pooled, and IgG isolated from the eluates by affinity chromatography with Protein A–Sepharose 4B (Pharmacia)[1].

Glycine–HCl eluates from the affinity column contained IgG and an additional peptide that was not part of the IgG molecule, as determined by polyacrylamide gel electrophoresis on gradient gels (Fig. 1). This peptide has a M_r of ≈62,000 and migrates between IgG heavy chain and its dimer on polyacrylamide gels and is not present in IgG isolated from serum with Protein A columns (Fig. 1). This peptide stains with dansyl hydrazine and thus is probably a sialoglycopeptide (not shown). Elution of the ≈62,000-M_r peptide from Protein A columns along with the IgG obtained from senescent cells suggests that it may be the senescent cell antigen for IgG autoantibodies.

As the peptide that co-purifies with the IgG eluted from senescent cells seems to be a sialoglycopeptide[1,2,4], I attempted to isolate the senescent cell antigen for IgG autoantibodies from preparations of RBC sialoglycoproteins. IgG eluted from senescent cells and purified by affinity chromatography with

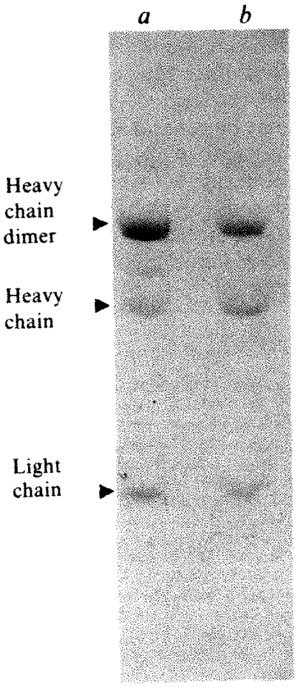

Fig. 1 Polyacrylamide gel electrophoresis of IgG eluted from senescent RBCs and purified with Protein A affinity columns. *a*, IgG eluted from senescent RBCs and purified with a Protein A–Sepharose column; *b*, IgG isolated from normal human serum by ion-exchange chromatography followed by Protein A–Sepharose chromatography. Blood was obtained from 250 healthy individuals between the ages of 21 and 35 yr, and was processed the same day that it was obtained. The blood was centrifuged for 15 min at 2,000*g* and the serum and white cells removed. RBCs were separated into populations of different ages by centrifugation[4,5,8], and young RBCs were removed. The remaining RBCs were washed three times with 50–100 vol of Dulbecco's phosphate-buffered saline (PBS), *p*H 7.4. IgG was eluted as described previously[1,6]. Briefly, RBC membranes (ghosts) were prepared by digitonin lysis, washed three times with PBS, and IgG eluted with 0.1 M glycine–HCl buffer, *p*H 2.3. Eluates were neutralized with 1 M NaOH and concentrated to 0.25–1.00 ml using an Amicon Diaflow with a PM 10 filter. Solid material was removed by centrifugation at 27,000*g*. Samples were stored at −80 °C until use. They were then thawed, pooled and incubated with Protein A–Sepharose 4B for 30–60 min at 37 °C and 24–48 h at 4 °C. The Protein A–Sepharose was poured into a 12-ml column prepared from a syringe and washed with 100 vol of PBS, then 100 vol of 10 × PBS followed by 100 vol of PBS. IgG was eluted with 2 vol of glycine–HCl buffer, *p*H 2.3, neutralized with 1 M NaOH and dialysed against distilled water (*a*). The amount of IgG obtained was 7.42 mg. Polyacrylamide gel electrophoresis was performed with 2.7-mm thick gradient slab gels containing 4–30% acrylamide. The buffer system of Laemmli was used[9]. Gels were stained for glycoproteins with dansyl hydrazine following the method of Eckhardt *et al.*[10] with the modifications of Lutz *et al.*[11]. Proteins were stained with Coomassie blue (shown here). Serum IgG was isolated by ion-exchange chromatrography on DEAE-cellulose (DE 52, Whatman)[1,2] followed by incubation with Protein A–Sepharose as described above (*b*).

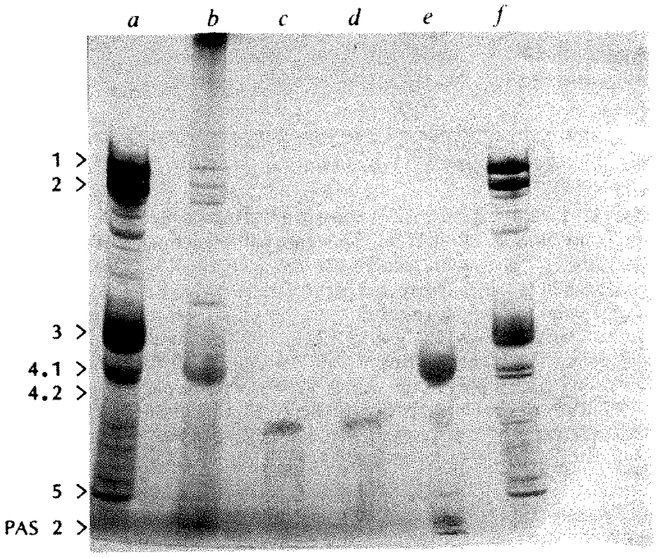

Fig. 2 Isolation of the antigen for IgG autoantibodies from human RBC sialoglycoproteins with affinity columns prepared from the IgG eluted from senescent RBCs. *a*, RBC ghost; *b*, Triton X-100 extract of ghosts; *c*, 62,000-M_r peptide isolated with senescent cell IgG affinity column from Triton X-100 extract; *d*, 62,000-M_r peptide isolated with the senescent cell IgG affinity column from lithium diiodosalicylate (LIS) extract of ghosts; *e*, LIS extract of ghosts; *f*, RBC ghost. Blood was obtained from healthy donors 21–30 yr old. Donor cells were typed for 27 known RBC blood group antigens, including ABO, Rh, MN, Ss̄, Duffy, Kell and Kidd. Donors did not have detectable autoantibodies to RBCs or antibodies to any known blood group antigen, as determined by the Immunohematology Laboratory, American Red Cross, nor did they have antibodies to nuclei, DNA, mitochondria, parietal cells or smooth muscle[12]. All blood was processed the same day that it was obtained. RBCs from 500 ml of human blood were depleted of white cells and young RBCs by centrifugation on self-forming Percoll gradients[4,8]. RBCs were washed three times in 50–100 vol of PBS with 75 μg ml^{-1} phenylmethylsulphonylfluoride (PMSF) at 4 °C. Right-side out RBC membranes were prepared by hypotonic lysis in 5 mM sodium phosphate buffer, *p*H 7.5, containing 50 μg ml^{-1} PMSF[11]. After five washes in 100 vol of the same buffer (*a* and *f*), ghosts were resuspended in a solution of 0.3 M LIS[7] or 1.0% Triton X-100 and partitioned in a phenol–water mixture according to the procedure of Marchesi and Andrews[7]. The water phase was dialysed extensively against distilled water at 4 °C and then lyophilized (*b*). The lyophilized material extracted with LIS was resuspended in 5 mM phosphate buffer and extracted with chloroform–methanol (2 : 1)[13]. The aqueous phase was dialysed against distilled water (*e*) and processed with the senescent cell IgG affinity column. Triton X-100 extracts were processed with the affinity column without chloroform–methanol treatment. The affinity column was washed with 100 vol of the following: PBS with 50 μg ml^{-1} PMSF, 10 × PBS, 5 mM phosphate buffer, and then PBS with 50 μg ml^{-1} PMSF. Material bound by the column was eluted with 15 vol of glycine–HCl, *p*H 2.3, neutralized, dialysed against distilled water at 4 °C and lyophilized (*c* and *d*). Electrophoresis was performed using gradient gels containing from 2 to 16% acrylamide and the buffer system of Fairbanks *et al.*[14], except that 0.2% SDS was used. Sample buffer: 10 mM Tris-HCl, *p*H 8.0, containing 1 mM Na EDTA, 40 mM dithiothreitol, 5% glycerol, 0.2% SDS and bromophenol blue. All of the proteins extracted with LIS stained with dansyl hydrazine. The photograph shows the gel stained with Coomassie blue. PAS, periodic acid-Schiff: designation for RBC sialoglycoproteins.

Protein A was conjugated to cyanogen bromide-activated Sepharose 4B (Pharmacia). Columns were prepared and washed with 15 vol of glycine–HCl buffer, *p*H 2.3, to break the bond between the insolubilized IgG and its senescent cell antigen. After neutralization with NaOH, preparations of pure RBC membrane sialoglycoproteins, obtained by extraction with lithium diiodosalicylate and partition in a phenol–water mixture according to the procedure of Marchesi and Andrews[7] (see Fig. 2 for details), were processed with the senescent cell IgG column. After extensive washing, the material on the column was eluted with glycine–HCl buffer, *p*H 2.3, neutralized, dialysed against deionized, distilled water at 4 °C, lyophilized and analysed by gel electrophoresis. Both dansyl hydrazine and Coomassie blue stains of the gels revealed a single band migrating at a M_r of ≈62,000 which appears below band 4.2 in Fig. 2. When this experiment was repeated using 1% Triton X-100 extracts of RBC membranes[8], the same results were obtained. A single peptide of $M_r \approx 62,000$ was observed on gels of the material eluted from the senescent cell IgG affinity column (Fig. 2). These experiments indicate that the ≈62,000-M_r peptide carries the antigenic determinants recognized by IgG obtained from freshly isolated senescent cells.

To confirm this finding, an erythrophagocytosis inhibition assay was performed[1,2]. IgG was absorbed by incubation at 37 °C for 30 min with either the 62,000-M_r peptide eluted from senescent cell IgG affinity columns or with the sialoglycoprotein mixture that had not bound to these affinity columns. The absorbed IgG was then incubated with stored RBCs[4] for 30 min at 37 °C because stored RBCs have the exposed receptor[1,2,4]. The RBCs were washed three times and incubated with autologous macrophage cultures[1,2,4]. RBCs incubated with the IgG absorbed with excess 62,000-M_r peptide were not phagocytosed (0% phagocytosis), indicating that no free antigen-binding IgG remained in solution. In contrast, 52±3% (±s.d.) of the RBCs incubated with IgG absorbed with the eluate that was not bound by senescent cell affinity columns were phagocytosed, indicating the presence of free antigen-binding IgG. The same amount of phagocytosis was observed when stored RBCs were incubated with IgG that was not absorbed (55±6%). Thus, the 62,000-M_r peptide, but not the remaining sialoglycoprotein mixture from which it was isolated, abolishes the phagocytosis-inducing ability of IgG. This indicates that the 62,000-M_r peptide is the antigen which emerges on the surface membrane of cells as they senesce.

Table 1 Inhibition of the phagocytosis-inducing ability of IgG autoantibody eluted from senescent RBC by previous absorption with *a*, stored platelets, lymphocytes or neutrophils, and *b*, human adult liver cells or human embryonic kidney cells

	Cell type used for absorption	% Phagocytosis (mean±s.d.)
a	None	37±4
	Platelets	2±2
	Lymphocytes	0
	Neutrophils	0
b	None	38±6
	Liver	0
	Kidney	7±7

In *a*, macrophages, lymphocytes, neutrophils and platelets were isolated by centrifugation on Percoll gradients[4]. Macrophages were cultured, and lymphocytes and platelets were stored in Alpha minimal essential medium with 10% fetal calf serum (FCS) at 4 °C (refs 2, 4). Citrate phosphate–dextrose solution was added to the platelet suspension to prevent activation. The specific IgG autoantibody eluted from senescent cells (6 μg) was added to 1-ml suspensions of ≈2×10^7 lymphocytes or 1×10^8 platelets and incubated for 30 min at 37 °C and 30 min at 24 °C (refs 1, 2, 4). Positive controls consisted of autoantibody incubated with medium only. Cells were removed by centrifugation and the supernatant containing the remaining antibody was added to 5×10^8 stored RBCs. RBCs were incubated for 15 min at 37 °C and 1.5 h at 24 °C. Aliquots of each sample (0.1 ml) containing 5×10^7 RBCs were added to macrophage cultures. Phagocytosis was determined as described previously[1,2,4,8]. Data are presented as the mean±1 s.d. The amount of IgG antibody used for absorption and the number of cells used were based on preliminary dose–response experiments. The phagocytosis-inducing ability of the senescent cell IgG could not be absorbed with freshly isolated young RBCs (43±9% phagocytosis) but was abolished by absorption with stored RBCs (0% phagocytosis). Data are presented as the mean±s.d. In *b*, human adult liver and human embryonic kidney (Chang and Flow 4000 respectively, Flow) cells were stored in liquid nitrogen, thawed and grown in tissue culture for 7 days before use. The media were changed 2 days after initiation of culture. The less viable non-adherent cells were collected by centrifugation and resuspended in 1 ml of Alpha minimum essential medium containing 10% FCS[4]. IgG eluted from senescent cells (3 μg) was incubated with 2.1×10^6 liver cells (57% did not exclude Trypan blue) or 5×10^6 kidney cells (82% did not exclude Trypan blue) for 20 min at 37 °C and 2 h at 24 °C. Cells were removed by centrifugation, and the supernatant incubated with stored RBCs. The phagocytosis inhibition assay was performed as described in the text.

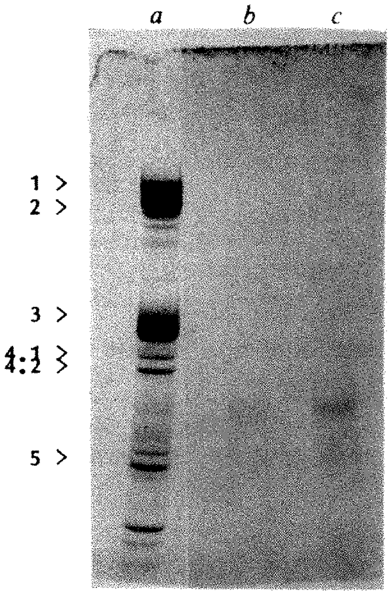

Fig. 3 Isolation of the antigen for IgG autoantibodies from human lymphocyte sialoglycoproteins with affinity columns prepared from the IgG eluted from senescent RBCs. *a*, RBC ghost; *b*, 62,000-M_r peptide isolated with the senescent cell IgG affinity column from LIS extract of RBC ghost; *c*, 62,000-M_r peptide isolated with the senescent RBC IgG column from LIS extract of lymphocyte membranes. Lymphocytes (8×10^8) were isolated from 500 ml of blood by centrifugation on Percoll gradients[4]. After three washes, membranes were prepared by hypotonic lysis in 5 mM NaPO$_4$ and 1 mM EDTA, *p*H 7.6 (ref. 15). Membrane suspensions were centrifuged at 248*g* to remove large particles. The supernatant containing the membranes was centrifuged at 27,000*g*. Membranes were washed three times in 100 vol of the same buffer, extracted with LIS and partitioned in a phenol–water mixture as described for RBCs in Fig. 2 legend. The aqueous phase was dialysed against distilled water and processed with the senescent RBC IgG affinity column.

Other somatic cells were then examined for the presence of the antigen which appears on senescent RBCs. Macrophages, lymphocytes, platelets and neutrophils were isolated by centrifugation on Percoll density gradients[4,9]. Cells were stored at 4 °C for 48 h. They were then washed and incubated with the autoantibody eluted from senescent cells (Table 1). Cells were removed by centrifugation and the supernatants containing any remaining IgG were incubated with stored RBCs. Stored RBCs were washed and incubated with macrophages. The phagocytosis-inducing ability of the autoantibody eluted from senescent cells was absorbed by stored lymphocytes, neutrophils and platelets (Table 1*a*).

Human adult liver cells and human embryonic kidney cells, grown in culture, were also examined for presence of the antigen. The less viable cells which were no longer adherent were collected from culture supernatants by centrifugation (Table 1*b*). Absorption of the IgG eluted from senescent RBCs with both liver and embryonic kidney cells abolished its phagocytosis-inducing ability (Table 1*b*).

As the results of the phagocytosis inhibition assay experiments indicated that the antigen that appears on senescent RBCs also emerges on other somatic cells, I attempted to isolate the antigen from lymphocytes. Sialoglycoprotein mixtures were prepared from lymphocyte membranes in the same manner as described for RBCs (for details, see Fig. 3). Lymphocyte sialoglycoprotein mixtures were processed with the senescent RBC IgG affinity column. Gel electrophoresis of material eluted from the column with glycine–HCl buffer revealed a band migrating at a M_r of ≃62,000, at the same position as the antigen isolated from senescent RBC (Fig. 3). This finding confirms the results obtained with the phagocytosis inhibition assay, indicating that the antigen which appears on senescent RBC also appears on other somatic cells.

Emergence of the ≃62,000-M_r protein initiates binding of IgG autoantibodies *in situ* and phagocytosis of senescent cells by mononuclear phagocytes. This antigen is present on stored lymphocytes, platelets, and neutrophils, and on cultured liver and kidney cells. Therefore, the immunological mechanism[2] for removing senescent and damaged red cells may be a general physiological process for removing somatic cells, at least in mammals.

I thank Drs John Cook, Takashi Makinodan and Andrew Saxon for reviewing the manuscript, and Dr Moses Schanfield for advice and for providing blood-typing reagents, typing donor RBCs and screening donors for anti-RBC antibodies. This work was supported by a NIH grant. Workspace was provided by the Research Service, Wadsworth Medical Center.

Helsinki, Haarmaninkatu 3, SF-00290 Helsinki 29, Finland

The thymus has a central role in directing the maturation and differentiation of T cells[1]. These processes involve movement of cells of haematopoietic origin through the thymus and are supposed to require intimate physical contact between T lymphocytes and cells of the thymic epithelium. Cytotoxic T cells (CTLs) induced by virus-infected or hapten-modified autologous cells exhibit dual specificity: for the products of the self major histocompatibility complex (MHC, H–2 in the mouse) and for the foreign antigen[2–5]. It has been proposed that 'self' specificity of MHC-restricted CTLs is determined by the MHC-encoded antigens expressed on the surface of thymic epithelial cells[6]. We show here that the differentiation of MHC-restricted CTLs can take place without thymic influence. In these experiments, self-MHC-restricted CTLs differentiate from spleen cells of *nu/nu* mice which lack thymuses after stimulation with 2,4,6-trinitrophenyl (TNP)-coupled autologous cells in the presence of T-cell growth factor.

Spleen cells of C57BL/6 *nu*/+ (*nu*/+) (H–2^b) and C57BL/6 *nu/nu* (*nu/nu*) mice were stimulated with TNP-coupled autologous cells *in vitro*. Cells were collected 5 days after stimulation and tested for lytic activity and specificity. An H–2-restricted cytotoxic T-cell response was generated from the cells of *nu*/+ mice, whereas *nu/nu* mice did not respond to the antigen (Table 1). However, when T-cell growth factor (TCGF) (Table 1) was added to the cultures, *nu/nu* cells responded to TNP-derivatized autologous cells. The cytotoxic cells killed preferentially TNP-derivatized autologous cells; TNP-coupled allogeneic cells (B10.BR, H–2^k) were killed to a lesser extent. The level of the cross-reaction was comparable with the cross-reaction by effector cells of *nu*/+ origin. The specificity of the population reacting with TNP-coupled autologous cells was further characterized by nonradiolabelled target-cell inhibition. The results presented in Fig. 1*a* show that the population exhibits a strict specificity. The specificity is restricted to both the self-MHC antigens and to the hapten: autologous cells derivatized with 4-hydroxy-5-iodo-3-nitrophenyl (NIP) or allogeneic cells derivatized with TNP did not compete with TNP-derivatized autologous target cells. Cytotoxic T cells generated in secondary cultures showed the same specificity (Fig. 1*b*). The *nu/nu* effector cells lysing TNP-modified autologous target cells specifically were characterized with respect to the expression of Thy-1 antigen in complement-dependent cytotoxic assay by using an antibody to Thy-1.2 antigen (Table 2). Anti-Thy-1.2 antibody and complement treatment of the effector-cell populations abolished the killer activity demonstrating that these cytotoxic cells were T lymphocytes.

The existence of cytotoxic cells in *nu/nu* mice has been observed previously[7]. The cytotoxic activity was mediated by natural killer (NK) cells, which are known to be Thy-1 negative; their specificity does not show restriction to MHC and their activity is usually determined in a 24-h cytotoxicity assay[8]. The cytotoxic cells induced by TNP-modified autologous cells in the presence of TCGF show all the characteristics of CTLs. They carry Thy-1 antigen, their specificity is restricted to the self-MHC structures and their activity can be determined in a 4-h cytotoxicity assay. The presence of alloreactive pre-effector T cells has been observed in the peripheral lymphoid organs of *nu/nu* mice[9]. These cells were able to differentiate to alloreactive CTLs in the presence of TCGF. Therefore it is supposed that the *nu/nu* mouse is defective in the production of a factor which helps pre-effector T cells to differentiate to immunocompetent, alloreactive, CTL precursor cells. Our experiments show that CTLs with specificity to TNP-modified self-MHC structures are differentiating from *nu/nu* spleen cells after stimulation with hapten-modified autologous cells in the presence of TCGF.

0028–0836/81/060494—02$01.00

Table 1 The specificity of anti-TNP CTL responses of *nu*/+ and *nu*/*nu* mouse spleen cells

Responder	Stimulator	Target	% Specific ^{51}Cr release at A:T 30:1	10:1	3.3:1
nu/+	—	B6–TNP	−6.2	−3.4	−1.0
nu/+	CM	B6–TNP	4.3	−1.2	−1.8
nu/+	B6–TNP	B6	−1.0	−1.0	−3.5
		B6–TNP	61.9	44.6	21.9
		B10 · BR	9.3	3.2	0.6
		B10 · BR–TNP	22.3	8.9	1.6
nu/*nu*	—	B6–TNP	−3.6	−2.2	0.6
	CM	B6–TNP	−10.8	−4.2	−1.7
	B6–TNP	B6–TNP	−4.8	−4.1	−3.0
	B6–TNP + CM	B6	−3.9	−2.3	−0.3
		B6–TNP	38.5	11.4	5.6
		B10 · BR	3.5	2.1	0.0
		B10 · BR–TNP	15.5	0.5	0.6

The generation and assay of CTLs of *nu*/+ origin were carried out as described previously[4]. Briefly, 5×10^7 responding cells and 2×10^7 TNP-derivatized[12] mitomycin C-treated stimulator cells were co-cultured in 25-cm^2 tissue culture flasks in RPMI 1640 medium containing 10% fetal calf serum (Gibco), supplemented with 10 mM HEPES, 200 mM glutamine, 50 IU ml^{-1} penicillin, 50 μg ml^{-1} streptomycin and 5×10^{-5} M 2-mercaptoethanol. After 5 d of co-culture in a humidified CO_2 incubator, the cells were collected and their cytotoxic activity and specificity determined. The target cells were concanavalin A (Con A)-stimulated T-cell blasts labelled with ^{51}Cr ($Na_2{}^{51}CrO_4$; Radiochemical Centre). The attacker (A) and target (T) cells were incubated at different ratios for 4 h, then the supernatants were collected for γ counting. The corrected per cent lysis was calculated according to the following formula:

$$\frac{\text{experimental release} - \text{medium release}}{\text{maximal release} - \text{medium release}}\times 100$$

Medium release was 12–34% of the maximal release. CTLs from *nu*/*nu* spleens were generated in the same way, except that conditioned medium (CM), containing TCGF, was added to the cultures. The CM was prepared according to the method of Gillis *et al.*[13], using rat spleen cells (strain SDK).

Table 2 Demonstration of the presence of Thy-1 antigen on cytotoxic cells derived from the spleens of *nu*/*nu* mice

CTL population	Treatment	% Specific ^{51}Cr release
Primary	Medium	20.8
	Anti-Thy-1,2	26.8
	Anti-Thy-1,2 + C′	0.9
	C′	20.1
Secondary	Medium	31.8
	Anti-Thy-1,2	41.3
	Anti-Thy-1,2 + C′	0.0
	C′	33.7

The antibody-plus-complement (C′) treatment of the attacker cells was carried out in the wells of U-bottomed microtitration plates. Attacker to target cell ratio was 20 : 1 for primary and 5 : 1 for secondary effector cells. Target cells were TNP-derivatized Con A blasts of B6 mice. Attacker cells were incubated with a monoclonal anti-Thy-1.2 antibody (supernatant F7D5) at the predetermined optimal dilution (1 : 50) for 30 min at 24 °C in RPMI 1640 medium. After incubation with the antibody, the cells were washed twice with medium and rabbit serum was added to the cells as a source of complement (1 : 8 dilution). The cells were further incubated for 40 min at 37 °C, then washed twice. 10^4 target cells were added per well and incubated for another 4 h at 37 °C in a CO_2 incubator, then the supernatants were collected for γ counting.

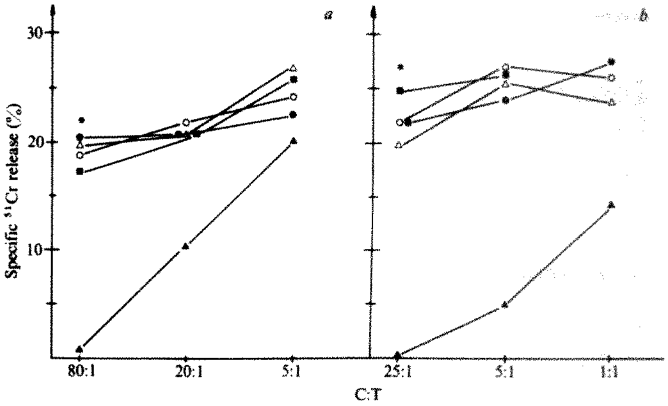

Fig. 1 Specificity of primary (*a*) and secondary (*b*) CTL populations of *nu*/*nu* mice reacting with TNP-derivatized autologous target cells. Secondary CTLs were generated by restimulating 10^5 cells 10 d after *in vitro* priming with 10^5 TNP-derivatized syngeneic lymphocytes in the presence of TCGF. The cells were collected 4 d after restimulation and their cytotoxic activity and specificity were determined. Target cells were TNP-derivatized Con A-induced T-cell blasts of B6 mice. Nonradiolabelled competitor cells were spleen cells, their modification with TNP was carried out as described in Table 1 legend. NIP derivatization was as described previously[14]. Attacker cells were seeded in 50-μl volume in the wells of U-bottomed microtitre plates, in triplicates. 50 μl of nonradiolabelled competitor (C) and 100 μl radiolabelled target (T) cells were added at 4 °C, the cells were spun briefly and incubated for 4 h at 37 °C, and the supernatants collected for γ-counting. The attacker to target cell ratio was 20 : 1 in the primary response and 1 : 1 in the secondary response. Competitors were: C57Bl/6 (△), C57Bl/6–TNP (▲), B10 · BR (○), B10 · BR–TNP (●) or C57Bl/6–NIP (■) cells. * Marks the level of kill in the absence of competitor cells.

Several hypotheses have been proposed to explain the thymic function in determining the H-2 restriction specificity of CTLs. These can be divided into three categories: (1) the thymus drives differentiation, that is, the high mutation rate of germ-line genes within the thymus, creates the specificities; (2) the thymus selects cells for further maturation from an already differentiated repertoire; (3) the thymus only influences the maturation of T cells. Our data strongly oppose the first alternative.

The possibility that *nu*/*nu* mouse spleen cells would not behave in the same way as prothymocytes from normal mice was also considered. The possible residual thymic function in *nu*/*nu* mice, as well as the maternal (*nu*/+) origin of the precursors, are difficult to exclude. Therefore, we have also used prothymocytes from normal mice (bovine serum albumin gradient purified[10], Thy-1 negative) as responders and the results obtained were similar to those with *nu*/*nu* spleen cells described above. Hünig and Bevan[11] have also reported that the anti-TNP CTL responses of nude mice are H-2 restricted.

I.A. was supported by a scholarship from the Hungarian and Finnish Academies of Sciences. We thank Professor Olli Mäkelä for useful discussions and for critical revision of the manuscript, and Dr E. Simpson for supernatant F7D5.

Interferon-neutralizing antibodies in a patient treated with human fibroblast interferon

Angelika Vallbracht*†, J. Treuner‡, B. Flehmig*, K.-E. Joester§ & D. Niethammer‡

§ Dr Rentschler & Co., Laupheim, FRG

During recent years clinical trials have shown that human leukocyte interferon (HuIFN-α) may be useful in the treatment of cancer, but very little has been done concerning the possible use of human fibroblast interferon (HuIFN-β). Treuner *et al.*[1] recently reported the successful treatment of a nasopharyngeal carcinoma with HuIFN-β: in the course of IFN-therapy a HuIFN-β neutralizing activity appeared in the serum of this patient. We report here that such activity is due to IgG antibodies—this study is the first to present evidence for antigenicity of IFN in a homologous system.

The IFN used in therapy was a diploid cell-strain IFN (HuIFN-β) (Rentschler Co., Laupheim) produced in human foreskin fibroblasts (FS-4) by superinduction with poly(I · C), cycloheximide and actinomycin D. The IFN preparations were purified and concentrated using perchloric acid and ammonium sulphate precipitation followed by column chromatography and ultrafiltration. The specific activity of the HuIFN-β preparation used was 1–2 × 10⁶ IU per mg protein.

The patient S.R. was treated by i.v. infusions with 4 × 10⁶ units of interferon daily for 5 weeks, followed by three applications per week[1]. Repeated analyses over a period of 6 months showed measurable IFN serum levels after injection[1]. Subsequent control analyses failed to show IFN activity after i.v. injection of 4 × 10⁶ IU. Therapy was stopped after treatment for 10 months (using a total of ~5 × 10⁸ units). The serum was analysed for neutralizing activity against HuIFN-β and immunoglobulins were purified. Unfortunately, no earlier serum samples were available.

Serial 2-fold dilutions of serum were incubated for 1 h at 37 °C and 2 h at 4 °C with eight units of either FS-4 HuIFN-β or HuIFN-α. IFN assays were done by plaque reduction assay in RITA cell culture microplates (monkey kidney cell line) using vesicular stomatitis virus (VSV) as challenge. A simultaneous titration of the IFN used was included in each case and the lowest dilution of antiserum examined for direct inhibition of VSV. IFN titres were expressed in terms of HuIFN-β reference standard G-023-902-527 (from NIH, Bethesda), and the neutralizing titre was taken as the highest dilution of serum that inhibited by 50% the protective activity of at least eight units of IFN. The anti-HuIFN-β titre of untreated serum from S.R. was about 10^{-3} using HuIFN-β (Rentschler) or HuIFN-β (NIH) as antigen, or when HuIFN-β (Rentschler) in the serum of an IFN-treated child was used. A neutralization assay in which the concentration of HuIFN-β was varied showed that 50 µl of serum from patient S.R. were able to neutralize ~10⁴ units of HuIFN-β. Substitution of human serum for fetal calf serum did not induce a change in the anti-HuIFN-β titre. Preincubation of RITA cells with serum from patient S.R. for 20 h inhibited the activity of eight units of HuIFN-β up to a dilution of 1:8—this inhibition could be due to HuIFN-β receptor antibodies or cross-reacting antigens of RITA and FS-4 cells.

Attempts to show neutralizing activity against HuIFN-α in the serum from patient S.R. were unsuccessful[2]. The assay was performed with eight units of HuIFN-α mixed with an appropriate amount of FS-4 cell preparation to rule out the possibility that the presence of antibodies to antigens of the FS-4 cell preparation other than HuIFN-β co-precipitated with IFN to produce a reaction which was erroneously interpreted as HuIFN-β neutralization. No inhibitory effect of serum from patient S.R. against HuIFN-α was seen in these conditions. However, we cannot exclude the possiblity that the antibody observed was produced against a complex of HuIFN-β + FS-4 protein, which could be a result of the method of purification.

Serum taken from the patient S.R. 9 months before IFN therapy showed no neutralizing activity against HuIFN-β. As we had no earlier preserum samples we were unable to check the possibility that disturbed immune function might have resulted in production of autoantibodies against endogeneous HuIFN-β.

Serum taken from patient S.R. after IFW therapy was heated at 56 °C for 30 min before use then 1 ml was absorbed three times with a total of 6 × 10⁸ FS-4 cells; serum–cell mixtures were incubated with agitation at 37 °C for 30 min and 4 °C for 30 min. Serum was centrifuged at 6,000*g* for 30 min to remove cells then the total IgG content measured by immunodiffusion with Tripartigen plates (Behring, Marburg)—this was reduced from

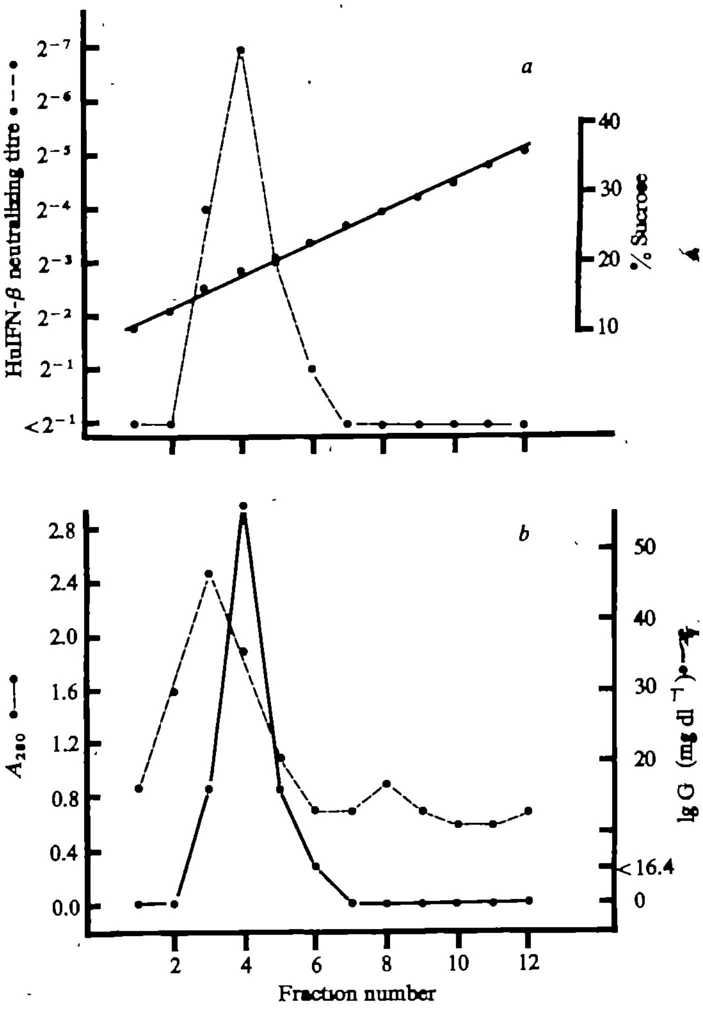

Fig. 1 *a*, Determination of HuIFN-β neutralizing titre. *b*, Total protein content and concentration of IgG after sucrose density-gradient centrifugation of FS-4 absorbed serum from the patient S.R. Serum was centrifuged in a 10–37% sucrose density-gradient for 20 h using a SW-40 rotor (Beckman Instruments, Palo Alto, California) at 154,000*g*. Fraction numbering was started at the top of the gradient. Determination of anti-HuIFN-β titre (broken line, *a*), IgG concentration (solid line, *b*) and total protein content (A_{280}, broken line, *b*) was done with fractions of the same gradient.

† To whom correspondence should be addressed

900 mg dl^{-1} before absorption to 550 mg dl^{-1} without diminishing the anti-IFN titre. Preincubation of RITA cells with the absorbed serum did not inhibit HuIFN-β activity.

To demonstrate that the HuIFN-β neutralizing activity was in fact due to antibodies, activity was determined after sucrose density-gradient centrifugation of FS-4 absorbed serum from S.R. Total protein content (E_{280}) and concentrations of IgG in sucrose density-gradient fractions of serum are shown in comparison with anti-HuIFN-β titres in Fig. 1. The peak of anti-HuIFN-β activity was found in fraction 4 (Fig. 1*a*) which correlates with the IgG (Fig. 1*b*) and the IgA peak (not shown). The IgM peak (fraction 8) showed no measurable HuIFN-β neutralizing activity. In addition, serum IgG from patient S.R. was purified by ion-exchange chromatography to demonstrate that the anti-HuIFN-β activity was due to IgG antibodies. FS-4 cell-absorbed serum was precipitated with saturated ammonium sulphate, *p*H 6.5, and the precipitate dialysed against 0.02 M phosphate buffer, *p*H 8.0. IgG was prepared from the precipitate by chromatography on DEAE-Sephacel column (Pharmacia, Uppsala, Sweden) equilibrated with the same buffer. The protein peak passed through with the first buffer volume contained most of the anti-HuIFN-β activity. Immunodiffusion showed that there was no IgA or IgM contamination of the purified IgG. Immunoelectrophoreses of 0.7 mg IgG ml^{-1} against rabbit anti-human serum protein (Medac, Hamburg) revealed only one component in the IgG preparation.

The first successful demonstration of antiserum to an IFN was reported by Paucker and Cantell[3]. However, studies on the antigenicity of IFN have shown that they are not antigenic in homologous systems[4]. In a number of clinical trials no neutralizing activity could be demonstrated in the sera of any patients, even after treatment with several millions of human IFN units[5,6].

This study presents a strong case for the presence of antibodies to HuIFN-β in the serum of patient S.R. treated successfully with $\sim 5 \times 10^8$ HuIFN-β units. A number of other patients in the Department of Pediatrics in Tübingen were treated with the same preparation of HuIFN-β—three of these had a nasopharyngeal carcinoma[7]. Total remission of the carcinoma after HuIFN-β therapy was shown only in S.R. who was the only patient in which HuIFN-β neutralizing antibodies could be demonstrated, although several others were treated with equally high doses.

We are now attempting to determine whether the patient's cells lack the genes for HuIFN-β and further experiments are being done to clarify this phenomenon of anti-IFN production and its possible clinical significance.

Functional deficits following brain lesions can be due not only to the disruption of conduction in specific input and output pathways passing through the site of injury, but also to the loss of important regulatory systems controlling the functional state of neuronal circuitries in areas distant from the lesion. For example, the behavioural disturbances that result from lesions of the nigrostriatal dopamine (DA) pathways[1-3] can be reversed by administration of dopamine receptor-activating drugs, such as L-dopa or apomorphine[4-6]. This suggests that the lesioned dopaminergic system, rather than conveying specific input and output signals, is normally acting on neuronal machineries whose activity levels are set by the activity at the dopaminergic synapses. Thus the neurological deficits resulting from these lesions are due to functional inactivation of otherwise intact neostriatal circuitries. Previous studies have shown that intracerebral transplants of embryonic substantia nigra can compensate for drug-induced[7-9] as well as spontaneous asymmetric motor behaviour[11] (expressed as a tendency to move in circles towards the lesioned side), whereas the sensorimotor asymmetry, which is pronounced in rats with a unilateral lesion of the nigrostriatal DA pathway[4,10], was unaffected by the transplant[11]. We report here that restoration of striatal dopaminergic neurotransmission by nigral transplants in animals with bilateral, complete lesions of the nigrostriatal DA pathways can reinstate not only certain aspects of spontaneous motor behaviour, but also sensorimotor orientation and sensory attention on the side of the body contralateral to the graft.

Young female Sprague–Dawley rats (180–200 g at the time of surgery) initially received a unilateral right lesion of the nigrostriatal DA pathway, produced by an intracerebral injection of 8 µg 6-hydroxydopamine (6-OHDA; Hässle) into the pathway[12]. The completeness of the lesion was tested by assessing the intensity of the amphetamine-induced rotational response according to Ungerstedt and Arbuthnott[13]. When injected intraperitoneally with 5 mg per kg metamphetamine 1 week after the 6-OHDA lesion, all the rats included in the study showed a mean of >8 complete 360° turns per min. This turning rate has previously been found to correspond to a reduction in striatal DA of 97% or more[9].

About 4 weeks after the 6-OHDA lesion the rats received transplants of the substantia nigra region taken from 16–17-day rat embryos (crown to rump length 15–20 mm) as described elsewhere[7,9]. The transplants were placed on the dorsal surface of the denervated neostriatum, within a suction cavity made through the anterior parietal cortex and the corpus callosum. Eight control rats received the cavity lesion but no transplants. Six months after transplantation, 14 of the transplanted rats which showed complete compensation of their initial amphetamine-induced turning response (Table 1) were selected for further behavioural testing. (The compensation of amphetamine turning has previously been shown to be a good criterion for animals with surviving transplants and with significant dopaminergic re-innervation of the dorsal part of the denervated caudate-putamen[9]. This was confirmed in the final fluorescence histochemical analysis which demonstrated DA-rich surviving transplants and significant DA fibre ingrowth in each case.)

Seven months after the first 6-OHDA lesion, all 22 rats received a second 6-OHDA lesion to the contralateral nigrostriatal DA pathway. They were maintained by intragastric tube-feeding for 8 weeks, giving 25–40 ml per day of a high-energy liquid diet preparation (Vivonex, Vitrum). All surviving rats were finally killed and the brains taken for fluorescence microscopical analysis using the ALFA method of Lorén *et al.*[14]. The rats underwent behavioural testing before and after the second lesion, which involved observations on amphetamine-induced and spontaneous asymmetric motor behaviour, arm

Table 1 Behavioural recovery in nigra-transplanted rats

	Unilateral (right) lesion		Bilateral lesion	
	No transplant (*n* = 8)	Right transplant (*n* = 14)	No transplant (*n* = 8)	Right transplant (*n* = 14)
Amphetamine-induced rotation (net ipsilateral turns per min)				
Before transplantation (1 week after 1st lesion)	14.0 ± 2.5	14.0 ± 0.7*	—	—
3 months after 1st lesion	16.3 ± 1.4	2.7 ± 1.0†	—	—
2 months after 2nd lesion	—	—	0.9 ± 1.4	−11.6 ± 0.8†
Spontaneous rotation (probability of left turn)				
Without activation	0.17 ± 0.04	0.32 ± 0.05†	0.57 ± 0.12	0.92 ± 0.04†
Tail-pinch activation	0.24 ± 0.06	0.46 ± 0.05†	0.61 ± 0.11	0.91 ± 0.03†
Arm preference in T-maze (probability of left choice)	0.03 ± 0.02	0.32 ± 0.07†	0.41 ± 0.09	0.79 ± 0.06†
Sensorimotor asymmetry (right–left scores)				
Without activation	3.00 ± 0.82	4.00 ± 0.72*	0.29 ± 0.52	−4.33 ± 0.67†
Tail-pinch activation	4.17 ± 1.05	3.23 ± 0.63*	1.14 ± 0.77	−4.67 ± 0.50†

Amphetamine-induced rotation was recorded in plastic bowls over 60 min after intraperitoneal administration of 5 mg per kg metamphetamine, after the method of Ungerstedt and Arbuthnott[13]. Scores are net ipsilateral (right–left) turns per min. Spontaneous rotation was recorded in the same bowls, and quarter-turns in each direction were recorded over a 3-min period. Ten min later, a paper clip was attached to the rat's tail to provide mild activation, and again quarter-turns were recorded over a 3-min period. Maze testing: rats were tested for arm preference in an unbaited T-maze of conventional design, with and without tail-pinch activation, as described in detail elsewhere[11]. Each test consisted of two trials separated by a 5–10-min interval. Three tests were carried out, each separated by several days, and the scores for each animal combined as no differences were found between tests. Sensorimotor asymmetry was tested in a battery modified from Marshall and Teitelbaum[10,20], and described in detail elsewhere[11]. Briefly, the orientation to a light pin-prick at different points on the body surface, to touch of the whiskers and snout, and to the odour of an ammonia-soaked swab, were each rated on a three-point scale (0 = absent, 1 = weak, 2 = normal). The asymmetry scores are the difference between total scores on the two sides of the body (right–left). All tests were performed 3–4 months after the initial unilateral lesion and transplantation in the unilateral animals. They all received bilateral lesions at 7 months, and were retested 6–8 weeks later. The amphetamine rotation and sensorimotor tests indicate net (right–left) scores, with positive values denoting bias towards the right (transplant/initial lesion) side. The spontaneous rotation and maze tests indicate the probability of a left turn, scores <0.5 denote a right bias, and >0.5 a left bias. All values are means ±s.e.m. and comparisons by unrelated Student's *t*-test.

* Not significant, $P>0.01$

† $P<0.001$.

preference in a T-maze, and asymmetry in sensorimotor responding, as summarized in Table 1.

After the second 6-OHDA lesion both the controls and the transplanted rats became severely akinetic. Both groups of rats also became aphagic and adipsic, and they had to be maintained by intragastric tube-feeding throughout the 8-week test period.

The akinetic state of the animals was partially reversed by tail-pinch activation. When activated in this way, the non-transplanted control rats showed no side bias in their spontaneous turning behaviour and no asymmetric posture. In contrast, the transplanted rats showed a high degree of turning away from the transplant side (towards the left) (right-hand panels in Table 1) and asymmetric posture, with the head, body and tail describing a curve concave on the side of the second lesion. Without tail-pinch activation the transplanted rats showed an equally pronounced bias for direction of turning in the spontaneous rotation test, although the turning rate was much lower. Before the second lesion (left panels in Table 1), the lesioned, non-transplanted controls showed a strong rotational bias towards the lesioned side; this bias was significantly attenuated in the transplanted rats, both with and without tail-pinch activation.

When tested for arm preference in the T-maze, which can be taken as a measure of the relative degree of sensory attention on the two sides of the rat's body, before the second lesion the non-transplanted controls showed a strong bias (97%) for the right arm contralateral to the intact nigrostriatal pathway. This bias was significantly reduced in the transplanted rats. After the second lesion the transplanted rats showed a marked preference (79%) for the left arm, contralateral to the transplant, whereas the bilaterally lesioned controls showed no such asymmetry (Table 1).

When performed before the second lesion, the sensorimotor orientation test demonstrated an equally marked sensory inattention on the left side of the body in both the transplanted and non-transplanted rats. This deficit was unaffected by mild tail-pinch activation. After the second lesion the controls became equally unresponsive on both sides of the body, whereas the transplanted rats showed a marked asymmetry, with significantly greater response towards stimuli applied on the left side of the body, contralateral to the transplant (Table 1). Thus, with respect to both motor asymmetry, choice behaviour in the T-maze and sensorimotor orientation, the bilaterally lesioned rats with unilateral nigral transplants showed a performance similar to that of rats with a unilateral lesion of the nigrostriatal system.

Thus, our results support the conclusion that an ectopic, intracortical nigral transplant, without any external (that is, drug-induced) activation, can induce recovery in certain aspects of motor behaviour, and in sensory attention and sensorimotor orientation specifically on the side contralateral to the transplant, in the spontaneously behaving animal. In contrast, the severe akinesia, aphagia and adipsia of the bilaterally lesioned rats were unaffected.

Figure 1 shows in diagrammatic form a possible model for the mechanism of action of the ectopic nigral transplant, based on the one previously proposed by Stricker and Zigmond[2]. In this model the DA systems regulate the behavioural responsiveness through modulation of an inhibitory control mechanism. In the intact animal the nigrostriatal DA pathway seems to act as a tonic regulatory system which sets the level of activity in the neostriatal machinery. Removal of this dopaminergic regulatory control function results in inhibition of neostriatal function. Reinstatement of dopaminergic neurotransmission by drugs[4–6], or—as in our experiments—by transplantation of DA neurones, can thus be interpreted as a reactivation of an inhibited, but otherwise intact, neuronal machinery. If we assume that the nigrostriatal DA system is inhibitory in nature (see ref. 15 for discussion), then the likely action of the nigral transplant would be to disinhibit elements of the nigrostriatal circuitry.

In the model in Fig. 1 the nigral transplant acts by reducing the threshold for behavioural response (R) to diverse sensory inputs (I). An interesting implication of this model is that recovery of responsiveness to sensory stimuli in the transplanted rats can occur without any access of sensory information to the transplant. In the intact animal various types of sensory stimuli have been shown to activate the nigrostriatal DA neurones[16,17]. However, in the transplanted animal such activation would not be necessary for behavioural recovery provided that the transplanted neurones have a sufficiently high spontaneous activity. Other parallel observations indicate that this indeed is the case. First, in biochemical determinations of DA and its metabolite, dihydroxyphenylacetic acid[18], the turnover of DA in both the transplant and the re-innervated neostriatum has been found to be as high as that of the intact nigrostriatal system. Second, ^{14}C-2-deoxy-D-glucose autoradiography has revealed a significant glucose uptake in the nigral transplants, amounting to about two-thirds of that of the intact substantia nigra[18], and third, measurements of the rotational response to the DA receptor agonist, apomorphine, in nigra-transplanted rats indicate that re-innervation of the neostriatum by nigral transplants is accompanied by a partial reduction in the supersensitivity of the neostriatal DA receptors[11]. This observation is compatible with a partial restoration of dopaminergic neurotransmission in the re-innervated neostriatum.

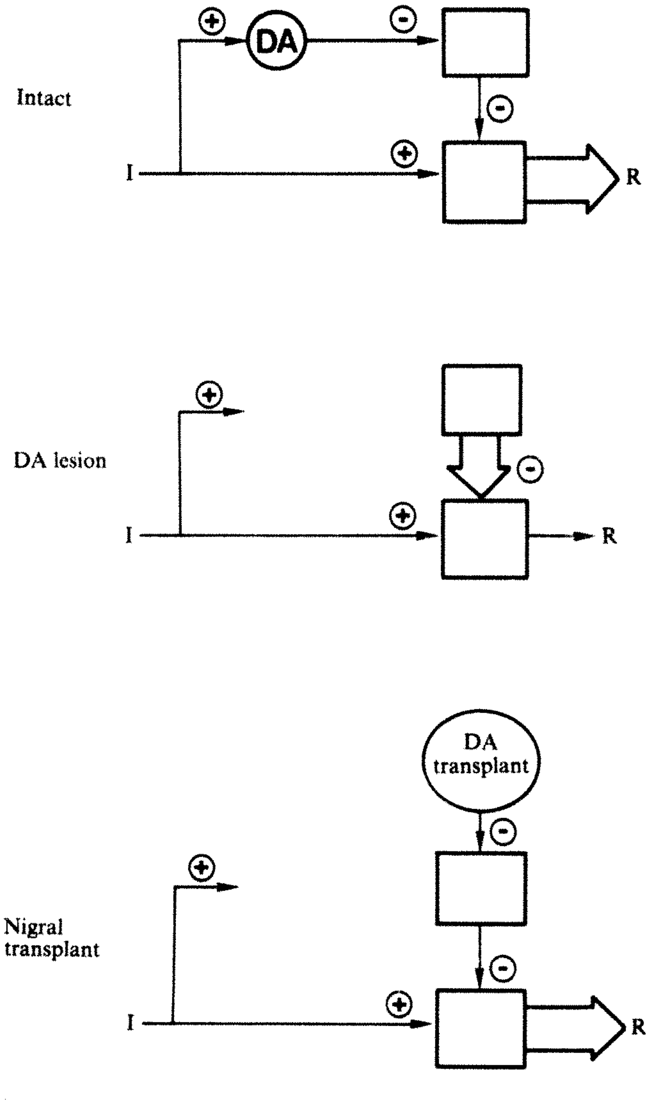

Fig. 1 Proposed mode of action of the DA-producing intracortical nigral transplants in the promotion of behavioural recovery in rats with unilateral or bilateral lesions of the nigrostriatal DA pathway. The behavioural response, R, evoked by an activating sensory input, I, is modulated by the transplant through an inhibitory control mechanism.

An important feature of the behavioural effects of the nigral transplants was the specificity of the transplant-induced recovery. Thus, in the bilaterally lesioned rats the transplants did not induce a diffuse, partial recovery in all aspects of the DA deficiency syndrome. Rather, the recovery appeared discrete and complete, such that in those behaviours where recovery did occur (motor asymmetry and choice behaviour) the transplanted animals performed as well as an intact rat, whereas in those behaviours where recovery did not occur (akinesia, aphagia and adipsia) they performed as badly as the lesioned control rats. This can be explained if one assumes that different parts of the striatal complex subserve, at least partly, different types of function (see ref. 19). If so, the transplant-induced recovery would depend on which parts of the striatal complex are re-innervated from the transplant. With the present intracortical transplantation site the ingrowing DA fibres are confined to the dorsal parts of the head of the caudate-putamen, whereas the ventral and lateral parts, as well as nucleus accumbens, are left denervated. The possibility that this regional restriction of the transplant-induced dopaminergic re-innervation determines the pattern and specificity of behavioural recovery is now being investigated.

These results demonstrate that intracerebral transplants can be functional not only after pharmacological activation but also in the spontaneously behaving animal, and that ectopic nigral transplants, which probably lack their normal afferent inputs, can nevertheless compensate for the loss of the rat's own substantia nigra, at least in certain types of behaviour. Functional reactivation of denervated central nervous system circuitries by neural transplants should thus offer an interesting approach to the analysis of mechanisms of neurological and behavioural recovery after brain or spinal cord damage as well as in animal models of neurodegenerative disorders, such as Parkinson's disease.

We thank Birgit Haraldsson, Ulla Jarl and Gertrude Stridsberg for technical assistance. The work was supported by grants from the Swedish MRC (04X-3874), the Wiberg and Kock Foundations, and the European Training Programme in Brain and Behaviour Research.

Central noradrenergic neurones concentrate ^{3}H-oestradiol

Madhabananda Sar & Walter E. Stumpf

Departments of Anatomy and Pharmacology, University of North Carolina, Chapel Hill, North Carolina 27514

Central catecholamines play an important part in the regulation of hormone secretion from the pituitary gland and in the mediation of male and female sexual behaviour[1-6]. Noradrenaline has been shown to stimulate the release of luteinizing hormone (LH) probably by influencing the secretion of LH-releasing hormone (LHRH)[7,8]. The medial preoptic and hypothalamic areas, including the median eminence, contain noradrenaline-containing terminals which originate from discrete noradrenaline-containing cell groups in the lower brain stem. These cell groups have been identified in the pons and the medulla oblongata by histochemical methods and pharmacological experiments[9-14]. Recent studies with antiserum to dopamine-β-hydroxylase (DBH), the enzyme that converts dopamine to noradrenaline, provided evidence for the existence of noradrenergic cells[15,16]. These include the locus coeruleus (group A6), a ventrally located more diffuse but continuous subcoeruleus group (group A5), a cell group located dorsal to the nucleus (n.) dorsalis motorius nervi vagi (group A2) and a cell group in or near the nucleus reticularis lateralis (group A1). Using the thaw-mount autoradiographic technique, oestradiol-concentrating neurones have been localized in many areas of the lower brain stem, including the locus coeruleus, n. tractus solitarii, n. dorsalis motorius nervi vagi, and reticular formation[17] where catecholamine-containing neurones exist. We report here the simultaneous localization, in the same histological section, of ^{3}H-oestradiol and the enzyme dopamine-β-hydroxylase in neurones of the rat lower brain stem with a combined technique of thaw-mount autoradiography and immunohistochemistry[18,19], demonstrating that noradrenaline- or adrenaline-containing neurones are oestradiol target cells.

Ten adult female Holtzman Sprague–Dawley rats, castrated 72 h previously, were injected intravenously with [2,4,6,7-^{3}H]oestradiol-17β, specific activity 95 Ci mmol^{-1}, at a dose of 0.5 μg per 100 g body weight and killed after 1 h. Four ovariectomized rats were used to demonstrate the specificity of localization: two each injected with 500 μg of progesterone or 500 μg of 5-α-dihydrotestosterone, 15 min before ^{3}H-oestradiol. Lower brain stem with pons and medulla oblongata was dissected, placed on a tissue holder and frozen in liquefied propane (−180 °C). Serial frozen sections (4 μm) were cut in a cryostat (Harris), thaw-mounted on photographic emulsion (Kodak NTB3) slides, and exposed in light-proof boxes at −15 °C. The thaw-mount autoradiographic procedure has been described elsewhere[20]. After 8–12 months of exposure, the slides were fixed for 30 s in 3% paraformaldehyde solution (*p*H 7.5) at ice temperature, rinsed briefly in 0.01 M phosphate-buffered saline (PBS) solution at *p*H 7.5, and developed in Kodak D-19 developer (diluted 1:1 in PBS), followed by fixation with Kodak rapid fixer. After photographic processing and subsequent washing with two changes of PBS the autoradiograms were treated with phenylhydrazine–egg albumin to reduce nonspecific staining[19,21]. After a brief wash with PBS, the autoradiograms were incubated at 4 °C for 48 h with a 1:250 or 1:500 dilution of DBH antiserum[22] in PBS containing 1% normal sheep serum and 0.03% Triton X-100. All subsequent steps were carried out at room temperature. After a 3-min wash in PBS, sections were incubated with sheep anti-rabbit γ globulin (1:100 in PBS) for 10 min. After a further 3-min wash with PBS, the autoradiograms were incubated for 20 min with rabbit peroxidase–antiperoxidase complex (1:50). Another 3-min wash in PBS was followed by immersion of the slides for 10 min in 200 ml Tris buffer (0.05 M, *p*H 7.6) containing 150 mg of diaminobenzidine tetrahydrochloride and 15 μl of 30% hydrogen peroxide. Autoradiograms incubated with normal rabbit serum were used to test the specificity of the reaction.

Thaw-mount autoradiograms of pons and medulla oblongata stained immunohistochemically with antiserum to DBH showed DBH-positive cells in certain regions of the hind brain (Figs 1, 2). The strongest DBH staining was observed in cells of the locus coeruleus throughout its extensions, both in its dorsal and ventral divisions. About 30–40% of these cells (group A6) showed nuclear concentration of radioactivity after ^{3}H-oestradiol administration. The localization was specific and probably represented oestradiol because administration of unlabelled oestradiol in excess abolished the nuclear uptake[23], whereas unlabelled progesterone or 5α-dihydrotestosterone did not. A few DBH-positive cells located at the rostral part near the dorso-lateral corner of the fourth ventricle and at the caudal end of the locus coeruleus were not labelled with ^{3}H-oestradiol. In addition to the locus coeruleus, positively stained scattered cells were found around the lateral and dorsal aspects of superior olivary nucleus (group A5) and in regions of the lateral lemniscus (group A7). These cells belong to the lateral tegmental area. About 30% of these DBH-positive cells showed nuclear concentration of ^{3}H-oestradiol. In the ventrolateral medulla oblongata, an accumulation of DBH-positive cells were found in and around the n. lateralis reticularis (group A1)—about 50% of these DBH-positive cells were labelled with ^{3}H-oestradiol. In the dorsomedial medulla oblongata, DBH-positive cells were located in the n. tractus solitarii near the n.

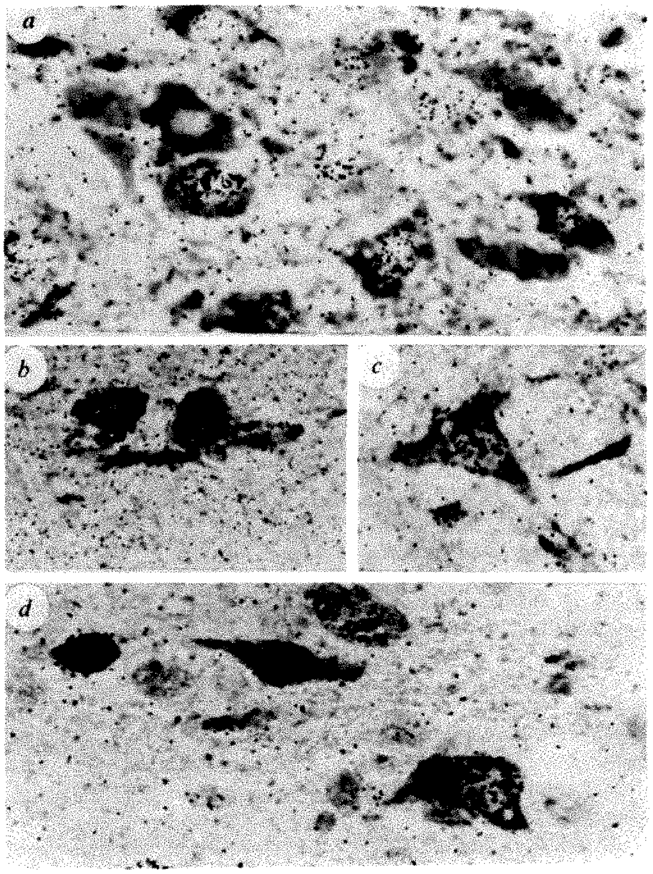

Fig. 1 Thaw-mount autoradiograms of rat lower brain stem 1 h after injection of ^{3}H-oestradiol, stained by immunoperoxidase method using antiserum to DBH (1:500). Concentration of radioactivity is seen in nuclei of DBH-positive cells in *a*, locus coeruleus, *b*, lateral tegmental area, *c*, n. reticularis lateralis, and *d*, n. tractus solitarii. Exposure time, 360 days; 4 μm. ×840 (*a*, *b*, *c*); ×1,050 (*d*).

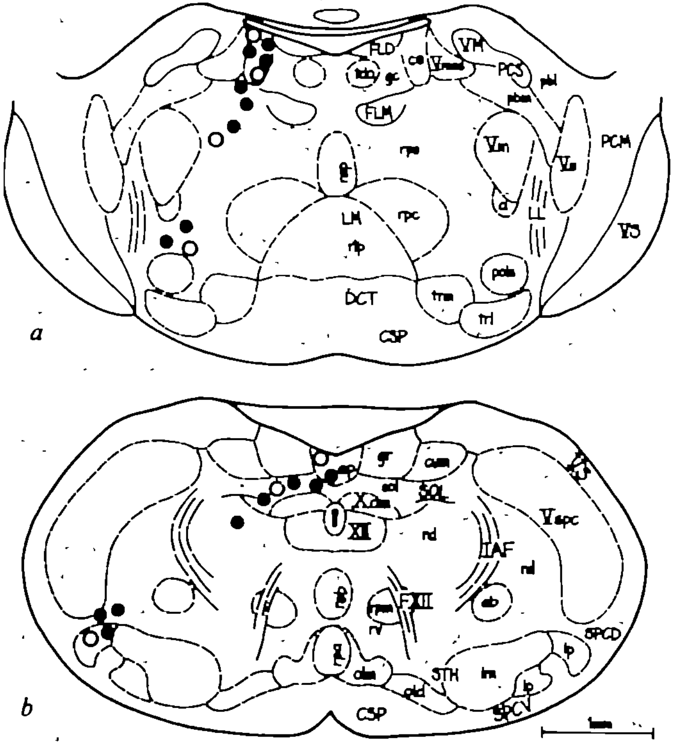

Fig. 2 Schematic drawings of DBH-containing neurones which concentrate ^{3}H-oestradiol (●) in pons (*a*) and in medulla oblongata (*b*). ○, DBH-containing neurones which do not concentrate ^{3}H-oestradiol. Frontal plane. α, nucleus (n.) alpha, ab, n. ambiguus; ap, area postrema; ce, locus coeruleus; CSP, tractus corticospinalis; cum, n. cuneatus medialis, DCT, decussatio corporis trapezoidei; FLD, fasciculus longitudinalis dorsalis, FLM, fasciculus longitudinalis medialis; gc, griseum centrale, gr, n. gracilis; IAF, fibrae arcuatae internae, LL, lemniscus lateralis, LM, lemniscus medialis; lm, n. reticularis lateralis magnocellularis; lp, n. reticularis lateralis parvocellularis; old, n. olivaris accessorius dorsalis; olm, n. olivaris accessorius medialis, pbl, n. parabrachialis lateralis; pbm, n. parabrachialis medialis; PCM, pedunculus cerebellaris medius; PCS, pedunculus cerebellaris superior pols, n. paraolivaris superior, rap, n. raphes pontis; rd, n. reticularis dorsalis medullae oblongata; rpa, n. raphe pallidus, rob, n. raphe obscurus; rpm, n. raphe paramedianus; rpo, n. reticularis pontis oralis; rtp, n. reticularis tegmenti pontis; SOL, tractus solitarius; sol, n. tractus solitarii; SPC, tractus spinocerebellaris; SPCV, tractus spinocerebellaris ventralis, STH, tractus spinothalamicus; tdo, n. tegmentalis dorsalis; trl, n. trapezoides lateralis; trm, n. trapezoides medialis; Vm, n. motorius nervi trigemini; Vmes, n. tractus mesencephali nervi trigemini, VS, tractus spinalis nervi trigemini; Vs, n. sensibilis nervi trigemini, Vspc, n. caudalis tractus spinalis nervi trigemini; Xdm, n. dorsalis motorius nervi vagi, XII, n. nervi hypoglossi.

dorsalis motorius nervi vagi, with a few scattered DBH-positive cells extending caudally into the nucleus commissuralis (group A2): ~70–80% of these positive cells were labelled with ^{3}H-oestradiol. In addition, certain cells of the area postrema showed immunoreactivity to DBH, a few of which were labelled with ^{3}H-oestradiol. When autoradiograms were incubated with the normal rabbit serum and stained immunohistochemically no positive staining was observed. The specificity of DBH antiserum has been established elsewhere[22].

These results provide direct evidence that DBH-positive neurones in lower brain stem are targets for oestradiol and suggest a direct action of oestradiol on the catecholaminergic neurones. This agrees with the previous observation of formaldehyde-induced fluorescence in oestrogen target neurones in rat lower brainstem[24]. The combined formaldehyde-induced fluorescence and autoradiography technique, however, does not distinguish between dopaminergic and noradrenergic neurones. Also, there is the possibility of fading of the fluorophore formed from the catecholamine as a result of exposure time of the autoradiograms. The use of antibodies to transmitter-synthesizing enzyme(s) provides a more specific and sensitive approach for the characterization of catecholaminergic neurones. This combined technique is also of great potential for studying morphological interrelationships between steroid hormones and neuropeptides such as LHRH, somatotropin release inhibiting factor and neurotensin. The positive staining observed here with DBH antiserum does not distinguish between noradrenaline- and adrenaline-producing neurones, because both catecholaminergic neurones contain DBH. Catecholaminergic neurones in regions of the n. tractus solitarii and n. reticularis lateralis may contain both noradrenaline and adrenaline. The question of whether adrenaline-producing neurones are targets for oestradiol can only be clarified by the application of this combination technique using antiserum to phenylethanolamine-*N*-methyltransferase (PNMT), the enzyme specific for adrenaline synthesis[25].

There is considerable evidence for the effects of gonadal steroids on central catecholamine metabolism. After ovariectomy, administration of oestradiol-17β results in changes in hypothalamic noradrenaline turnover rates[26–28], increased tyrosine hydroxylase activity[29] and changes on monoamine oxidase activity[30]. As oestradiol localizes in noradrenergic and, probably, adrenergic neurones, certain effects of gonadal steroids on the regulation of gonadotropin secretion and sexual behaviour are likely to be mediated through direct activation of catecholamine-containing neurones. Results from physiological experiments[31,32], although often conflicting, have favoured this hypothesis. For example, noradrenaline systems mediate the stimulatory effects of oestrogen on the release of prolactin[8,33,34] and of progesterone on release of LH and follicle-stimulating hormone[7,35]. DBH inhibitors have been shown to provoke anti-ovulatory effect, supporting the stimulating role of noradrenergic neurones in the control of LHRH secretion[36]. Thus, the positive oestradiol feedback that produces the pre-ovulatory LH surge probably involves activation of the noradrenaline system by a direct effect on catecholaminergic neurones in the n. tractus solitarii and n. reticularis lateralis of the medulla. Day *et al.*[37] have used the combined localization of retrogradely transported horseradish peroxidase and catecholamine-fluorescence to demonstrate that the noradrenaline innervation of the medial preoptic area is derived from these nuclear groups. Noradrenaline-containing terminals in the medial preoptic area may stimulate LH secretion by influencing the release of LHRH[8,35]. The direct association of noradrenaline-containing terminals with the LHRH-producing cells, however, remains to be demonstrated.

Enkephalins co-exist with oxytocin and vasopressin in nerve terminals of rat neurohypophysis

R. Martin & K. H. Voigt

Sektion Elektronenmikroskopie und Labor für Neuroendokrinologie,
Universität Ulm, D-7900 ULM, FRG

Evidence is accumulating that opiates inhibit the release of oxytocin and vasopressin by acting on nerve terminals in the neurohypophysis[1,2]. Extracts of neurohypophysis have been shown to contain substantial amounts of Met- and Leu-enkephalin[3,4], and Leu-enkephalin-immunoreactive (IR) nerve fibres originating in the magnocellular hypothalamic nuclei have been described in the neural lobe, where the two hormones are secreted[3]. We have compared the distribution of oxytocin, vasopressin and enkephalin immunoreactivity (IR) in the neurohypophysis of the rat, and report here that Met-enkephalin-IR is invariably associated with nerve terminals that contain oxytocin-IR whereas the terminals that contain vasopressin-IR often, but not invariably, are Leu-enkephalin immunoreactive.

Neural lobes of five normal white rats and four Brattleboro rats homozygous for hypothalamic diabetes insipidus were fixed with paraformaldehyde and glutaraldehyde and embedded in Epon. Resin was removed from serial 0.5-μm sections and Sternberger's unlabelled antibody–enzyme method applied for light microscopic immunocytochemistry[5] (antibodies are listed in Table 1). Serial ultra-thin and semi-thin sections were cut to examine the fine structure of immunoreactive terminals—the semi-thin section was processed for immunocytochemistry and the ultra-thin section stained with uranium and lead salts for electron microscopy[6]. Cross-reactivity of antibodies was examined in preabsorption controls and in radioimmunoassay (RIA) (Table 1, Fig. 1).

Affinity-purified antibodies against oxytocin and vasopressin recognized two populations of nerve terminals[7] (Fig. 2*b*, *c*, *e*). In their fine structure vasopressin terminals differed from oxytocin terminals by having more densely packed neurosecretory granules. Nerve terminals in neural lobes from Brattleboro rats reacted with oxytocin antibody but not vasopressin antibody.

Preabsorption tests showed that, of the three enkephalin antibodies, only affinity-purified Met-enkephalin antibody I specifically recognized Met-enkephalin (Fig. 1*a*, *b*). This was confirmed by RIA with several enkephalin analogues and other peptides (Table 1). Met-enkephalin antibody II cross-reacted with Leu-enkephalin (Fig. 1*c*, *d*) and Leu-enkephalin antibody cross-reacted with Met-enkephalin. This specificity was not affected by addition of Leu-enkephalin or Met-enkephalin in decreasing concentrations or by varying the dilution of the antiserum. Thus, presumably, nerves that were stained by all three antibodies contained Met-enkephalin-like material, and nerves stained by the two cross-reacting antibodies only contained Leu-enkephalin-like material. However, it cannot be ruled out that nerves exhibiting Met-enkephalin-IR contained Leu-enkephalin-like material. Furthermore, it is possible that all the antibodies cross-reacted with larger peptides containing the sequence against which the antibodies were raised—in preabsorption controls and RIA the Met/Leu-enkephalin antibodies but not the Met-enkephalin antibody I recognized the larger dynorphin[9].

When enkephalin antibody I, oxytocin and vasopressin antibodies were applied in turn to serial sections, Met-enkephalin-IR nerves were indistinguishable in size, shape and position from most of the oxytocin-IR terminals in a subsequent section (Fig. 2*a*, *c*, *f*; Fig. 3), but not from vasopressin-IR terminals (Fig. 2*a*, *b*, *g*). Fine structure revealed that the immunoreactive structures were nerve terminals or varicosities filled with electron-dense granules >100 nm in diameter; oxytocin-IR terminals were indistinguishable from Met-enkephalin I-IR terminals. Among terminals with diameters >1 μm in the neurohypophysis of a Brattleboro rat (Fig. 3), 111 out of 117 Met-enkephalin I-IR terminals coincided with oxytocin-IR terminals in consecutive sections. Six enkephalin-IR terminals without corresponding oxytocin-IR structures were all small and may not have appeared in the next section.

Oxytocin-IR terminals were recognized by Met-enkephalin antibody II (Fig. 2*d*, *c*, *h*) and by the Leu-enkephalin antibody which cross-reacted with Met-enkephalin. We therefore assume that oxytocin terminals contain Met-enkephalin-like material. As we had no specific Leu-enkephalin antibody we cannot exclude the possibility that they also contain Leu-enkephalin-like material. In well stained preparations there was nearly one to one correspondence between Met-enkephalin-IR and oxytocin-IR in consecutive sections.

Met-enkephalin antibody II, and the Leu-enkephalin antibody, which cross-reacted with both Leu- and Met-enkephalin respectively, stained certain vasopressin-IR terminals in addition to oxytocin-IR structures (Fig. 2*b*–*d*, *h*, *i*). The Leu/Met-enkephalin antibodies probably recognized Leu-enkephalin-like material but not Met-enkephalin-like material in vasopressin terminals, for the specific Met-enkephalin antibody I did not stain the corresponding structures. However, correspondence

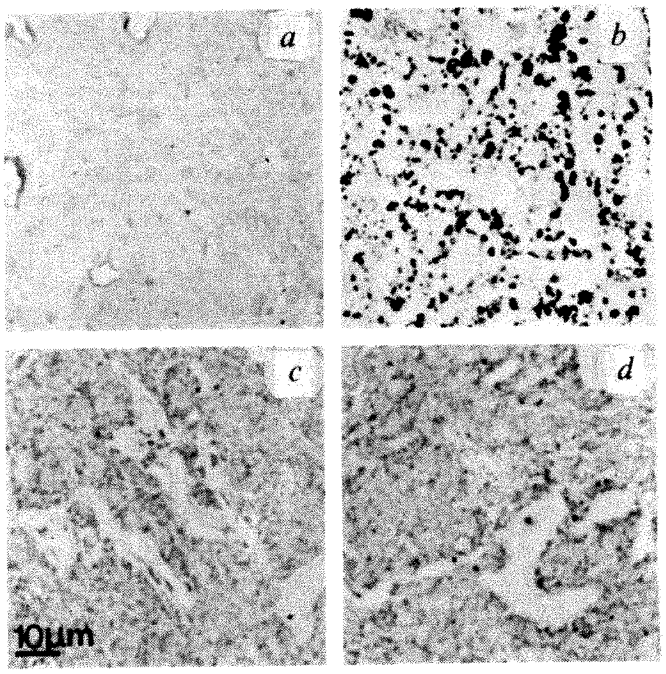

Fig. 1 Preabsorption tests using neural lobe sections with the two Met-enkephalin antibodies. *a*, *b*, Antibody I; *c*, *d*, antibody II. *a*, *c*, Preabsorption by Met-enkephalin; *b*, *d*, by Leu-enkephalin. When preabsorbed by Met-enkephalin immunoreaction was absent, that is, both antibodies had recognized the antigen and binding sites were blocked. Antibody I, in contrast to antibody II, had not recognized Leu-enkephalin and was reacting with the tissue (*b*). ×580.

Table 1 Antibodies and specificity tests

	Antibodies				
	Anti-Met-enk. I (R26)*	Anti-Met-enk. II†	Anti-Leu-enk.†	Anti-oxytocin (02C)	Anti-vasopressin (125)
Working dilution	1:2,000	1:4,000	1:4,000	1:3,200	1:1,600
Purification by affinity chromatography	+	–	–	+	+
Recognized antigens	Met-enk.	Met-enk. Leu-enk. Dynorphin	Leu-enk. Met-enk. Dynorphin	Oxytocin	Vasopressin α-MSH
Antigens not recognized	Leu-enk. Oxytocin Dynorphin	Oxytocin Arg-vasopressin Lys-vasopressin Vasotocin	Oxytocin Arg-vasopressin	Arg-vasopressin Met-enk. Leu-enk. Neurophysin I/II	Oxytocin Met-enk. Leu-enk. Neurophysin I/II

Antibodies were raised against synthetic peptides. Cross-reactivities with the listed antigens were examined in preabsorption controls by incubating the antibodies for 24 h with the peptides (20 µl of the antibody solution at half the working dilution +5 µg peptide in 5 µl phosphate-buffered saline (PBS) + 15 µl PBS). Absence of staining in neural lobe sections after application of the antibody–antigen mixtures indicated that the added peptide had been recognized by the antibody (Fig. 1).

* In a RIA[8] (using ^{3}H-Met-enkephalin as tracer and unpurified antiserum R 26, 1:16,000), the Met-enkephalin antibody I did not cross-react with the amino acids methionine and leucine, nor the sequences Phe-Met, Phe-NLeu, Phe-Leu, Gly-Gly-Phe-Met, Gly-Gly-Phe-NLeu, and the peptides α-melanocyte-stimulating hormone (α-MSH), β-endorphin, lipotropin hormone (β-LPH), ACTH_{1-24}, oxytocin and vasopressin. It cross-reacted less than 0.5% with dynorphin or Leu-enkephalin, but 11% with NLeu-enkephalin.

† It was not possible to isolate a specific population of these antibodies by affinity chromatography. The purification procedures and cross-reactivities of oxytocin and vasopressin antibody have been described elsewhere[7]. The vasopressin antibody stained intermediate lobe cells which indicated cross-reactivity with α-MSH[7]. When preincubated with synthetic α-MSH, staining of intermediate lobe was abolished but staining of neural lobe terminals was not impaired. Application of two α-MSH antibodies[6] did not reveal α-MSH-IR in the neural lobe.

between Leu-enkephalin-IR and vasopressin-IR was less complete than between Met-enkephalin-IR and oxytocin-IR. In many regions vasopressin terminals were not recognized by Met/Leu-enkephalin antibodies. The correlation was better in larger than in smaller terminals (see Fig. 2). In Brattleboro rats in which only oxytocin-IR terminals were found, all these terminals seemed to react with all three enkephalin antibodies. No additional stained structures were observed when the immunoreactivity of the two Met/Leu-enkephalin antibodies was compared with that of the Met-enkephalin antibody I.

Immunoreactive terminals used for comparison had diameters of 1–12 µm, so that most of them would appear in consecutive 0.5-µm sections. In one series, 91% of the enkephalin-IR terminals (Met-enkephalin antibody II) coincided with either oxytocin or vasopressin terminals; the remaining 9% were all rather small and were presumably cut tangentially. Thus there was no indication of separate enkephalinergic nerves.

Our observation of nerves with coexisting Met(Leu)-enkephalin/oxytocin-IR and Leu-enkephalin/vasopressin-IR does not necessarily contradict the report of enkephalin-IR nerves in the rat neurohypophysis[3], for that study did not include differential staining with enkephalin, oxytocin and vasopressin antibodies. However, the cell bodies of those enkephalin nerves were located in hypothalamic nuclei that contain oxytocin and vasopressin neurones. In dehydrated rats the decrease in vasopressin and Leu-enkephalin content[3,10], but not of thyrotropin-

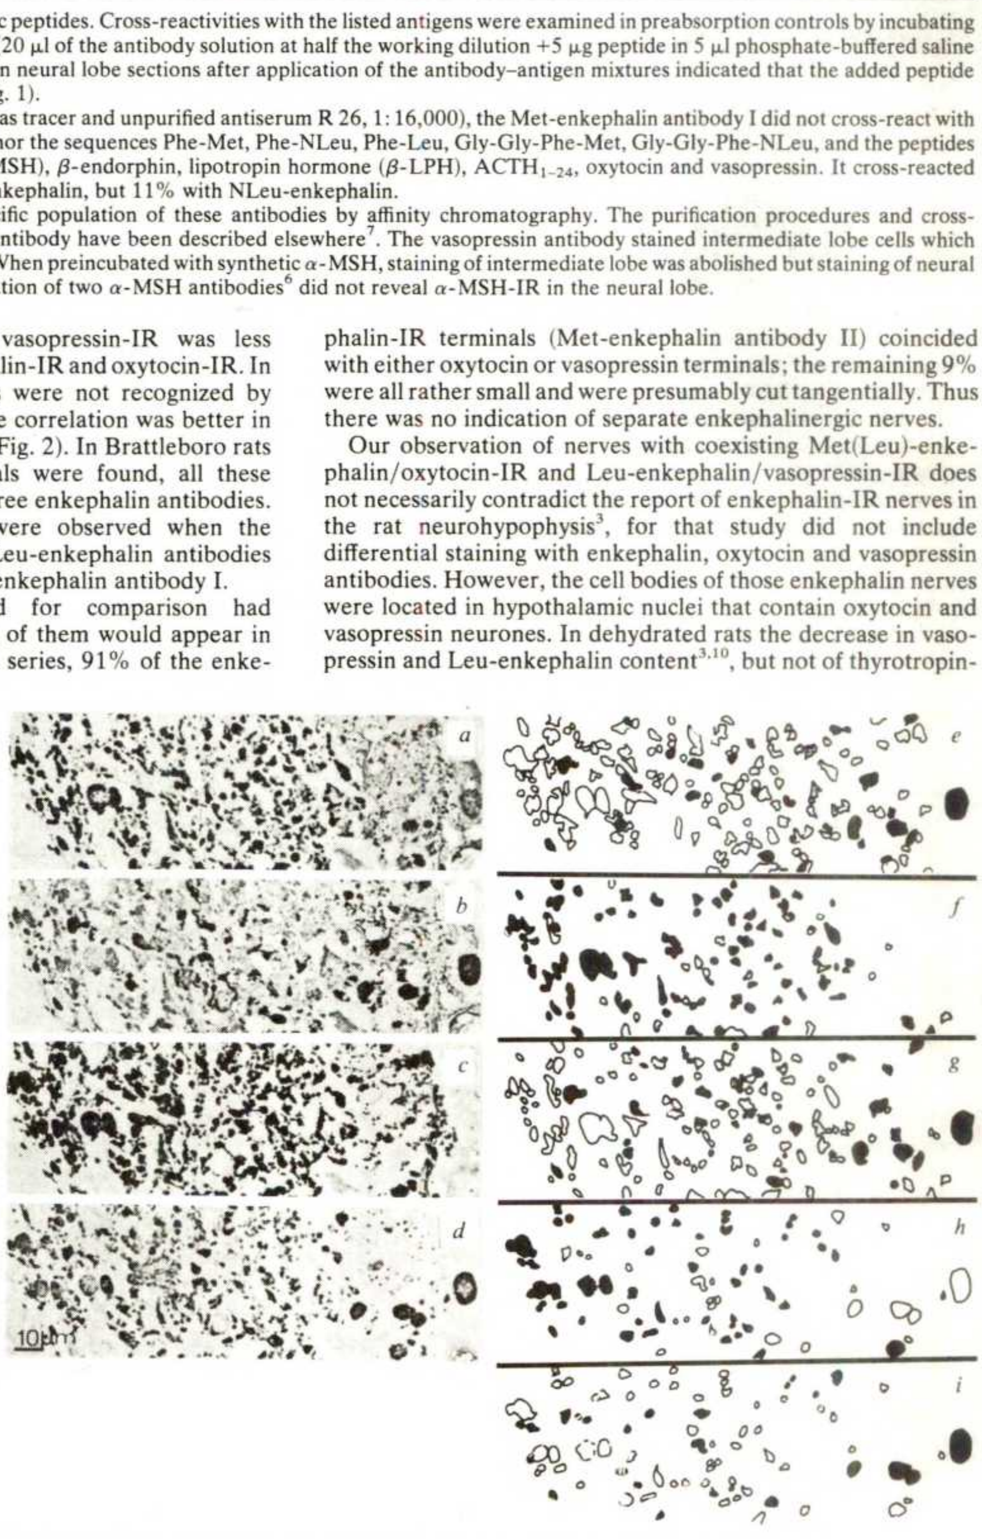

Fig. 2 Four consecutive 0.5 µm-thick sections through a neural lobe showing: *a*, Met-enkephalin I-IR; *b*, vasopressin-IR; *c*, oxytocin-IR; *d*, Met-enkephalin II-IR. ×350. *e–i*, The immunoreactive structures on two of the sections were compared: *e*, vasopressin-IR (*b*) (black spots) compared with oxytocin-IR (*c*) (contours). The vasopressin antibody recognized other terminals than the oxytocin antibody. *f*, Met-enkephalin I-IR (*a*) (contours) compared with oxytocin-IR (*c*). Coincidence of immunoreactive structures is marked by black filling. The Met-enkephalin antibody I recognized most oxytocin terminals. *g*, Met-enkephalin I-IR (*a*) (contours) compared with vasopressin-IR (*b*) (black spots). The Met-enkephalin antibody I did not recognize vasopressin terminals. *h*, Met-enkephalin II-IR (*d*) (contours) compared with oxytocin-IR (*c*); coincidence marked by black filling. The Met-enkephalin antibody II recognized oxytocin terminals. *i*, Met-enkephalin II-IR (*d*) (contours) compared with vasopressin-IR (*b*); coincidence marked by black filling. The Met-enkephalin antibody II also recognized vasopressin terminals.

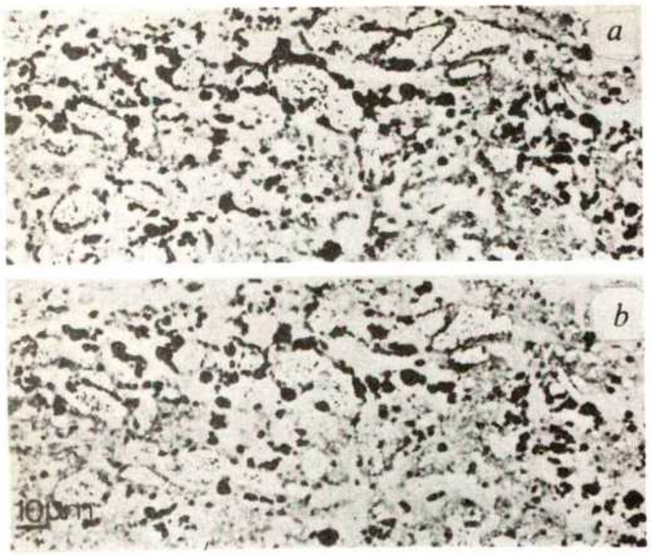

Fig. 3 Two serial sections through a Brattleboro rat neural lobe showing *a*, oxytocin-IR, and *b*, Met-enkephalin I-IR. Most immunoreactive terminals coincide on the two sections. ×400.

releasing hormone or of somatostatin stores[3], agrees with coexistence of the two peptides in the same nerves. Also, in homozygous Brattleboro rats enkephalin content was distinctly lower than that in heterozygote littermate controls[3,10]. Thus it is possible that in this vasopressin-deficient strain a vasopressin-related enkephalin system is impaired.

Our study suggests that enkephalins are co-peptides of the oxytocin and vasopressin neurosecretory systems and that Met(Leu)- and Leu-enkephalin occur in separate neurones. Whether the two peptides are stored in the same secretory granule is not known. The secreted enkephalins may act on autoreceptors on their own nerve fibre or may influence neighbouring terminals, interfering with oxytocin and vasopressin release.

Differential distribution of Met- and Leu-enkephalin-IR has been found in another neuronal system[11]. However, the existence of separate neurones for the two enkephalins has been questioned by the characterization of a putative common precursor of Met-enkephalin and Leu-enkephalin in the adrenal medulla[12]. However, so far only peptides containing either the Met- or Leu-enkephalin sequence have been extracted from brain tissue[13,14] or pituitaries[9,15].

We thank Dr F. W. van Leeuwen for purified oxytocin and vasopressin antibodies. Anti-Met-enkephalin II and anti-Leu-enkephalin were from the Immuno Nuclear Corporation. Anti-Met-enkephalin I was from K.H.V. This work was supported by the Deutsche Forschungsgemeinschaft (SFB 87, B2). K.H.V. is a recipient of a Heisenberg Stipendium.

Milk ejection in a marsupial, *Macropus agilis*

Dennis W. Lincoln & Marilyn B. Renfree

School of Environmental and Life Sciences, Murdoch University, Western Australia 6150

Marsupials give birth to young which are almost embryonic in form, and for the first few months of postnatal life they remain continuously attached to the nipples of the lactating mammary glands. The immature appearance of the neonate and the presence of an elaborate musculature in the wall of the pouch led observers to suggest that the contraction of the pouch functioned to compress the lactating mammary glands and thus force milk into the mouth of the young[1]. This view was dismissed when Enders[2] demonstrated that milk was not expressed in the opossum, *Didelphis virginiana*, following electrical stimulation of the motor nerves supplying the muscles of the pouch, and he implied that milk was obtained solely by the sucking of the young. In most eutherian mammals very little milk can be extracted unless facilitated by an oxytocin-induced contractionof the myoepithelial cells surrounding the alveoli of the mammary gland. It is not known whether such a process of milk ejection exists in a marsupial, although oxytocin has been identified in the posterior pituitary gland[3,4] and has been used as an aid in the collection of milk[5]. We recorded intramammary pressure from the lactating mammary gland of the agile wallaby, *Macropus agilis*, and examined the pressure responses evoked by injection of oxytocin and electrical stimulation of the presumptive oxytocin neurones. We report here three striking differences from those reported for eutherian mammals: the mammary gland of the wallaby, particularly during the early part of lactation (<100 days), was more sensitive to oxytocin, produced higher intraductal pressures and contracted at lower frequencies of brain stimulation (4 pulses per s). We may therefore conclude that the wallaby, far from discarding during its evolution the milk-ejection response to oxytocin, has refined the response to permit it to feed simultaneously both newly born pouch young (<1 g) and young at foot (>2,500 g).

Studies were made of 18 adult female agile wallabies maintained in the Native Fauna Research Unit of Murdoch University, Western Australia. The agile wallaby is a continuous and opportunistic breeder found abundantly in the wild in the northern parts of Australia and New Guinea[6,7]. Pregnancy lasts for less than 1 month and the neonate (~650 mg) attaches to one of the four nipples in the pouch and induces a lactation confined to that mammary gland for about 350 d. Lactation is characterized by three stage: (1) pouch young continuously attached to the nipple (0–100 days); (2) pouch young detached from the nipple (80–210 days), and (3) young at foot and sucking occasionally (190–360 days). Evacuation of the pouch occurs at ~200 days—this triggers reactivation in the growth of the embryo in the uterus with the birth of the baby 26 days later[7]. The neonate attaches to one of the three unused nipples and as a result a second lactation develops in parallel to the previous one, but lagging by over 200 days.

After capture, the pouch young were removed and aged[6], and the mothers (10–15 kg) were anaesthetized with intravenous sodium pentobarbitone (30 mg per kg). Intramammary pressures were recorded from one or more of the 20–30 galactophores in the nipples of the lactating mammary glands. Recordings were made from glands, which according to the age of the dependent young, varied over 38–350 days of lactation.

Injections of oxytocin, either into a catheterized tail vein or external jugular vein, promoted a rise in intramammary pressure after 23–60 s, depending on the dose of oxytocin and the

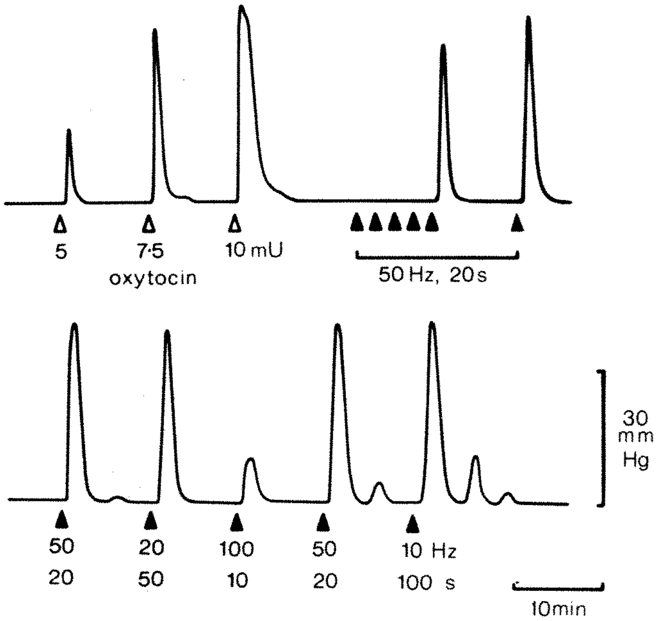

Fig. 1 Recordings of pressure from a galactophore of a mammary gland of an agile wallaby *Macropus agilis* at day 82 of lactation, illustrating the response to injections of oxytocin and electrical stimulation of presumptive oxytocinergic neurones in the region of the basal hypothalamus. The wallaby was anaesthetized with sodium pentobarbitone (30 mg per kg) and the galactophore, one of 27 in the nipple, was cannulated with a 25-gauge needle and connected to a pressure transducer filled with 1% sodium citrate. The two traces are continuous. In the upper trace the first three peaks are the responses to three bolus injections of oxytocin into the external jugular vein. A stimulating electrode was then lowered into the basal part of the hypothalamus from a point of entry in the skull 28 mm anterior to the bregma suture. A 50 Hz × 20 s pulse train (1 ms × 700 μA biphasic pulses) (solid triangles) was applied at intervals as the electrode was lowered, until a position was obtained within the brain at which milk-ejection was induced. The lower trace illustrates a stimulation protocol in which 1,000 pulses were applied at frequencies ranging from 10 to 100 Hz, at 10-min intervals.

lactational age of the mammary gland. Peak pressures occurred after 60–90 s and baseline pressures returned after 120–180 s. The threshold dose of oxytocin for the production of a mammary contraction was 2–15 mU, and was substantially lower in recordings from mammary glands in early lactation (< 100 d). The dose–response curve was steep and the pressure responses attained a plateau of 30–60 mm Hg after injections of ≥20–30 mU oxytocin (Figs 1, 2).

Electrical stimulation of the hypothalamo-neurohypophysial tract in the region of the basal hypothalamus with a 50 Hz × 20 s pulse train was most effective at promoting milk ejection. The pressure wave evoked by stimulation was slightly more progressive in onset than that produced by a bolus injection of oxytocin, although the peak of the pressure wave was slightly more abrupt. A 50-Hz frequency is optional for the induction of oxytocin release in the rabbit and rat and insufficient oxytocin is released in these species to promote milk ejection at ≤20 Hz (refs 8, 9). Surprisingly, when 1,000 pulses were applied to the wallaby in the form of a 10 Hz × 100s pulse train the milk-ejection response was equal in amplitude to that seen with higher frequencies of stimulation. Subsequently, very effective increases in pressure were obtained with prolonged stimulation at 4.5 Hz and some evidence of oxytocin release was seen with even lower frequencies (Fig. 2).

Marsupials have evolved a highly successful reproductive strategy when compared with eutherian mammals. A key feature of their success seems to be the refinement of the milk-ejection response to oxytocin to permit the mother to nourish the very immature young continuously in the months immediately after birth and, in some species, to allow her intermittently to feed an older sibling on a second lactating mammary gland. Two observations make this a practical possibility: release of oxytocin in response to low-frequency electrical stimulation and the extreme oxytocin sensitivity of the mammary glands in early lactation. In eutherian mammals, the posterior pituitary gland contains a calcium-dependent process of spike facilitation where action potentials entering the nerve terminals in the gland, at ≥30 Hz, release 100–1,000 times more oxytocin than impulses arriving at ≤10 Hz, and such facilitation is used to generate a pulsatile pattern of hormone release[9]. Frequency facilitation was not observed in the wallaby, which suggests that the process of hormone release differs in some fundamental respect from that in the rat. However, the observation of milk ejection in response to electrical stimulation at 5 Hz raises the possibility that low levels of electrical activity in the oxytocinergic neurones during the early stages of lactation such as might be evoked by the activities of a small pouch young, could result in a small but sustained release of oxytocin sufficient to contract the highly sensitive mammary gland. Such a release would serve in the absence of a tight teat sphincter to produce 'continuous' milk-ejection, with mammary contractions recurring at intervals of ~4 min (Figs 1, 2). Furthermore, the pressures generated in these young glands at milk ejection are fivefold higher than those recorded in a rat and are sufficient to cause milk to leak from the nipple in the absence of an attached young. Thus, the original idea that milk was forced into the neonate may not be so far from the truth, although the mechanism is one of milk ejection rather than contraction of the pouch muscles. The decline in oxytocin sensitivity as lactation progresses makes it possible to run two lactations in parallel, but >200 days out of step. A low level of oxytocin, as discussed above, would not contract a mammary gland feeding a young at foot. Clearly, however, a juvenile of >3,000 g sucking on the enlarged nipple of a mammary gland in late lactation must generate an enormous sensory stimulus compared with that produced by a neonate of <1 g. In such circumstances it seems plausible that a large release of oxytocin could occur and cause a contraction of the older mammary gland. One consequence, though of little

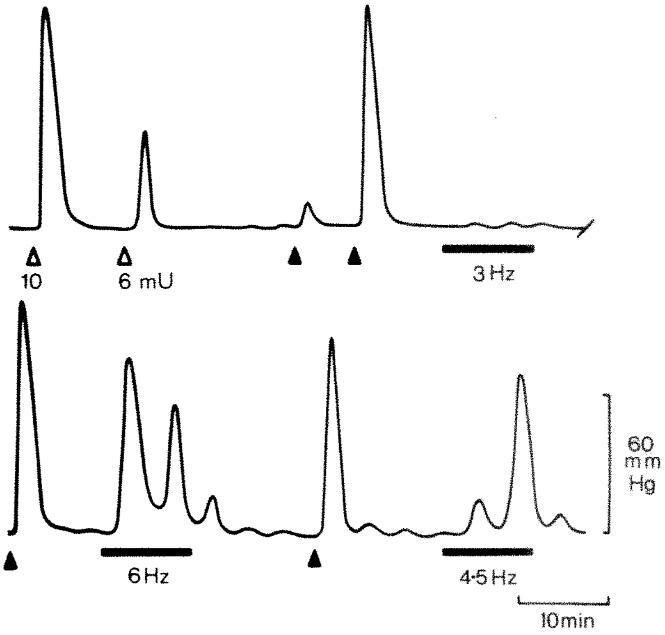

Fig. 2 Intramammary pressure recordings from an agile wallaby at day 116 of lactation. The recording technique and the presentation of the data are as described in Fig. 1 legend. The two traces are continuous, and illustrate the relative effectiveness of prolonged low-frequency stimulation at 3–6 Hz (solid bar) compared with a short burst of high-frequency stimulation (50 Hz × 20 s) (solid triangles) on the induction of milk ejection. Note that prolonged stimulation produced multiple contractions with pressure peaks at intervals of ~4 min.

significance, as the mammary pressure response peaks at 30–60 mm Hg with oxytocin injections >30 mU, is that the older young may give the younger sibling an additional meal.

A neuropterous larva uses an allomone to attack termites

J. B. Johnson & K. S. Hagen

Division of Biological Control, Department of Entomological Sciences, University of California, Berkeley, California 94720

Larvae of *Lomamyia* spp. (Neuroptera: Berothidae) have been tentatively associated with several types of prey since they were first identified[1]. In all cases, the assumed prey lived in a confined habitat—an ant nest or termite gallery[2]. *Lomamyia latipennis* Carpenter has been the most thoroughly studied of these unusual Neuroptera. The immature states were described[3,4] and the association with termites strengthened using *Zootermopsis angusticollis* Hagen (Isoptera: Kalotermitidae) as prey for a group of larvae[4]. A low survival rate of the larvae suggested that another termite might be the normal host. We now report field and laboratory findings which demonstrate the predator–prey relationship between *L. latipennis* and the subterranean termite *Reticulitermes hesperus* Banks (Isoptera: Rhinotermitidae) and describe their unique method of attacking prey with an aggressive allomone.

During the summers of 1979 and 1980 field studies and collections were conducted in Gates Canyon, Solano County, California. Three significant field observations were made concerning the association of *L. latipennis* and *R. hesperus.* On 18 June 1979, a cluster of eight hatched berothid eggs was found hanging on a single stalk from a projection of sapwood on an oak log (*Quercus* sp.) infested with *R. hesperus.* If the larvae behaved like those observed in the laboratory, they crawled up the stalk and across the log surface entering holes and crevices, seeking the termites in the log. When the log was chopped open a well fed first instar berothid larva was found. Then, on 14 June 1980 an adult female *L. latipennis* emerged from a stump of elderberry (*Sambucus coerulea* Raf.) which had been brought into the laboratory about 1 month earlier as a source of *R. hesperus.* No evidence of berothids was found in or near colonies of *Z. angusticollis* or *Zootermopsis nevadensis* Hagen, the only other species of termites recorded in northern California.

Nine female *L. latipennis* were collected under mixed UV/visible light on 2 June 1979 and 9 June 1980. They deposited fertile eggs in the laboratory when fed artificial honeydew consisting of dried yeast (*Kluyveromyces fragilis*), autolysed brewers yeast (*Saccharomyces cerevisiae*) and honey (6 g : 1 g : 10 g). After hatching, individual larvae were placed in 3-cm^3 glass vials half-filled with frass from the termite colonies. Live termites were supplied daily from source colonies maintained in the laboratory. All three species of termite were tested as prey for *L. latipennis* larvae. Only larvae fed *R. hesperus* successfully completed their larval development.

Observations of *L. latipennis* larvae in laboratory colonies of *R. hesperus* indicated that they are true termitophiles, living and moving freely among the termites in their galleries. In the colonies and rearing vials the larvae generally exhibited some caution when near the much more heavily sclerotized termites, but no larva was observed to be attacked. This pattern of coexistence changed only when the larvae were ready to feed.

First instar *L. latipennis* larvae ($\sim$0.07 mg), which are much smaller than *R. hesperus* workers ($\sim$2.5 mg), displayed a consistent attacking behaviour. A larva repeatedly approached and retreated until the tip of its abdomen was directed at the termite's head. The apex of the abdomen was then lifted and waved past the termite's face, apparently without contact. The termite apparently was not repelled, as it made no obvious effort to escape. One to three minutes later it was incapacitated, lying supine, with its legs moving irregularly. Two to five minutes after the collapse, motion ceased. During this time, the berothid larva continued to advance and withdraw. Feeding occurred only after the prey had become still. If not fed upon, the termite's heart would continue to beat for long as 3 h, showing that the initial immobility was merely paralysis, though death ultimately occurred. The termite may also be preserved by the allomone, but initial tests were inconclusive.

Third instar *L. latipennis* larvae behaved similarly, but the obvious wave of the abdomen was not seen and individuals were observed to kill as many as six *R. hesperus* simultaneously, in the rearing vials. Apparently, the larger larvae produce enough of the allomone to eliminate the need for such precise application to the prey. Second instar larvae are sessile and do not feed[4]. As with the active instars, they were not attacked by the termites, although they were exposed and apparently defenceless.

Soldiers and reproductives of *R. hesperus* were affected in the same manner as the workers. Individual 'pseudoworkers' of the *Zootermopsis* spp. were not affected in this way by *L. latipennis* larvae, although the larvae could feed, with apparent difficulty, on freshly killed *Zootermopsis.* This difference could be due to physiological differences between the termites or simply a matter of dosage, because the *Zootermopsis* spp. are much larger ($\sim$8 to >50 mg). If it is a matter of dosage this could explain the partial success of the group rearing using *Z. angusticollis* as prey[4].

Two compartment test chambers were used to verify that contact between the larva and termite was not required. In each case, a berothid larva and one *R. hesperus* were put into one compartment and a termite into the other. The first type of test chamber was a 0.7-cm^3 glass vial divided longitudinally by a strip of filter paper. In 10 tests the second termite was invariably incapacitated within a few minutes after the first had been attacked by the berothid. The second variety of test chamber was a 0.5-cm^3 glass tube divided transversely by a disk of cork pierced by a piece of organdy screened capillary tubing. When the prey termite had been attacked, a syringe was used to pull a volume of air, equivalent to that in the first chamber, into the second, as a capillary tube vent permitted air to enter the first. In 7 out of 20 trials, the test termite was also affected. The inconsistent results were attributed to the relatively crude construction of the test chamber and variability in the timing of the suction. In 20 tests without a berothid larva, none of the 40 termites exhibited any signs of distress.

As it can pass through a filter paper barrier and be moved by an air current, the toxin must be active as a gas or an aerosol. This observation of an allomone used in predation is unique among the insects. The only arthropod previously known to use an allomone in this way seems to be the mite, *Womersia strandtmanni* Wharton (Acarina: Leeuwenhoekiidae)[5]. Because the *L. latipennis* allomone apparently lacks a defensive function, we believe that its primary purpose is aggressive, and we propose the term aggressive allomone to describe this situation. Theoretically, it is possible, and in fact seems probable, that the berothid's allomone evolved from a defensive allomone which was necessary early in their association with *R. hesperus*, before their termitophilia evolved to its current state.

0028–0836/81/060506—02$01.00

While rearing *L. latipennis* larvae, we noted that Psocoptera (Psocidae) lived in the vials unaffected by the allomone. To test the specificity of the toxin further small Diptera (Drosophilidae) and Hymenoptera (*Coccophagus cowperi* Girault, Aphelinidae and *Metaphycus funicularis* Annecke and *Metaphycus stramineus* Compere, Encyrtidae) were placed in the test chamber. None of these insects, or other berothid larvae, was affected by the allomone.

Motivated by the unique nature of the allomone, its specificity and the importance of the target insects, efforts are now directed at establishing laboratory cultures of *L. latipennis* and isolating and identifying the active compound(s). Synthesis of the allomone would permit detailed study of its activity and specificity and could yield a valuable new means of controlling termites.

We thank Dr Peter Duelli for his assistance and discussions. This research was supported, in part, by the USDA Western Regional Biological Control Project (W-84).

Circulating angiotensin II and adrenal receptors after nephrectomy

G. Aguilera, A. Schirar, A. Baukal & K. J. Catt

Endocrinology and Reproduction Research Branch,
National Institute of Child Health and Human Development,
National Institutes of Health, Bethesda, Maryland 20205

Mineralocorticoid secretion is predominantly controlled by the octapeptide angiotensin II, which exerts trophic actions on the adrenal glomerulosa and acute regulatory effects on aldosterone biosynthesis. The trophic actions include stimulation of angiotensin II receptors and enzymes of the aldosterone biosynthetic pathway[1,2], with corresponding enhancement of the aldosterone secretory capacity of the adrenal gland. The positive regulatory action of angiotensin II on its adrenal receptors occurs with elevations of the circulating peptide concentration within the physiological range and probably contributes to the increased sensitivity of the adrenal during sodium deficiency[3,4]. In this action, angiotensin II differs from other hormones which decrease their target-cell receptors[5–7]. However, the increase in adrenal angiotensin II receptors following nephrectomy has been interpreted as evidence for a tonic down-regulating effect of angiotensin II on its adrenal receptors[8]. To clarify these conflicting views we evaluated the effects of nephrectomy on adrenal angiotensin II receptors in relation to blood angiotensin II and plasma electrolyte levels. We show here that hyperkalaemia contributes markedly to the post-nephrectomy increase in adrenal angiotensin II receptors, and that circulating angiotensin II levels persist for an unexpectedly long period after nephrectomy, presumably due to tissue generation of the octapeptide.

Adult male Sprague–Dawley rats were bilaterally nephrectomized and groups killed at intervals up to 48 h. Angiotensin II receptors were measured in the zona glomerulosa by binding assay of adrenal capsule homogenate as described previously[9] and blood samples were obtained for analysis of plasma renin activity (PRA)[10], blood angiotensin II (ref. 11) and serum

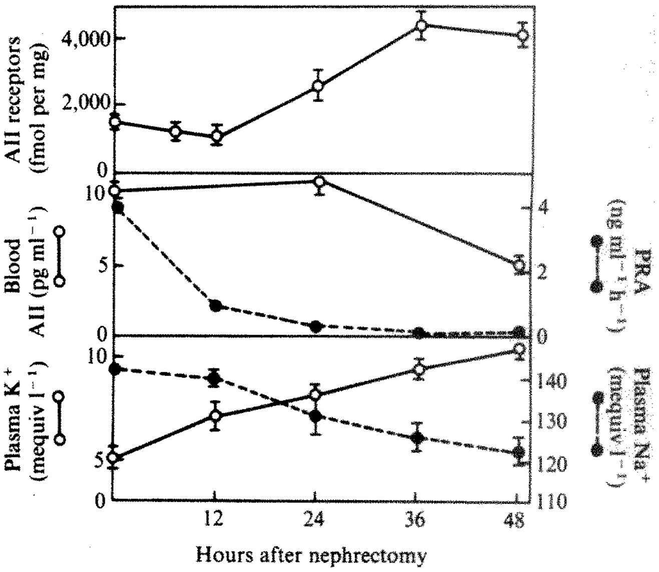

Fig. 1 Effects of nephrectomy on adrenal glomerulosa angiotensin II (A II) receptors (upper panel), plasma renin activity (PRA) and angiotensin II (middle panel) and plasma sodium and potassium (lower panel). The number of angiotensin II receptors was measured in the 300,000*g* particulate fraction of adrenal capsular tissue[9], and data points represent the mean and s.e. of three experiments. The data for PRA and blood angiotensin II are the mean and s.e. of assays performed on 6–15 individual animals. Angiotensin II was assayed in 5–7-ml aliquots of blood, collected in acetone and processed as previously described[11]. The extracts were resuspended in 1 ml of HEPES buffer and angiotensin II concentration was determined by radioimmunoassay (RIA). The ED_{50} of the RIA was 30–40 pg angiotensin II and the lower limit of sensitivity was less than 5 pg, allowing the detection of values as low as 2 pg ml^{-1} of blood.

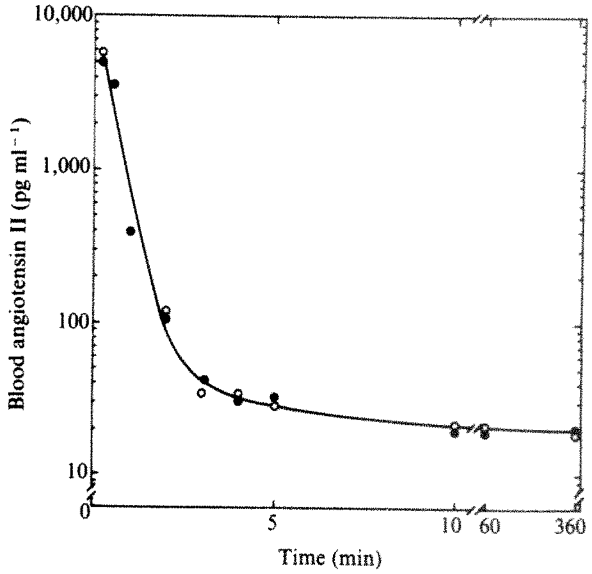

Fig. 2 Rate of disappearance of angiotensin II from the circulation of intact (○) and nephrectomized (●) rats. After injection of 500 ng angiotensin II as a single intravenous injection under ether anaesthesia, animals were killed at timed intervals by decapitation and blood was collected into acetone for extraction and RIA of angiotensin II. Each point represents the mean of values derived from three or four rats.

electrolytes. After nephrectomy, the number of adrenal angiotensin II receptors was unchanged for 12 h, and then increased progressively over the next 24 h to almost double the control level (Fig. 1). As expected, PRA was markedly decreased after nephrectomy and became almost undetectable by 36 h. However, when PRA was reduced by 90% at 24 h, blood angiotensin II levels did not show a commensurate fall, but remained at the levels found in intact rats. Thus, the concentration of blood angiotensin II in 21 nephrectomized rats was 14.7 ± 6.9 pg ml^{-1} (mean ±s.d.) and in 22 normal animals 13.2 ± 6.0 pg ml^{-1}. Furthermore, after 48 h, when PRA was undetectable, there was only a 50% fall in blood angiotensin II concentration. In contrast, low blood angiotensin II levels were found in sodium-loaded rats (1.3 ± 1.5 pg ml^{-1}, $n = 11$) and in animals treated with the converting-enzyme inhibitor, captopril (2.1 ± 2.1 pg ml^{-1}, $n = 9$). In nephrectomized rats, plasma sodium decreased, and plasma potassium increased markedly to levels over 10 mequiv l^{-1} within 48 h (Fig. 1). Elevation of the extracellular potassium concentration is known to exert a direct trophic action on the zona glomerulosa, causing marked increases in the number of angiotensin II receptors and aldosterone secretion[12]. The rise in plasma potassium following nephrectomy would therefore contribute to the observed increase in angiotensin II receptors in the adrenal gland. These results also demonstrate that the increase in angiotensin II receptors observed after nephrectomy cannot be attributed to the removal of a negative effect of circulating angiotensin II on its adrenal receptors.

The unexpected persistence of normal circulating levels of angiotensin II after nephrectomy was not due to a decrease in the metabolic clearance rate of the peptide in the absence of the kidneys. As shown in Fig. 2, the disappearance of angiotensin II from the circulation after a single injection of the peptide was identical in intact and nephrectomized rats. Computer analysis of the data[13] gave half times of 0.46 ± 0.1 and 4.0 ± 0.2 min for the fast and slow components of the disappearance curves. The rapid clearance of angiotensin II from the circulation indicates that angiotensin formation from non-renal renin or renin-like enzymes must be responsible for the circulating peptide observed in anephric animals.

Such extravascular generation of angiotensin II is also suggested by the finding that several tissue extracts contain immunoreactive angiotensin-like material. The tissue content of angiotensin II in adrenal capsule, decapsulated adrenal, aorta and uterus was: 22.2 ± 5, 7.3 ± 2, 11.5 ± 3 and 14.2 ± 2 pg per mg, respectively (mean ±s.e. of 5–10 determinations). In diaphragm extracts, only negligible amounts of the peptide were found. The relatively high content of immunoreactive angiotensin II in the adrenal capsule was not decreased after nephrectomy. The adrenal capsular content of angiotensin II is not solely attributable to receptor-bound peptide, as adrenal angiotensin II was decreased rather than increased after infusion of the peptide (Fig. 3). The absence of increased capsular angiotensin II is not simply the result of receptor down-regulation by the infused peptide[8], because high doses of angiotensin II reduce but do not abolish its adrenal receptors[4].

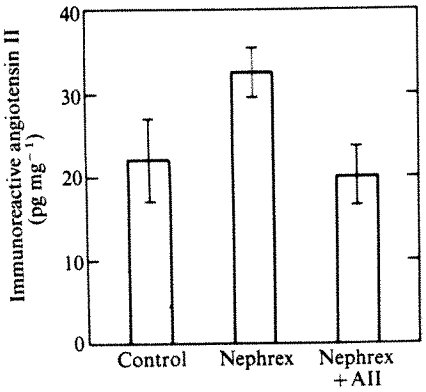

Fig. 3 Immunoreactive angiotensin II in extracts of rat adrenal capsule: effects of nephrectomy and angiotensin II infusion. Angiotensin II was infused at the rate of 200 ng min^{-1} from osmotic minipumps (Alza) implanted intraperitoneally immediately after nephrectomy. Adrenal capsules were rapidly frozen on dry ice, homogenized in 0.01 M acetic acid, boiled for 10 min and extracted in 85% acetone. The extracts were dried down and redissolved in phosphate buffer, and angiotensin II concentration was measured by RIA. Bars represent the mean and s.e. of values obtained for the paired adrenal capsules of 6–10 individual rats.

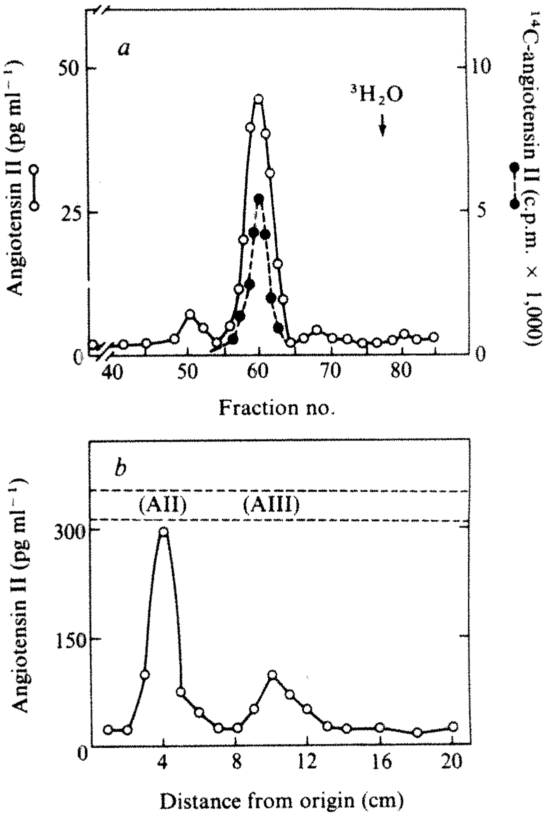

Fig. 4 *a*, Chromatography of adrenal capsule extract on Sephadex G-15 (1 × 75 cm) in 0.01 M acetic acid. Angiotensin II concentration was measured by RIA in the individual fractions, and ^{14}C angiotensin II was used as a marker in separate experiments to calibrate the column. *b*, Fractionation of immunoreactive angiotensin II by TLC in butanol–3% ammonia (5 : 1). The positions of angiotensin II and des-Asp^1-angiotensin II are indicated as AII and AIII, respectively.

The identity of the angiotensin-like material in adrenal capsules was examined in acetone extracts of tissue homogenates prepared in 0.01 M acetic acid and heated at 100 °C for 10 min. Chromatography on Sephadex G-15 revealed a single peak of immunoreactive angiotensin II, corresponding to the established elution profile of ^{14}C-angiotensin II. TLC of such adrenal extracts revealed two peaks of immunoreactive material, the major component of about 80% corresponding to the R_F of angiotensin II, and a smaller peak corresponding to des-Asp^1-angiotensin II (Fig. 4). The angiotensin II peak was eluted with methanol–ammonia (2 : 1), dried down and redissolved in phosphate buffer for evaluation of biological activity by adrenal radioligand–receptor assay and by bioassay in collagenase-dispersed adrenal capsular cells[14]. The eluted immunoreactive angiotensin displaced ^{125}I-angiotensin II from adrenal membranes and stimulated aldosterone production in glomerulosa cells, with equivalent potency to the peptide concentration determined by radioimmunoassay.

The persistence of normal circulating levels of immunoreactive angiotensin II after nephrectomy was observed in assay conditions which detect extremely low blood levels of the peptide after converting-enzyme inhibition[4] or sodium loading. As plasma renin in addition to injected angiotensin II is rapidly cleared from circulation, generation of angiotensin II in the tissues must account for the presence of the peptide in the blood after nephrectomy. Such local production was supported by the demonstration of angiotensin II in several tissue extracts, including the adrenal capsule. The possible contribution of angiotensinase-dependent hydrolysis of tracer angiotensin II to the apparent presence of the tissue peptide has been noted in kidney extracts[15,16]. This effect was avoided in the present study by boiling the homogenates for 10 min before acetone extraction. Also, after chromatographic purification, the angiotensin-like material maintained its immunoreactivity and biological activity. The generation of such significant amounts of biologically active angiotensin II in the tissues may account for the normal blood levels of the peptide detected 24 h after nephrectomy. Although decreases in blood angiotensin II levels were previously observed 18 h after nephrectomy in sodium-restricted rats[12], this earlier fall could be related to the higher plasma angiotensinase activity present during sodium deficiency[17].

Renin-like[18–20] and converting-enzyme[21–23] activity are present in several tissues; we have confirmed that renin activity is present in the adrenal capsule and other tissues, and seems to vary with the PRA during altered sodium intake. Such tissue renin could have at least partly accumulated from renal renin in the circulation, as renin activity in the aorta begins to decrease several hours after nephrectomy[24]. In a related study, PRA fell rapidly after nephrectomy, whereas the blood pressure and the hypotensive response to converting-enzyme inhibition decreased over several hours[25]. Such a process would also be consistent with the gradual fall of blood angiotensin II observed in the present experiments, with no major decrease until 48 h after nephrectomy. However, tissue isorenin is probably responsible for the local generation of a significant proportion of the angiotensin II that is present in the tissues and continues to circulate after bilateral nephrectomy. Normal levels of renin and angiotensin II have been found in the blood of nephrectomized humans and did not rise after sodium depletion[26,27]. Such findings, with those presented here, suggest that extra-renal renin may provide a basal level of local and circulating angiotensin II against which the actions of renal renin are superimposed in normal physiological conditions.

Gating of a muscle K^+ channel and its dependence on the permeating ion species

P. R. Stanfield, Frances M. Ashcroft & T. D. Plant

Department of Physiology, University of Leicester,
Leicester LE1 7RH, UK

In excitable cells, ions permeate the cell membrane through ionic channels, some of which open and close in response to changes in the potential difference across the membrane. It has been supposed that this opening and closing (or gating) process is largely independent of the permeating ion. However, we show here that the gating of the resting potassium permeability of frog skeletal muscle depends on the species of ion which carries current across the membrane. The potassium permeability investigated allows K^+ to move in across the membrane more easily than out[1,2]. This property is known as inward or anomalous rectification and is shared by cell membranes of skeletal muscle[1–3], egg[4] and certain other cells[5–7]. In both egg cells[8] and skeletal muscle fibres[9], the group IIIB metal ion Tl^+, which can replace K^+ in several other systems in experimental conditions[10–12], also permeates the inward rectifier. Indeed, Tl^+ is more permeant than K^+ (refs 8, 9). However, when Tl^+ carries current inwards across the membrane, the inward rectifier inactivates over a brief period when the membrane is hyperpolarized, whereas when K^+ carries current, the permeability increases with time under hyperpolarization.

Our experiments were carried out on frog sartorius muscle in voltage-clamp conditions[13] at 1–3 °C, and Fig. 1 summarizes the main result. In muscle fibres immersed in a solution containing 80 mM K^+, the current flowing under hyperpolarization increases with time (Fig. 1*a*) along an exponential time course whose time constant falls with increasing hyperpolarization[14–16].

Thus, in K^+, steady-state currents are larger than initial currents (Fig. 1*b*), although initial currents themselves yield an inwardly rectifying current–voltage relation[14–16]. In the solution we used there was a subsequent slow fall in current caused by K^+ becoming depleted from the lumen of the transverse tubular system, in whose walls much of the K^+ permeability resides[14,17,18]. (The inactivation of K^+ currents under extreme hyperpolarization, described by Almers[14,19], has been shown to be a voltage-dependent block by Na^+ (ref. 18) and our solutions contained no Na^+.)

In contrast to the results in K^+, when muscle fibres are immersed in a solution containing 80 mM Tl^+ (but no K^+), the currents which flow under hyperpolarization (Fig. 1*c*) inactivate along an exponential time course. Thus, steady-state currents are smaller than instantaneous currents, as may be seen from the current–voltage relations of Fig. 1*d*, and the steady-state current–voltage relation has a region of negative slope.

Steady-state currents, expressed as a fraction of instantaneous currents, are plotted against membrane potential in Fig. 2*a*. The steady-state inactivation curve may be fitted by a Boltzmann relation of the form:

$$p_\infty = \{1 + \exp[-(V - V_p)/a]\}^{-1} \qquad (1)$$

where p_∞ is the fractional current in the steady state at a membrane potential V; $p = 0.5$ at a membrane potential $V_p = -172$ mV, and $a = 48$ mV.

The time constants for inactivation are plotted against membrane potential in Fig. 2*b*, showing that the rate of inactivation falls as hyperpolarization is increased, is at its slowest at about −160 to −180 mV, and then increases again under further hyperpolarization. This voltage dependence of the rate of inactivation, and the fact that similar time constants are obtained whether they are measured from the onset of inactivation under a single hyperpolarization or from recovery from inactivation using a two or a three pulse method, suggests that

0028–0836/81/060509—03$01.00

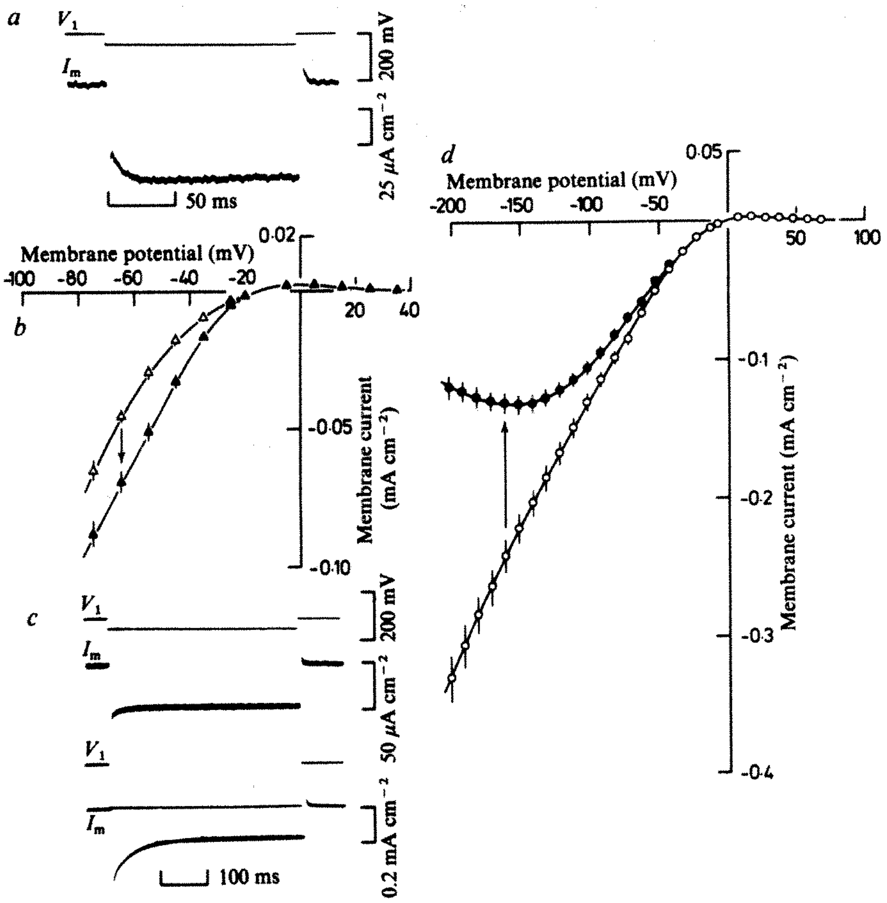

Fig. 1 The gating of inward rectification in K^+ (*a, b*) and in Tl^+ (*c, d*) solutions. *a*, Records of membrane potential (V_1) and membrane current (I_m) from a muscle fibre immersed in a solution containing 40 mM K_2SO_4 (80 mM K^+), 8 mM $CaSO_4$, 113 mM sucrose, 2 mM Tris-maleate buffer (*p*H 7.2). Fibre resting potential (*RP*), −16 mV; holding potential (*HP*), −16 mV, *T*, 1.2 °C, the hyperpolarization is 40 mV in amplitude. *b*, Current–voltage relations for 12 fibres in 80 mM K^+ solution for instantaneous (△) and steady-state (▲) currents. A least squares method was used to fit the exponential turn-on of currents and to compute instantaneous currents by extrapolation. Symbols and vertical bars give mean ±s.e.m. of 12 fibres. *RP*, −14.8 ± 0.6 mV. Abscissa, membrane potential; ordinate, membrane current. *c*, Records of V_1 and I_m from a fibre immersed in a solution containing 40 mM Tl_2SO_4, 8 mM $CaSO_4$, 113 mM sucrose, 2 mM Tris-maleate buffer (*p*H 7.2). Fibre *RP*, −2 mV; *HP*-2 mV; *T*, 1.2 °C, the hyperpolarizations are 40 and 180 mV in amplitude. *d*, Current voltage relations for fibres in 80 mM Tl^+ solutions for instantaneous (○) and steady-state (●) currents. Steady-state currents were computed by correcting for depletion of Tl^+ by extrapolation to zero time using a least squares fit for a straight line to currents between 250 and 400 ms. Depletion is sufficiently slow to allow such a fit at times <400 ms. Instantaneous currents were computed by making a least squares fit to the exponential decline of currents at short times. Abscissa, membrane potential; ordinate, membrane current. *RP*, −2.7 ± 0.4 mV ($n = 9$). In both *b* and *d*, a linear element, treated as leak, has been subtracted from the current voltage relations. This was obtained by extrapolating from currents obtained with depolarizations greater in amplitude than 60 mV through the holding potential.

the inactivation has simple first order kinetics, which could be represented in the following way:

$$\underset{(1-p)}{\text{Channels closed}} \underset{\beta_p}{\overset{\alpha_p}{\rightleftharpoons}} \underset{(p)}{\text{channels open}}$$

with *p* giving the fraction of channels open at a given membrane potential and time, and with the rate constants α_p and β_p approximating to exponential functions of membrane potential (Fig. 2*c*) of a form expected from equation (1).

The rate of inactivation has a high temperature dependence (Fig. 3*a*), with the Q_{10} being 2.75 ± 0.14 ($n = 6$); at room temperature, the onset of the inactivation cannot easily be separated from the capacity transient accompanying hyperpolarization. The voltage dependence of steady-state inactivation is unaltered by changing temperature (Fig. 3*b*). The Q_{10} for the amplitude of the Tl^+ currents was 1.42 ± 0.18 ($n = 6$), similar to that found for K^+ currents[14,19].

The results we describe are very similar to those expected if a blocking cation, present in the external solution, were driven into the membrane by hyperpolarization, blocking the inward movement of Tl^+. However, our solution contained only Ca^{2+},

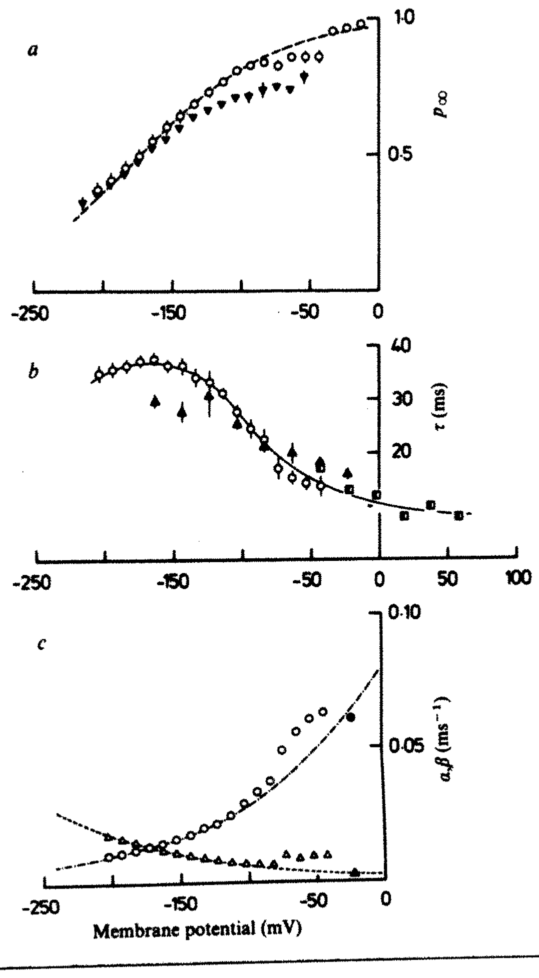

Fig. 2 Inactivation of inward rectification in Tl solutions. *a*, Steady-state inactivation for 80 mM Tl^+ (○) and 40 mM Tl^+ + 40 mM K^+ (▼) solutions. Abscissa, membrane potential; ordinate, p_∞, the steady-state current expressed as a fraction of the instantaneous current. Dashed line, Boltzmann relation given in equation (1) of the text. *b*, Time constants for inactivation (ordinate) plotted against membrane potential (abscissa). ○, Values obtained from inactivation of currents under hyperpolarization (mean ± s.e.m., $n = 9$); ▲, values obtained from recovery of current at the given membrane potentials after a 180 mV hyperpolarization of 150 ms duration (mean ± s.e.m., $n = 4$); ◧, rate of recovery at given membrane potential obtained by applying a hyperpolarizing test pulse of 180 mV amplitude and 150 ms duration a variable interval after an inactivating pulse of 180 mV amplitude and 150 ms duration ($n = 1$). The line to the points was drawn by eye. $T = 1$–3 °C. *c*, Rate constants for the inactivation. ○, ●: α_p; △, ▲: β_p. Open symbols computed from the open symbols of *a* and *b*. Closed symbols, computed from ▲ for a 20-mV hyperpolarization in *b* and the relevant open symbol in *a*. Dashed and dotted line, $\alpha_p = \bar{\alpha}_p \exp[(V - V_p)/2a]$; dashed line, $\beta_p = \bar{\beta}_p \exp[-(V - V_p)/2a]$ with $\bar{\alpha}_p = \bar{\beta}_p = 1.34 \times 10^{-2}\ \text{ms}^{-1}$; $V_p = -172$ mV; $a = 48$ mV.

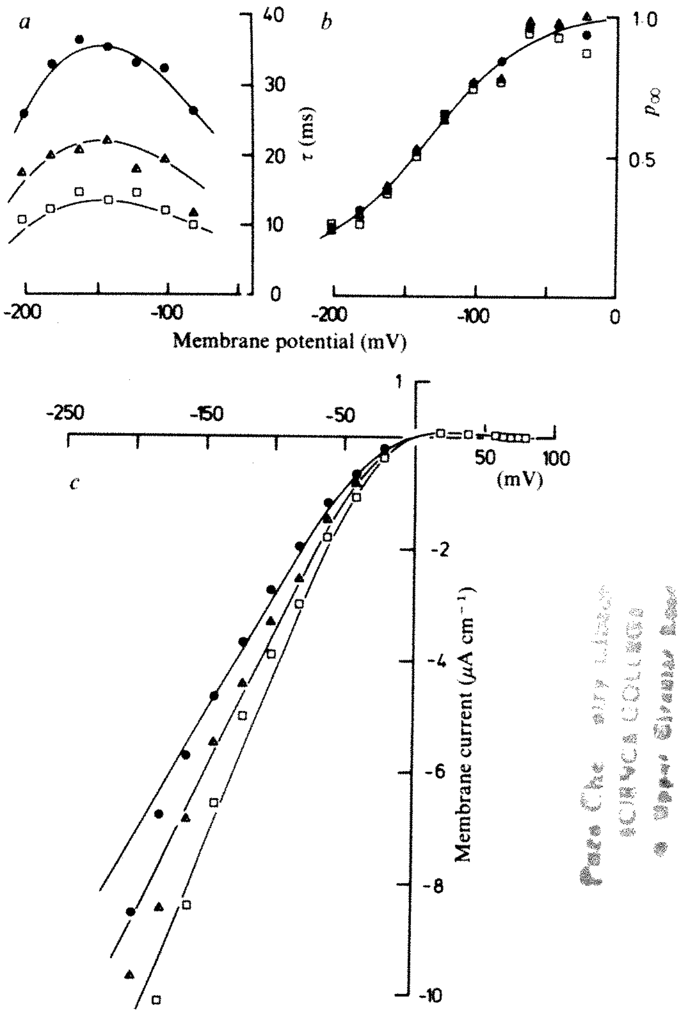

Fig. 3 Q_{10} for inactivation in Tl^+ solutions. *a*, Time constants for inactivation (ordinate) against membrane potential (abscissa), measured at 1.5 °C (●), 5.7 °C (▲) and 10.3 °C (□). The line to the filled symbols (●) was drawn by eye; the others were drawn assuming that the rate of inactivation has a Q_{10} of 3.05 in this fibre. *RP*, −2 mV; *HP*, −2 mV. *b*, Relation between p_∞ (ordinate) and membrane potential (abscissa) at the three temperatures as in *a*. *c*, Relation between membrane current per unit length (ordinate) and membrane potential (abscissa) for the temperature given in *a*. The line to the open symbols (□) was drawn by eye. Those to the other symbols assume a $Q_{10} = 1.57$ for this fibre. Currents per unit length were computed using measured values of r_i (Ω cm^{-1}; sarcoplasmic resistance per unit length) from cable analysis of the response to a 5-mV hyperpolarization (see ref. 13).

apart from Tl^+, and the effect is unlikely to be a block by Ca^{2+} because: its replacement by Mg^{2+} does not alter the inactivation; Ca^{2+} does not block in K^+ solutions[20]; those alkali metal ions (Ba^{2+}, Sr^{2+}) which do block inward rectification do so with an effective valency of 1.4, (ref. 20) not 0.5 ($= aF/RT$) as implied for this inactivation by equation (1).

The inactivation cannot be caused by depletion of Tl^+ from the lumen of the T-system. Depletion would not occur at such a high rate[18], its rate would not have such a high Q_{10} (ref. 19 and Fig. 3*a*), the rate would not fall with increasing hyperpolarization[17,19], and depletion would not give a steady-state current–voltage relation with a region of negative slope[19,21]. The same arguments also exclude the possibility that local intracellular accumulation reduces the driving force on Tl^+. In addition, the steady-state inactivation (Fig. 2*a*) and its rate of onset are little altered in solutions containing 40 mM Tl^+ and 40 mM K^+.

The mechanism of the inactivation we describe is unclear. It is possible that Tl^+ blocks its own inward movement, but such a self-block seems unlikely to account for inactivation time constants as high as 30–40 ms (Fig. 2*b*). An interaction, within the channel, between K^+ from the internal solution and Tl^+ from outside might also be responsible. An alternative is that Tl^+ (but not K^+) stabilizes a conformational change produced by hyperpolarization, which results in closure of the channel. The high Q_{10} for the rate at which inactivation occurs may favour this alternative.

Whatever the mechanism underlying inactivation in Tl solutions, the property we describe—dependence of the gating of an ionic channel on the permeating ionic species—may not be unique to inward rectification. It has recently been shown that the inactivation of the Ca^{2+} channels of certain cells[22–25] depends on the ion (Ca^{2+}, rather than Sr^{2+} or Ba^{2+}) moving through the channels.

We thank Dr N. B. Standen for helpful discussion and critically reading the manuscript, Mr P. Mallory for technical help, the MRC for a fellowship to F.M.A. and the Royal Society for an equipment grant to P.R.S.

Cell-free synthesis and processing of multiple precursors to glucagon

Dennis Shields, Thomas G. Warren, Sara E. Roth & Michael J. Brenner

Department of Anatomy, Albert Einstein College of Medicine,
1300 Morris Park Avenue, Bronx, New York 10461

Glucagon, a polypeptide hormone of 29 amino acids, is synthesized in the islets of Langerhans and immunoreactive forms of the molecule have been found in several tissues[1]. Like many other polypeptide hormones, glucagon is synthesized via a larger precursor molecule, proglucagon[2–7]; however, estimates of its size vary considerably and the biosynthetic relationship between some of the putative precursors and authentic secreted glucagon is unclear. Consequently, it was of interest to investigate the primary translation product of glucagon mRNA to relate its size to that of previously described glucagon precursors[5,6]. Here we provide evidence for three distinct immunoreactive preproglucagon molecules, two of which have an apparent molecular weight (MW) of ~14,000 (14K), the third with a MW of ~16,000 (16K). Furthermore, when microsomal membranes were present during translation, the nascent 14K preproglucagon polypeptides were processed to proglucagon with a higher apparent MW of 15,000. In contrast, the nascent 16K preproglucagon was co-translationally processed to a slightly smaller polypeptide. The data indicate that the 14K and 16K preproglucagons undergo different types of post-translational modification.

When poly(A)-containing mRNA isolated from angler fish islets of Langerhans[8] was translated in the wheat-germ cell-free protein synthesizing system, four major translation products were identified[8–10] (Fig. 1, lane 2). Treatment of the products synthesized in the absence of microsomal membranes with a

0028-0836/81/060511—04$01.00

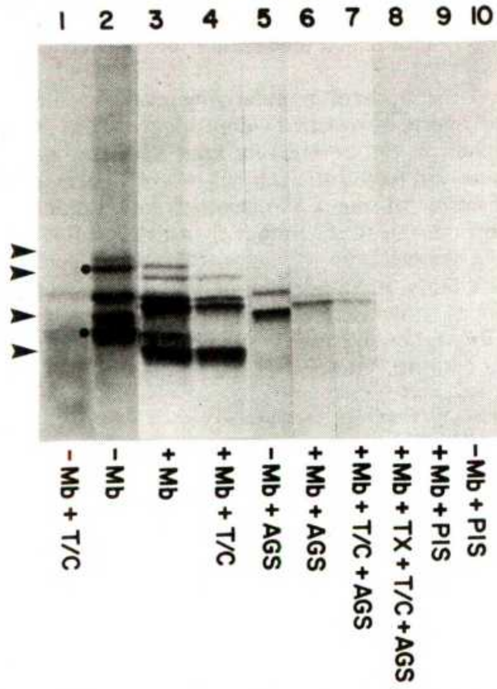

Fig. 1 Synthesis, processing and segregation of proglucagon precursors. Resolution of the translation products was by SDS-polyacrylamide gel electrophoresis using gradients of 12–20% acrylamide[8]; the autoradiograph of the dried gel is shown. Islet mRNA (1 A_{260} unit per ml) was translated in the wheat-germ system, containing 300 µCi ml^{-1} of ^{35}S-methionine, in the absence (−Mb) or presence (+Mb) of dog pancreas microsomal membranes at 4 A_{260} units per ml (ref. 21). Incorporation into acid-precipitable radioactivity was 100,000 and 55,000 µl^{-1} in the absence and presence of membranes, respectively. After 60 min incubation at 26 °C, aliquots of the translation products were prepared for electrophoresis directly (lanes 2, 3) and the remainder was subjected to various post-translational assays. Segregation (assayed by resistance to proteolysis), lanes 1, 4, 7, 8: aliquots were adjusted to 5 mM $CaCl_2$ followed by treatment with a mixture of 250 µg each of trypsin and chymotrypsin per ml (+T/C) for 90 min at 4 °C. Immunoreactive translation products. Lanes 5–8: samples were boiled in 1% SDS then 4 vol of solution A (ref. 22) were added followed by 5 µl of rabbit anti-bovine glucagon serum (+AGS). After incubation for 16 h at 4 °C, the immunoprecipitates were processed for gel electrophoresis[22]. Lane 7: proteolysis, before immunoprecipitation, was terminated by treatment with 1,000 units of Trasylol and 2 mM phenylmethylsulphonyl fluoride; the samples were then treated with SDS followed by solution A[22] and 5 µl anti-glucagon serum. Lane 8: treatment was as for lane 7 except that proteolysis was performed in the presence of 1% Triton X-100 (+TX). Lanes 9, 10: translation products treated with 5 µl of preimmune rabbit serum (+PIS). Upper and lower dots represent the migration of preprosomatostatin and preproinsulin, respectively. Arrows indicate the mobility of soybean trypsin inhibitor, sperm whale myoglobin, egg white lysozyme and bovine proinsulin representing MWs 21,400, 17,000, 14,300 and 8,700 respectively.

Table 1 Relative efficiency of processing and segregation of proglucagons, prosomatostatin and proinsulin

Prehormone	Prepro-hormone	Processed prohormone	Segregated prohormone	% Pro-hormone segregated	% Total pre-hormone segregated
Insulin	8,330	5,250 (63%)	4,413	84	53
Somatostatin	2,630	1,150 (44%)	675	59	26
Glucagon, 14K	2,070	1,990 (96%)	1,360	68	66
Glucagon, 16K	2,360	2,390 (100%)	1,330	56	56

The indicated polypeptides were located by autoradiography, excised from a dried gel similar to that shown in Fig. 1 and the radioactivity (c.p.m.) determined in each gel band[10]. Segregated prohormones are those polypeptides that were resistant to post-translational proteolysis by a mixture of trypsin and chymotrypsin (Fig. 1). Values in parentheses represent the percentage of the total preprohormone processed to the propolypeptide. Note that the radioactivity in the processed 16K proglucagon may be due in part to several unidentified polypeptides in addition to glucagon precursors.

specific rabbit antiserum raised against bovine glucagon, resulted in precipitation of three polypeptides (Fig. 1, lane 5; Fig. 2). Two of the immunoprecipitates, of apparent MW 14,000, were the most prominent and seemed to migrate as a doublet on SDS-polyacrylamide gels. The third immunoreactive polypeptide, which was less abundant than the 14K precursors, had an apparent MW of 16,000. Identical results were obtained using purified monospecific glucagon antibodies (data not shown). As expected, treatment of the translation products with preimmune serum (lane 10) did not result in precipitation of any detectable polypeptides. The three glucagon-immunoreactive translation products have been tentatively designated preproglucagons.

Translation of the islet mRNA in the wheat-germ system supplemented with dog pancreas microsomal membranes, resulted in the synthesis of several additional polypeptides (Fig. 1, lane 3) two of which have been identified as proinsulin[8] and prosomatostatin[9]. Treatment of these cell-free products with anti-glucagon serum resulted in precipitation of two polypeptides (lane 6). The 16K preproglucagon seemed to have been co-translationally processed to a slightly smaller polypeptide which migrated marginally faster than the precursor. In contrast, the microsomal membranes processed both 14K preproglucagons to a higher molecular weight form, ~15K, as judged by the relative intensities of the immunoprecipitates (Fig. 1, lanes 6, 7). Following processing, we were unable to resolve each of these segregated proglucagon molecules as separate bands, and conclude that they have an identical increase in MW. The processed proglucagon molecules were segregated into the heterologous microsomal membrane vesicles, as evinced by their resistance to post-translational proteolysis (lane 7), and consistent with this observation was the finding that proteolysis in the presence of detergent resulted in complete degradation of the segregated proglucagon molecules (lane 8). We conclude that all three nascent proglucagon polypeptides were segregated into the microsomal vesicles but underwent different post-translational processing. The relative efficiency of processing and segregation of the nascent proglucagons as well as proinsulin and prosomatostatin is summarized in Table 1.

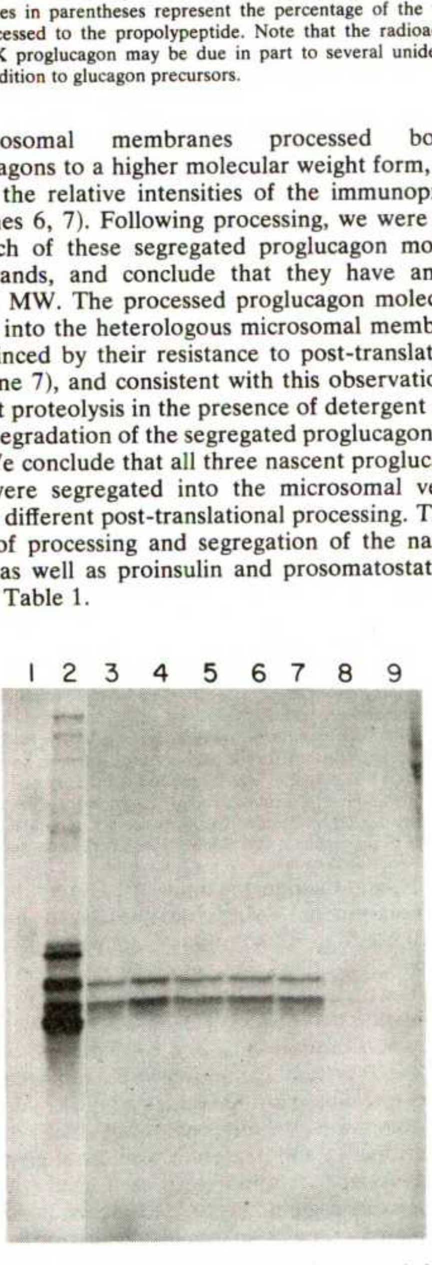

Fig. 2 Immunological characterization of the cell-free translation products having glucagon-like immunoreactivity: competition between unlabelled glucagon and the three putative preproglucagons for binding by anti-glucagon antibodies. Samples of ~300,000 c.p.m. of ^{35}S-methionine-labelled translation products were processed for antibody precipitation as described elsewhere[22], using the following conditions. Lane 1: 5 µl of preimmune serum; lane 2: control total translation products; lane 3: 5 µl of anti-glucagon serum; lanes 4–9: samples were treated with 5 µl anti-glucagon serum in the presence of 0.01 ng, 0.1 ng, 1 ng, 10 ng, 100 ng and 1 µg of unlabelled glucagon, respectively. The immunoprecipitates were processed for gel electrophoresis and autoradiography as outlined in Fig. 1. legend.

In the absence of purified glucagon from angler fish and because the amino acid sequence of angler fish glucagon has not been determined, we could not use heterologous glucagon in peptide mapping experiments to identify the translation products. Instead, we used antibody competition experiments to characterize the glucagon immunoreactive polypeptides further. Increasing concentrations of unlabelled glucagon were added to the cell-free translation products, which were then treated with the rabbit anti-glucagon serum (Fig. 2). With increasing concentrations of unlabelled glucagon there was a diminution in the binding of antibodies to all three preproglucagon polypeptides. Furthermore, all three precursors exhibited parallel responses to competition with unlabelled glucagon (Fig. 3). At the higher concentrations of unlabelled glucagon, antibody binding to all three glucagon precursors was abolished (Fig. 3). Most significantly, the antibody displacement curves of the 14K preproglucagons and the 16K precursor were identical to each other and to that obtained for radioimmunoassay of mature secreted bovine glucagon. These results suggest that the same glucagon antigenic determinants are recognized in all three glucagon precursors. It might be argued that these three molecules were immunoreactive because the antiserum was not specific for glucagon, and contained antibodies against other islet polypeptides. Several lines of evidence make this unlikely. (1) All three cell-free antigens manifested the same displacement curves during antibody competition; it is unlikely that three totally unrelated antigens would exhibit the same competition curves. (2) There was no detectable cross-reactivity of our antiserum with bovine pancreatic polypeptide, neither were the major translation products preproinsulin or preprosomatostatin, immunoprecipitable (Fig. 1). Nevertheless, to show unequivocably that all three precursors contain the glucagon amino acid sequence, we are now purifying angler fish glucagon for use in peptide mapping studies.

Three putative preproglucagon molecules are evident on translation of angler fish islet mRNA in the wheat-germ system, and similar results were obtained using the rabbit reticulocyte cell-free system. Two of the precursor molecules (MW ~14,000) are closely related, at least with respect to having similar migrations on SDS-polyacrylamide gels. In addition, these molecules have the expected molecular weight for proglucagon of 12,000 (ref. 5), possessing an NH_2-terminal signal peptide of 20–30 amino acids[8,9,11]. The third preproglucagon, of MW 16,000, migrated quite separately from the 14K precursors on SDS-gel electrophoresis. The finding of multiple preproglucagon molecules is not without precedent, for two forms of islet preprosomatostatin have recently been described[10,12,13] and two distinct somatostatin molecules have been isolated from catfish islets[14] and sheep hypothalamus[15].

All the glucagon precursor molecules are somewhat smaller than predicted by Patzelt *et al.*[6]; they found a single proglucagon molecule of MW about 18,000 during pulse-chase experiments using isolated rat islets. The discrepancies in molecular weight may be explained by differences in the gel electrophoresis systems. As the preproglucagon molecules are about four or five times larger than the secreted hormone, it is possible that they contain additional hormone amino acid sequences. It would be of interest to determine if the glicentin amino acid sequence is present in any of the putative preproglucagon molecules. Glicentin, which is a 100-amino acid polypeptide isolated from intestinal mucosa[16], has glucagon immunoreactivity and was recently shown[17] to contain the entire sequence of glucagon.

The most intriguing result of these experiments is that the various nascent preproglucagon molecules undergo different post-translational modifications. The 14K preproglucagons exhibit an apparent increase in MW on SDS-gel electrophoresis when the islet mRNA is translated in the presence of microsomal membranes. Similar observations were made by Patzelt *et al.*[6] in their studies on rat islet proglucagon. By analogy to other secretory and membrane glycoproteins[18,19], this result is consistent with the co-translational removal of a signal peptide and the addition of core-sugars to the growing nascent glycopeptide. In preliminary experiments we were unable to demonstrate binding of these processed polypeptides to several different lectin affinity columns. Furthermore, there is no evidence that mature glucagon is a glycoprotein, although this does not exclude the possibility that another region of the precursor molecule contains sugar residues whose conformation prevented binding to the columns. In contrast to the 14K preproglucagons, the 16K precursor was co-translationally processed and segregated to a slightly lower molecular weight proglucagon molecule, results which suggest the removal of an NH_2-terminal signal peptide[8,11]. Thus, it would be of considerable interest to investigate the different modes of post-translational processing that the various processed and segregated proglucagon molecules undergo, particularly with respect to prohormone conversion to authentic glucagon.

During the preparation of this manuscript, a 14.5K precursor to angler fish proglucagon was reported[20].

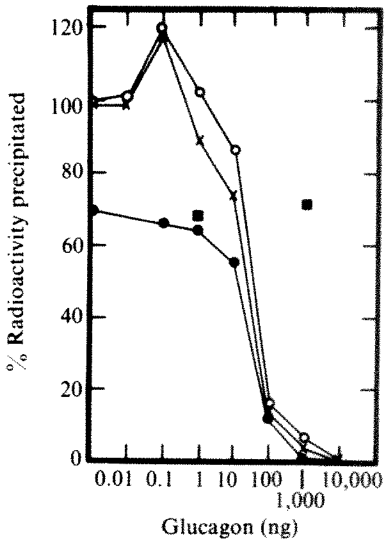

Fig. 3 Quantification of the competition between unlabelled glucagon and preproglucagons for binding by anti-glucagon antibodies. Incubations and treatments were as outlined in Figs 1 and 2 legends. Post-translational incubation with rabbit anti-glucagon serum in the presence of increasing amounts of unlabelled glucagon was as indicated. Control samples received 5 µl of preimmune serum. The bands corresponding to the 16K and both 14K preproglucagons (not separately resolved) were located by autoradiography, excised from the dried gel and solubilized[10] and the radioactivity determined by liquid scintillatin counting. 100% precipitation was equivalent to 1,100 c.p.m. (16K precursor ○—○) and 2,400 c.p.m. (14K preproglucagons ×—×). Background precipitation determined with preimmune serum was 199 c.p.m. Results were calculated after background subtraction. For radioimmunoassay of the anti-glucagon serum (●), aliquots of ^{125}I-glucagon containing 75,000 c.p.m. of trichloroacetic acid-precipitable radioactivity (~0.75 ng glucagon) were treated exactly the same as the translation products[22] and the indicated concentrations of unlabelled glucagon were added followed by 2 µl of anti-glucagon serum. The antibody–antigen complex was precipitated as described previously[9] and the radioactivity determined in a γ counter. ■, Competition between ^{125}I-glucagon and pancreatic polypeptide (10 ng and 1 µg).

We thank Dr R. Chance (Lilly) for gifts of bovine glucagon, pancreatic polypeptide and rabbit antibovine pancreatic polypeptide serum, and Gary Weiss for helpful discussions. This work was supported by NIH research grant AM-21860 to D.S. and a career development award from the Juvenile Diabetes Foundation. T.G.W. is a post-doctoral fellow of training grant AM-07329 and S.E.R. is a predoctoral fellow of the NSF.

Relationship of glicentin to proglucagon and glucagon in the porcine pancreas

A. J. Moody, J. J. Holst*, L. Thim & S. Lindkaer Jensen*

Novo Research Institute, DK-2880 Bagsvaerd, Denmark

We have previously[1] isolated from porcine small intestine a peptide known as glicentin. The C-terminal portion of glicentin consists of the sequence of glucagon extended at its C terminus by an octapeptide[2,3], and differs slightly from the sequence of a proposed fragment of proglucagon[4]. Glicentin-like material has been demonstrated in the pancreatic A cell[5,6], wherein it is located in the periphery of the secretory granules[7], whereas glucagon is located in the centre of the granules. To study the relationship of glicentin to the biosynthesis of glucagon, we have now investigated the glucagon-like and glicentin-like peptides in extracts[8] and perfusates of the porcine pancreas. Our findings that a peptide with glicentin-like immunoreactivity, and intermediate in size between glicentin and glucagon, is secreted synchronously with glucagon suggest that this glicentin-related peptide is a major cleavage product of proglucagon.

Gel permeation chromatography of 10 extracts of porcine pancreas resolved the glicentin-like immunoreactivity into three peaks (Fig. 1): one (K_d 0.22 ± 0.01; mean ± s.e.m.) with an apparent size similar to that of glicentin; a second (K_d 0.44 ± 0.01), which accounted for the bulk of the immunoreactivity, intermediate in size between glicentin and glucagon; and a third (K_d 0.66 ± 0.01), which eluted in the leading edge of the glucagon peak. The first peak of glicentin-like immunoreactivity (K_d 0.22) was associated with glucagon-like immunoreactivity (GLI), implying that this peak could be similar to intact glicentin. The second (K_d 0.44) was not associated with GLI and could represent a fragment of glicentin which did not contain the sequence of glucagon. The third peak (K_d 0.66) could have possessed glicentin-like and glucagon-like immunoreactivities. The glicentin-related immunoreactivity and GLI recovered from these columns were immunometrically approximately equal.

Isoelectric focusing of an extract of porcine pancreas (Fig. 2) revealed one peak of glicentin-like immunoreactivity with a *p*I close to 4.0. This immunoreactivity was immunometrically equimolar with, but clearly dissociated from, the GLI, which had a *p*I of 6.4, the isoelectric point of porcine glucagon.

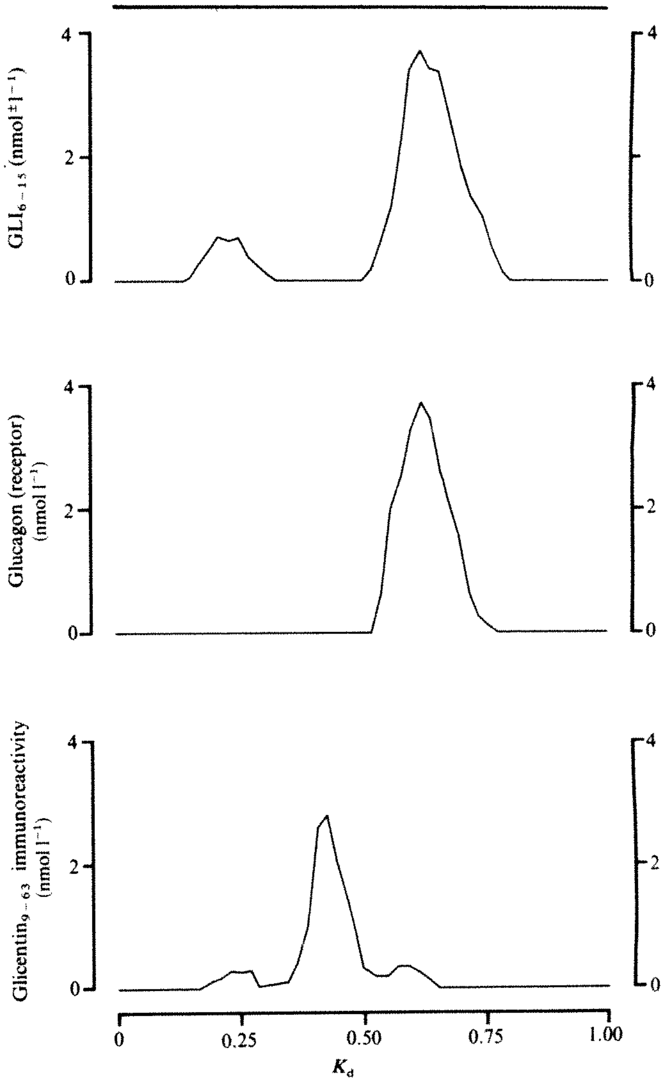

Fig. 1 Gel permeation chromatography of an extract of porcine pancreas on Sephadex G-50. Frozen porcine pancreas was extracted in acid-ethanol at −20 °C, the extract centrifuged and 5 vol diethyl ether added. The peptide-containing aqueous phase was recovered and a sample corresponding to 190 mg of pancreas applied to a 1.6 × 90-cm column of Sephadex G-50 fine equilibrated with 0.5 mol l^{-1} acetic acid. The radio receptor assay for glucagon was carried out using procine liver cell membranes[13]. The glucagon-like immunoreactivities (GLIs) were assayed by the radioimmunoassay for glucagon according to Heding[14]. Anti-glucagon serum 4304 was used to measure GLI homologous with glucagon$_{6-15}$ (ref. 11). Anti-glicentin serum R64 (which reacts with the *N*-terminal portion of glicentin) was used in a radioimmunoassay for glicentin to measure glicentin-like immunoreactivity. The immunoassay consisted of incubating 100-μl aliquots of standards of porcine glicentin, or of unknowns, with equal volumes of antiserum diluted (1:65,000) in a 1:200 dilution of non-immune rabbit serum for 72 h. ^{125}I-glicentin (100 μl of a solution containing 60 pg ^{125}I-glicentin per ml) was then added and the incubation continued for 24 h. The free and antibody-bound ^{125}I-glicentin were separated by centrifugation 24 h after the addition of 100 μl anti-rabbit IgG serum (Dako). In these conditions, R64 does not react significantly with extracts of rat or human pancreas, or with vasoactive intestinal polypeptide, glucagon or gastric inhibitory polypeptide.

To examine further the relationship between porcine pancreatic glicentin-like immunoreactivity and glucagon, we have measured the secretion of these materials by the perfused porcine pancreas. If the glicentin-related peptides and glucagon are located within the same secretory granules—as indicated by the immunocytochemical findings—the secretory patterns of these two materials should be synchronous. Furthermore, if the glicentin-related peptides are cleavage products of glucagon biosynthesis, which are stored and then released together with

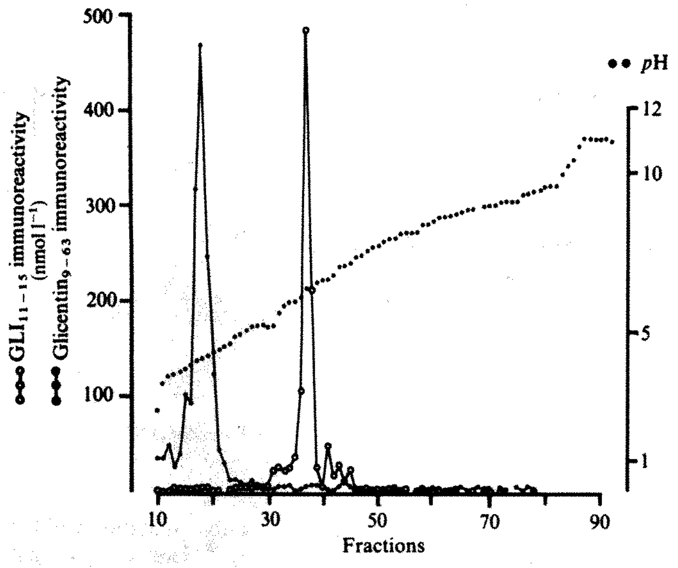

Fig. 2 Isoelectric focusing of an extract of porcine pancreas. A single porcine pancreas was carefully freed from adherent intestine, extracted in acid alcohol and the peptides recovered from the extract as described previously[1]. The peptide pool was desalted on a column of Sephadex G-50 equilibrated with 150 mmol l^{-1} acetic acid. The total peptide pool was recovered from the column and freeze-dried. The freeze-dried material, corresponding to 40 g wet weight of pancreas, was dissolved in ampholine/water and fractionated on a 440-ml LKG isoelectric focusing column with a pH 3.5–10 mixture of ampholines[15] (LKB). The column was emptied in 5-ml fractions, and the glicentin-like immunoreactivity and GLI in the fractions were assayed as described in Fig. 1 legend, except that anti-glucagon serum K 4023 was used to measure GLI homologous with glucagon$_{11-15}$.

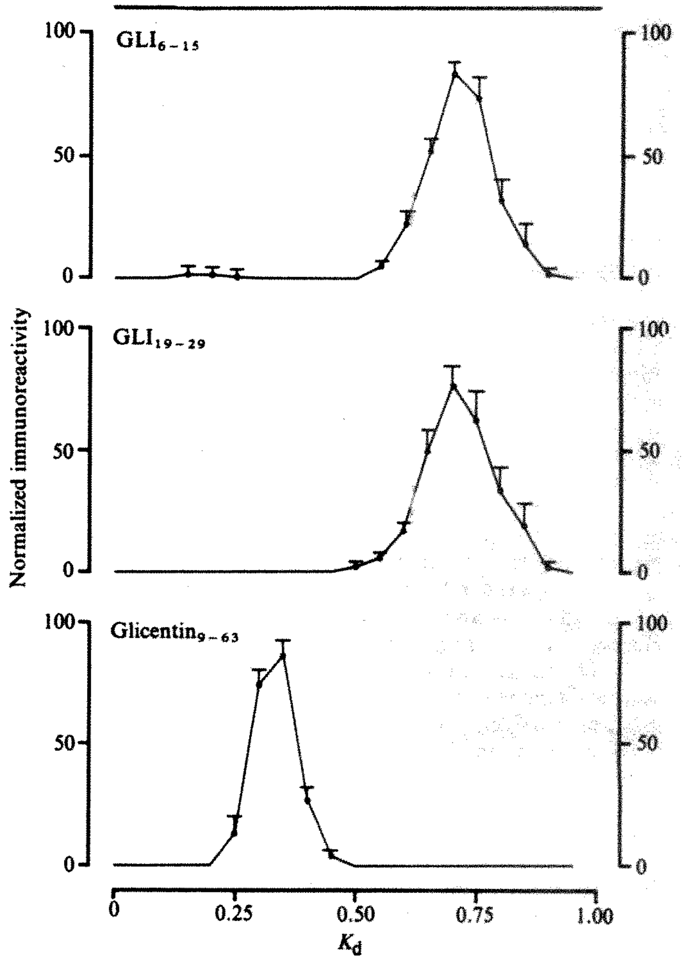

Fig. 4 Gel permeation chromatography of pancreas perfusates on Sephadex G-50 fine. Seven samples of perfusates taken from five different perfused pancreata stimulated with 5 mmol l^{-1} arginine were applied separately to columns of Sephadex G-50 fine equilibrated with 150 mmol l^{-1} NaHCO$_3$ containing 100 mmol NaCl, 20 μg ml^{-1} human serum albumin and 600 μmol l^{-1} thiomersal. The glicentin-like immunoreactivity and GLIs in the effluents were assayed as described previously. The data are the means (+s.e.m.) of the data from seven columns; the relative amounts of immunoreactivities recovered from each column were normalized as follows. The immunoreactivity recovered from each fraction (corresponding to a K_d interval of 0.05) was calculated for each column. The largest amount of immunoreactivity (irrespective of the assay used) recovered in any fraction from the column was taken to be 100, and the immunoreactivities in the other fractions for the column converted to a percentage of this value.

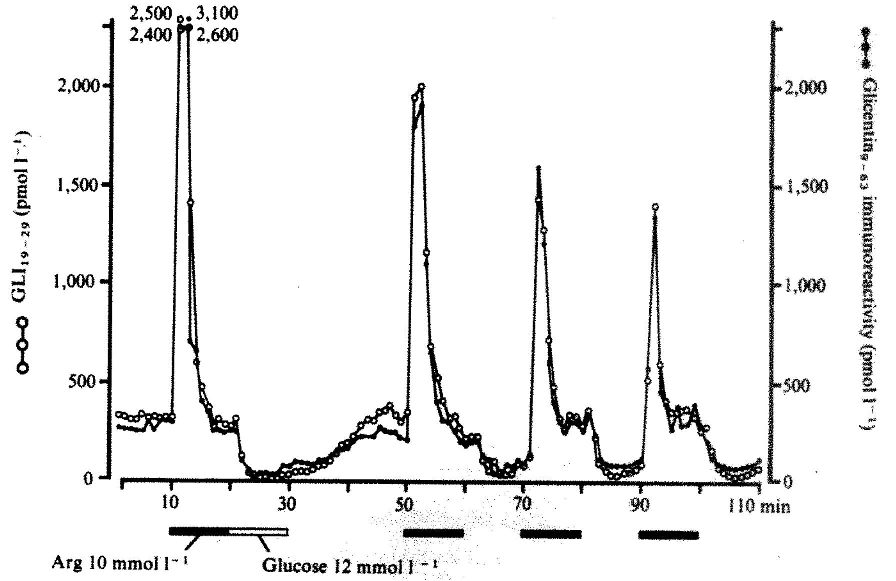
Fig. 3 The effects of arginine and glucose on the secretion of glicentin-related peptides and glucagon by the perfused isolated porcine pancreas. A porcine pancreas was isolated and perfused as described previously[16]. Glucagon release was stimulated by infusion of arginine into the arterial catheter to give a final concentration of 10 mmol l^{-1} and suppressed by the infusion of glucose (12 mmol l^{-1}). GLI and glicentin-like immunoreactivity in the perfusate were assayed as previously described, except that anti-glucagon serum K 4305 was used to measure GLI homologous with glucagon$_{19-29}$ (ref. 11).



glucagon, glicentin-related peptides and glucagon should be secreted in approximately equimolar amounts. Both these suppositions have been found to be correct: stimulation of the glucagon secretion of the perfused porcine pancreas with 10 mmol l^{-1} arginine caused synchronous and immunometrically equivalent increases in the secretion of glicentin-related immunoreactivity and of glucagon (Fig. 3). Gel permeation chromatography of perfusates from pancreases stimulated with arginine showed that the perfusates contained only one glicentin-related peptide, which was larger than glucagon (measured with anti-glucagon sera that reacted with the N- and C-terminal portions of glucagon) and which was devoid of GLI (Fig. 4). Isoelectric focusing of perfusate taken after a stimulation with arginine showed that the glicentin-related material had a *p*I of 4.0. The glicentin-related peptide secreted by the perfused pancreas was therefore similar to the major component of the glicentin-related peptides extracted from the pancreas.

The pancreatic glicentin-related peptides described here can be related to the biosynthesis of glucagon as follows. The peptide with the largest molecular weight, and which was found in small amounts in the pancreas, was very similar to glicentin and could be a stable early intermediate in the biosynthesis of glucagon, that is, proglucagon. The peptide which formed the bulk of the pancreatic glicentin-related material, and which was secreted synchronously with glucagon, could be a major fragment of proglucagon formed during the excision of glucagon from proglucagon. The existence of such a major fragment of proglucagon which is devoid of GLI has been described in rat islets[9].

Final proof of this proposal requires further knowledge of the structure of pancreatic glicentin-related peptides, and a direct demonstration of their relationship to the biosynthesis of glucagon. Supporting evidence for this proposal, which suggests that the biosynthesis of gut GLIs in the intestine and of glucagon in the pancreas share common precursors, is provided by the findings that identical glucagon-containing peptides are found in the rabbit intestine and pancreas[10], that glicentin can be converted into glucagon$_{1-17}$ and glucagon$_{19-29}$ by trypsin and carboxypeptidase B[11], and that ileal glicentin-containing 'L' cells develop glucagon C-terminal immunoreactivity after exposure to the same enzymes[12].

The findings that the pancreas stores and secretes a glicentin-related peptide, which is a possible fragment of proglucagon, suggest that the pancreatic A cell, like the B cell, stores and secretes a large fragment of the precursor molecule of its hormonal secretory product. Further investigation of the nature of pancreatic glicentin-related peptide is required to establish the biological significance of its co-secretion with glucagon.

We thank Karin D. Jørgensen for providing fresh porcine pancreas, and K. Christensen, D. Petersen, W. Jørgensen and E. Gammelgaard for technical assistance.

Molecular cloning and organization of two leghaemoglobin genomic sequences of soybean

D. Sullivan, N. Brisson, B. Goodchild & D. P. S. Verma†

Department of Biology, McGill University, Montreal, Quebec, Canada F3A 2T5

D. Y. Thomas

Department of Molecular Genetics, National Research Council, Ottawa, Canada K1A 0R6

The leghaemoglobins (Lb) are myoglobin-like proteins found in all nitrogen-fixing root nodules of legumes[1–3]. They are encoded by plant nuclear genes[4] which are specifically induced and form the predominant protein in nodules developed in symbiosis with the appropriate species of *Rhizobium*. The Lb is located in the host-cell cytoplasm of the infected cell[5] and is thought to facilitate oxygen diffusion[6,7]. Amino acid sequencing of the soybean Lbs has revealed at least four primary structures differing only in a few amino acids[8–10]. We have previously estimated about 40 copies of Lb sequences in the soybean (*Glycine max* L.) genome by cDNA hybridization[4]. To investigate Lb gene organization and function, we prepared and characterized a Lb cDNA recombinant molecule, pLb1, and used it to isolate two genomic Lb sequences from a library constructed in Charon 4. We report here that the organization of the two genomic Lb sequences is quite distinct and one of them seems to have an intervening sequence(s). Hybridization of pLb1 with genomic DNA from various tissues showed that Lb sequences are dispersed through more than 30 kilobases of genomic DNA and that there is no apparent sequence rearrangement or methylation changes following induction of Lb genes.

Double-stranded cDNA prepared to nodule RNA was digested with *Sau*3A restriction endonuclease and ligated into the *Bam*HI site of the plasmid pBR322 (see Fig. 1 legend). Clones containing Lb sequences were identified by their ability to hybridize with soybean root nodule cDNA, by their hybridization to 9S RNA from root nodules and lack of hybridization to RNA from roots, and by their specific hybridization to sequences in root nodule RNA which are translated into Lb protein in a wheat-germ protein synthesis system (data not shown).

Restriction enzyme analysis of one of the Lb clones demonstrated that the insert was about 145 base pairs long, contained a site for *Alu*I (but not for *Hae*III, *Taq*I or *Hin*fI) and was bounded by sites for *Bam*HI. (The appropriate bases required to regenerate the *Bam*HI site at each end of the insert must have been adjacent to the *Sau*3A sites in the cDNA.) The *Alu*I site corresponds to the position of an *Alu*I site found in a previously described Lb cDNA clone[11]. The DNA sequence of the insert and the predicted amino acid sequence are shown in Fig. 1, together with a partial amino acid sequence of the soybean Lb c$_2$, c$_1$ and Lba. The sequence of the cloned DNA encodes from amino acid residue 99 to the carboxy-terminal phenylalanine (residue 143) of Lbc$_2$ with the exception of an additional valine between residues 102 and 103, and the substitutions of *Asp* for *Asn* and *Gln* for *Glu* (positions 99 and 101 of the Lbc$_2$ sequence[8], respectively). The amino acid sequences of Lbc$_1$ (Fig. 1*e*) and Lba (Fig. 1*f*) differ in 4–8 amino acid residues at this end of the molecule. Thus the cloned Lb sequence represents either a variant of Lbc$_2$, for example, Lbc$_3$ (see ref. 12) or the minor differences may have arisen during molecular cloning[13].

Fig. 1 Characterization of the double-stranded cDNA clone, pLb1. *a*, Diagram of pLb1 insert area; heavy line is cDNA sequence, light lines are pBR322 sequences. *b*, Nucleotide sequence of the 145-base pair insert. *c*, Predicted amino acid sequence encoded by *b*. *d*, *e* and *f*, amino acid sequences of soybean Lb c_2, c_1 and a, respectively[8–10]. The amino acids underlined in *e* and *f* are different from those in *d*. cDNA and double-stranded cDNA[16] were synthesized with reverse transcriptase from oligo (dT)-bound RNA isolated from 3-week-old soybean root nodules[17] (*Glycine max* var. Prize infected with *Rhizobium japonicum* strain 61A76). *Sau*3A-cleaved double-stranded cDNA (10–50 ng) was ligated to *Bam*HI-cleaved pBR322 (1 μg) in 5 μl of 20 mM Tris HCl (*p*H 7.5), 10 mM $MgCl_2$, 10 mM dithiothreitol, 0.5 mM ATP and 0.1U T_4 DNA ligase (BRL) at 10 °C for 12 h. *Escherichia coli* strain 490 or HB 101 cells were transformed[18] and ampicillin (25 μg ml^{-1})-resistant and tetracycline (20 μg ml^{-1})-sensitive colonies were selected by replica plating on media containing the appropriate antibiotic. Colonies were screened for leghaemoglobin sequences by hybridizing replica filters[19] with ^{32}P-labelled cDNA in 0.6 M NaCl, 50 mM HEPES (*p*H 7.8), 100 μg ml^{-1} heat-denatured sonicated salmon sperm DNA, 0.5% SDS and 50% formamide at 37 °C. Further characterization of positive clones is discussed in the text. The pLb1 insert, including pBR322 sequences, bounded by *Hae*III sites, was isolated by polyacrylamide gel electrophoresis, cut with *Taq*I, and sequenced by the methods of Maxam and Gilbert[20].

Hybridization of restriction enzyme-digested genomic DNA with nick-translated pLb1 reveals several bands (Fig. 2*a*) consistent with the idea of a family of genes[4]. The hybridizing sequences of pLb1 are found within at least 10 regions of the soybean genome differing in their *Eco*RI sites (Fig. 2*a*, tracks 1 and 2). A similar diversity of bands is seen in *Hha*I- (Fig. 2*a*, tracks 3 and 4) and *Hin*dIII-cleaved (Fig. 2*a*, tracks 5 and 6) genomic DNA. The total amount of DNA contained in these fragments ranges from about 30 kilobases (*Hha*I fragments) to almost 50 kilobases (*Eco*RI fragments). The more intensely hybridizing bands (for example, the 1.4- and 4.2-kilobase bands in tracks 1 and 2) may be explained by multiple pLb1 sequences within these fragments or by multiple genes containing the same fragment size. Thus the family of Lb genes is dispersed in the soybean genome and is not composed primarily of identical tandem repeats.

The fragment patterns and intensity of the bands are basically identical whether the DNA was isolated from embryos or nodule tissue. This suggests that the Lb genes are not specifically amplified or rearranged in nodule tissue developed as a result of infection by *Rhizobium*[4]. Furthermore, the *Hha*I results (in addition to those of *Msp*I and *Hpa*II, data not shown) indicate that the induction of the Lb genes is not accompanied by major changes in methylation at these sites.

A soybean genomic library constructed in Charon 4 was screened with cDNA and pLb1 and yielded two clones which contain hybridizing *Eco*RI fragments of ~11.5 (Ch4 Gm Lb11) and 4.2 (Ch4 Gm Lb4) kilobases (Fig. 2*b*, lanes 2 and 3). These fragments correspond to the 11.5 and 4.2-kilobase bands observed in *Eco*RI-cleaved genomic DNA. Both clones contain approximately 14 kilobases of genomic DNA but those sequences which hybridize to the Lb probes are within quite distinct restriction-endonuclease domains (Fig. 3). The use of Ch4 Gm Lb11 and Ch4 Gm Lb4 as hybridization probes to *Eco*RI-cleaved genomic DNA reveals bands which correspond to the *Eco*RI bands in the respective Charon clones, as well as two to four additional bands (data not shown). The relative intensities of the bands indicate approximately equimolar amounts of the fragments in the genome and, when compared with the intensity of hybridization of a ribosomal DNA recombinant probe[14], each band seems to be present in fewer than 10 copies per haploid genome.

The general organizational maps of the two clones were constructed by various single and multiple restriction-enzyme digestions followed by blotting and hybridization (Fig. 3*a*, *b*). A more detailed map of Ch4 Gm Lb11 was obtained by sequential hybridization with pLb1 followed by cDNA to reveal both 3′ and 5′ ends of the sequences. pLb1 sequences represent the 3′ end of the coding region of Lb mRNA (Fig. 1); a complete cDNA probe would represent sequences predominantly to the 5′ end of pLb1. Representative data are given in Fig. 2*c*. Tracks 1 and 6 (*Msp*I and *Hae*III) clearly show the presence of two sequences which are hybridized by both pLb1 and cDNA (1.3 and 1.7 kilobases, track 1) and a 1.6-kilobase band hybridized exclusively to cDNA (track 6). Tracks 2–5 and 7–10 show similar data on pLb1 and/or cDNA hybridizations for the enzyme combination *Mbo*II plus *Hae*III. The fragment hybridized exclusively by cDNA is reduced from about 400 base pairs to 300 base pairs. Applying this sequential hybridization strategy with several restriction enzymes has allowed us to construct the detailed map of Ch4 Gm Lb11 shown in Fig. 3*c*. This map is confirmed by the Smith and Birnstiel[26] method of 5′-end labelling of DNA. Note that the separation of the sequences which hybridize exclusively to cDNA from the nearest pLb1 hybridizing sequences is ~1.3 kilobases. Another region containing pLb1 hybridizing sequences is at least 1 kilobase further away. The region hybridized by the cDNA spans up to 5 kilobases. If the sequences in Ch4 Gm Lb11 represent a complete or even a partial gene, there must be at least one intervening sequence within the Lb coding region. Sufficient DNA to encode the entire mRNA is contained within the exclusively cDNA hybridizing and the nearest pLb1 hybridizing regions. The present data do not allow us to limit the positions of cDNA and pLb1 hybridization sequences, particularly those to the right of the

*Msp*I site. With the above organization of Lb gene, the direction of transcription would be from left to right. In comparison with Ch4 Gm Lb11, the Lb4 has a very restricted region of hybridization with both cDNA and pLb1 indicating that it may not have an intervening sequence or it contains a partial gene sequence. The Lb proteins are very similar[8-10] (see Fig. 1*d*, *e*, *f*) and the cDNA and mRNA sequences seem to cross-hybridize fully[4]. Thus, the genomic sequences hybridized to pLb1 are expected to include all the Lb genes, and Lb clones cannot be identified as encoding any specific Lb protein without sequencing the DNA. Finer mapping and sequencing of fragments could also demonstrate the interrelationship between these genes as well as among other isolated Lb genes in the family.

The organization and regulation of the Lb genes is of interest at several levels[15]: (1) the basic molecular biology of a higher plant nuclear gene; (2) the elegantly orchestrated interactions between the plant and the prokaryote which induces these genes, and (3) the significant agricultural importance of the legume/*Rhizobium* association leading to the fixation of atmospheric nitrogen.

We thank Dr D. Housman for helping to construct and manipulate the Charon libraries and Dr R. Goldberg for providing a soybean library. This study was supported by grants from the Rockefeller Foundation and the Natural Sciences and Engineering Research Council of Canada. The recombinant DNA work was carried out in a B-level facility in accordance with the guidelines of the MRC Canada.

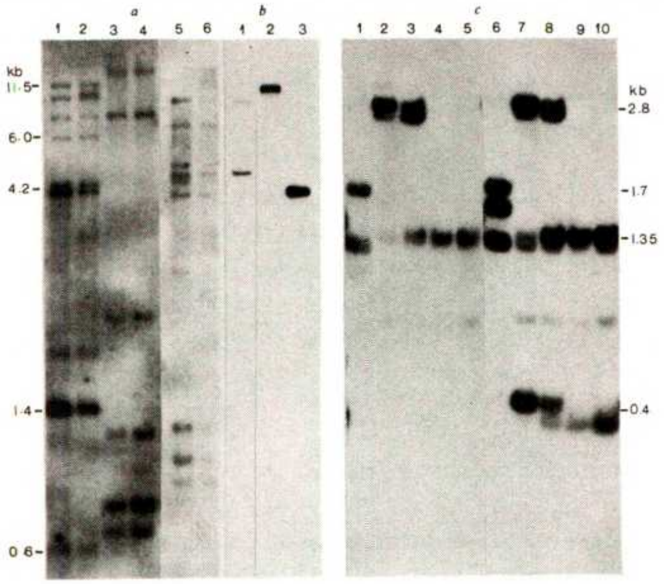

Fig. 2 Analysis of total genomic and cloned genomic Lb sequences. *a*, Restriction endonuclease-digested soybean DNA (5 μg per track) or *b*, *c*, recombinant clone DNA (~0.5 μg per track) was separated by agarose gel electrophoresis, blotted on to nitrocellulose paper[21] and hybridized with ^{32}P nick-translated[22] pLb1 at ~10^8 c.p.m. μg^{-1} and root nodule cDNA (*c*, tracks 6–10) at ~10^7 c.p.m. μg^{-1}. Hybridization conditions were 6×SCP (1×SCP = 0.1 M NaCl, 0.03 M Na_2HPO_4, 0.001 M Na_2 EDTA, *p*H 6.2), 1% Sarkosyl, 2.5% Dextran sulphate at 68 °C for 24–48 h. Exposure of the hybridized filter to pre-fogged X-ray film at −70 °C with intensifying screens was for *a*, 6 d, or *b*, *c*, 12–24 h. Fragment sizes (in kilobases (kb)) were determined from the positions of *Eco*RI-cleaved λ phage and *Taq*I-cleaved pBR322. *a*, Soybean DNA extracted from embryos (track 1) or nodule tissue (track 2) was digested with *Eco*RI; tracks 3 and 4 were digested with *Hha*I; tracks 5 and 6 with *Hin*dIII. *b*, Ch4 Gm Lb11 DNA digested with *Hin*dIII (track 1) or *Eco*RI (track 2); Ch4 Gm Lb4 DNA digested with *Eco*RI (track 3). *c*, Ch4 Gm Lb11 DNA digested with *Hae*III and *Msp*I (tracks 1 and 6) or *Mbo*II followed by *Hae*III partial digestions (tracks 2–4 and 7–9) and complete *Hae*III digestion (tracks 5 and 10). Tracks 1–5 were hybridized to pLb1 and 6–10 to pLb1 followed by Lb cDNA. The genomic recombinant molecules containing Lb sequences were isolated from a library constructed by R. Fisher and R. Goldberg in Charon 4 with partial *Eco*RI-digested soybean DNA by the procedures of Maniatis *et al.*[23]. About 400,000 plaques were screened[24] with ^{32}P-labelled cDNA and pLb1 and three 'positives' were plaque purified[25]. Two of these had identical *Eco*RI and *Hin*dIII sites and have been designated Ch4 Gm Lb11 in reference to the size of the *Eco*RI fragment which is hybridized to pLb1. The third recombinant (Ch4 Gm Lb4) contains a 4.2-kilobase *Eco*RI fragment that hybridized to pLb1.

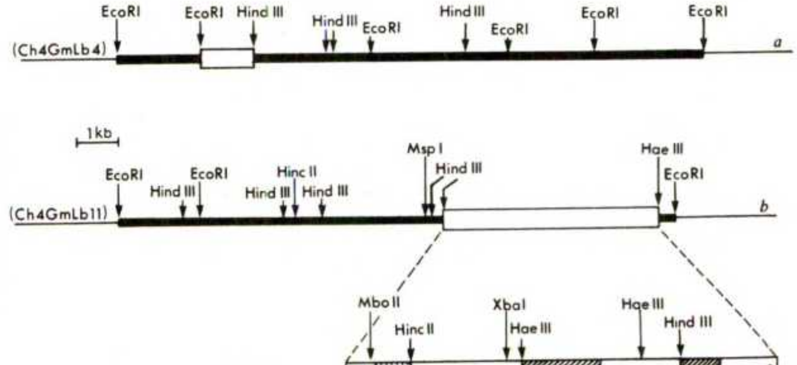

Fig. 3 Organizational map of two Lb genomic sequences. *a*, *b* represent entire insert (heavy line) containing regions of pLb1 hybridization (open box) representing 1.3 and 5 kilobases (kb) in Ch4 Gm Lb4 and Ch4 Gm Lb11, respectively. Light lines represent the arms of Charon 4. *c*, Detailed map of Ch4 Gm Lb11 containing Lb sequences. The dotted area represents sequences exclusively hybridized to Lb-cDNA whereas hatched areas contain sequences hybridized to pLb1.

BOOK REVIEWS

Fast breeders: all cons, no pros?

Alvin M. Weinberg

The Fast Breeder Reactor: Need? Cost? Risk? Edited by Colin Sweet. Pp.232. (Macmillan Press: London, 1980.) £20.

THAT nuclear energy would grind to a halt unless a breeder were developed was understood by the original workers in nuclear energy. What was not clear then, and what is still not entirely clear, is the kind of breeder that ought to be developed. In 1952, Bennett Lewis, father of the Canadian CANDU system, along with E. O. Lawrence, proposed the electric breeder based on an enormous proton accelerator. A variant of electric breeding, the so-called fission/fusion hybrid is now being discussed fairly seriously. I, along with H. G. MacPherson, espoused breeders based on the thorium cycle, particularly those using molten salts. And a thorium breeder based on light-water reactor technology has been built by H. G. Rickover in Shippingport, Pennsylvania. But the plutonium fast breeder, pioneered by W. H. Zinn, gained momentum and is now essentially the only show in town.

We could always give a plausible rationale for the ultimate deployment of breeders, but we could never say when breeders, of whatever kind, would be necessary. Since the fuel cycle cost of the breeder is far less sensitive to the cost of the raw uranium than is the fuel cycle cost of non-breeder pressurized water or gas-cooled reactors, eventually breeders would provide cheaper energy than would non-breeders. Our argument for aggressive development and quick deployment of the breeder was therefore based on the hope that breeders might be cheaper than non-breeders. The only way to find whether or not this was the case was to build large breeders. This remains the strongest argument for vigorous development of a full-size fast breeder. We had two other, albeit secondary, arguments favouring quick deployment of breeders: they would confer on their users a measure of energy autarky and thus would relieve pressure on non-renewable energy sources; and their deployment would put a virtual end to the mining of uranium, the only part of the fuel cycle that poses a technically difficult problem of waste disposal.

The basic economic arguments have hardly changed in the intervening 30 years, as these proceedings of the Polytechnic of the South Bank 1978 Conference on the Fast Breeder demonstrate. The main change is the emergence of non-economic issues — political, social and ethical — that were barely identifiable in the early days. As the editor, Colin Sweet, says,

> It is necessary to subject the official view to a critical assessment and it was the purpose of the conference . . . to do that . . . the issues . . . go far beyond what is to be found in the official literature . . . There is no question of trying . . . to strike 'a balanced view,' because there is no way in which such a phrase can be interpreted.

The resulting 14 papers and five appendices examine not only the old questions (will the fast breeder be economic; and will it be safe?) but also the far broader question of whether nuclear energy itself is needed. Most of the authors are opposed to nuclear energy. Their attack on the fast breeder is an attack on nuclear energy itself. When David Widdicombe argues that nuclear energy and civil liberties are incompatible or when Professor Patricia Lindop says that "the radiation hazard to the population may prove to be the factor limiting the utilization of nuclear energy" they are calling for an end to nuclear energy, not merely an end to the fast breeder.

For those seeking a balanced account of the debate over the fast breeder reactor, these proceedings will be disappointing: it is not only that the positions are far too polarized, it is that there is no real confrontation between the different points of view. Though the nuclear advocates are called to task, their opponents always have the last word. I find those last words, such as Peter Odell's claim of 70% efficiency for oil burning heaters, incomplete and tendentious; they scarcely conceal a profound distrust of nuclear energy.

The editor of *Nature,* in asking me to review this book, implied that the fast breeder reactor issue in the United Kingdom is controversial and thus that the book would be best dealt with by an outsider. As an American, I am reluctant to become involved in a family squabble. Nevertheless, for what it is worth, I offer these points for consideration.

(1) The denial of nuclear energy amounts to a denial of human ingenuity. For example, much is made of the loss of civil liberties entailed in nuclear energy. Yet, since Strategic Air Command bases can be made secure with minimal infringement on civil liberties, I don't see why the same cannot be done for nuclear sites.

(2) I have never been a strong supporter of the fast breeder reactor; I have always thought the thermal system based on thorium was a better bet. In the best of all possible worlds, many different breeders would be pursued, and the choice of the fast breeder would not have pre-empted development of the alternatives to the point where a fair comparison could be made between the various possibilities.

But in the real world, the fast breeder is now practically the only option. Despite the real possibility that fast breeders will prove too costly to make economic sense in the short run, active development of the breeder is at least as sensible as is active development of solar energy. The two are the only inexhaustible energy sources that we know to be technically feasible. We shall know the price of the breeder only by building several, just as we shall know the price of solar power towers only after we have built some.

(3) In the final analysis, we must decide whether the risk in going ahead with the fast breeder and then discovering we do not need it (fusion may work, or solar may be cheap) is less than the risk of not going ahead with the breeder and discovering in, say 2025, that we need it. Considering what is at stake — our energy future, not to speak of the spectre of CO_2induced climate change — I believe we must go ahead with development of the breeder, expensive though this may be.

France, which has chosen to generate 40 per cent of its primary energy from non-fossil sources by 1990, has decided to depend on nuclear energy — that is, on the breeder. It is not unlikely that, in the year 2000, the rest of us may envy the degree of energy autarky enjoyed by France as a result of this decision while we bicker over whether nuclear energy can be mended, and fight over the oil that remains in the Middle East. □

Conservation: the hopes and the fears

Brian Bertram

Conservation Biology: An Evolutionary–Ecological Perspective. Edited by Michael E. Soulé and Bruce A. Wilcox. Pp.395. (Addison-Wesley/Sinauer: 1980.) Pbk £7.95, $14.50.

THIS will be a disturbing book to anyone who believes that conservation is a matter merely of defining and protecting a number of reserve areas which are representative of ecosystems being destroyed. Michael Soulé and Bruce Wilcox have gathered a fine series of papers demonstrating the vast problems ahead of us all, and showing what we can expect the results of our conservation efforts to be.

Part I contains four chapters on the ecological principles of conservation. They concentrate on tropical forests, which are particularly vulnerable and of which it is likely that two-thirds will have disappeared within a mere 20 years. These early contributions by Gilbert, Eisenberg, Diamond and Foster, show what it is that we risk losing — a fabulously intricate set of interactions among plants and animals, varying both with locality and over time. We are clearly shown that small isolated "representative" portions of the vanishing tropical forests do not contain or cannot maintain more than a fraction of the species of the whole area represented.

Isolated reserves dotted about in a barren waste of altered or destroyed habitat act like islands; the five chapters in Part II consider the consequences of this "insularization" (horrid word). It is well known that true islands generally contain fewer species than the adjacent mainland, and a frequent cause is that the small populations on small islands are highly vulnerable to extinction. Recolonization depends on accessibility from other land areas. Wilcox, and Terborgh and Winter, draw on principles from insular ecology and extrapolate to isolated reserves.

Even if they do not become extinct, small populations face unusual evolutionary problems, as is shown in Franklin's and Soulé's chapters. They are subject to genetic drift, and they contain only a limited amount of genetic variability with which to respond to selection pressures. The level of inbreeding among members of the small population rises, fixing deleterious recessive genes and resulting in higher mortality, lower fecundity and distorting the sex ratio towards surplus males. Two particularly important conclusions emerge. First, that the effective population size must be not less than about 50 individuals to keep inbreeding to a level low enough for the population to survive. Second, that in Soulé's words "significant evolutionary change in most higher organisms is coming to a screeching halt in the tropics".

Part III, on captive propagation and conservation, deals with the similarly small populations which can be kept and bred in zoos. Some species can certainly be preserved in captivity even when extinct in the wild. But, as Conway shows, all the zoos in the USA together contain only enough space for viable populations of about 200 species of mammals. Co-ordination among zoos is required and is growing, but recognition by society of their important role is far too slow. Benirschke and colleagues describe some of the variety of modern aids in captive propagation, and Kleiman surveys the application of sociobiological study to animals in captivity; both enable greater breeding potential to be realized. Successful reintroduction to the wild is the ultimate and difficult objective, and Campbell reviews the numerous problems involved and the successes achieved.

The final section in the book deals with exploitation and strategies of conservation. Coe examines ecological interactions between human beings and wildlife in Africa, and assesses the present and future importance of game hunting, pastoralism, the tsetse fly, tourism, and the prospects for the culling, ranching and domestication of wild species of mammal. With Kenya's population now increasing at 4% per year, major problems are looming fast. Whitmore describes the extent and consequences of the destructive exploitation of tropical forests — some 50 hectares have been destroyed and disappeared while you have been reading this review, and another 30 will have gone before you finish. The direct effect on local species of animal is obvious; the indirect effects on all animals everywhere, because of the climatic changes caused, are unknown.

What we should do is the subject of the last two chapters. Pyle discusses the general management of nature reserves in the developed world. But that is not where most of the problem lies, although many of the causes of the problem do, according to Ehrlich. Human population growth threatens all tropical habitats; but so too does economic growth or the expectation of it. The Amazon forests are being erased only partly to provide living land for burgeoning Brazilians but also to provide timber and beef for North America and Europe. Ehrlich urges us to initiate and follow a more aggressive and wider conservation strategy. We must not be misled by the relatively slow rate of habitat loss in our own countries.

The papers in this book are diverse in character, but they all point very clearly in one direction. The editors summarize it eloquently:

> The green mantle of Earth is now being ravaged and pillaged in a frenzy of exploitation by a mushrooming mass of humans and bulldozers. Never in the 500 million years of terrestrial evolution has this mantle we call the biosphere been under such a savage attack. . . There is no escaping the conclusion that in our lifetimes, this planet will see a suspension, if not an end, to many ecological and evolutionary processes which have been uninterrupted since the beginnings of palaeontological time. We hope it is only a suspension — that the horrible onslaught can be stopped before the regenerative powers of ecosystems are killed. This book is a statement of that optimism. . . This is the challenge of the millenium. For centuries to come, our descendants will damn us or eulogize us, depending on our integrity and the integrity of the green mantle they inherit.

This book is not the uninformed emotional outburst of an eco-freak. It is a collection of the informed statements and pleas of 21 experts. But it is well written, so anyone can read it. And everyone should. □

Brian Bertram is Curator of Mammals at the Zoological Society of London.

Weather and water

William R. Cotton
Kevin R. Knupp

Clouds and Storms: The Behaviour and Effect of Water in the Atmosphere. By F.H. Ludlam. Pp.405 + plates. (Pennsylvania State University Press: 1980.) £24.95, $57.50.

THE late Dr Frank H. Ludlam was a keen observer of nature. His ability to combine and synthesize fragments of data and thereby construct data-consistent conceptual models of weather-phenomena is unmatched in this century. In this book, Dr Ludlam focused on the various forms of water in the atmosphere as the underlying factor in controlling the unique characteristics of many weather systems.

The book is largely devoted to the observed characteristics of the physics and dynamics of convective clouds (Chapters 5,7 and 8). Discussion of topics closely related to cloud processes — radiation, atmospheric optics, atmospheric thermodynamics, atmospheric aerosol physics and cloud microphysics — in the preceding chapters serves as a useful background. A transition chapter (6) compares the timescale and energy of clouds to related atmospheric processes. The ninth and final chapter deals with clouds associated with larger-scale systems.

The book is unique in several respects. First, it contains a copious amount of information, particularly on observed details of convective clouds in Chapters 7 and 8. These two chapters alone contain 397 references to various world-wide studies, and provide an excellent reference list for those new and even well-established in the field. A second notable feature is the description of observed phenomena presented in the appendices (a total of 33) at the end of many of the chapters. Finally, the book is well illustrated with many figures and 88 photographs which depict the various physical phenomena described in the text.

It is unlikely that this book will serve as the main textbook for a course in cloud physics, cloud dynamics or mesoscale aspects of clouds or cloud systems. Cost alone would prohibit its general use as a class textbook. Without prior training in dynamic meteorology, radiative transfer theory and cloud physics, an undergraduate would find many of the discussions hard to follow and would be overwhelmed by the sheer volume of the material. As a graduate-level text, however, the book is limited by the lack of theoretical depth. Much of the theory in cloud physics, radiative transfer theory and cloud dynamics is that which was current during the late 1950s and mid-1960s.

To the lecturer, the book will provide excellent, easily accessible material for preparing lectures in cloud physics and cloud dynamics. Ludlam's descriptions, together with the appropriate illustrations, give form to physical concepts and provide insight into the processes governing the behaviour of clouds and related phenomena in the atmosphere.

Because this book embraces a variety of observational information not available in other texts on cloud physics or atmospheric dynamics, it will be a valuable resource book for the serious student, researcher or teacher of cloud physics or cloud dynamics. □

William R. Cotton is Associate Professor and Kevin R. Knupp a first-year PhD student in the Department of Atmospheric Science at Colorado State University.

Spectroscopy for the neophyte

SCIENCE COLLEGE
Upper Circular Road
CALCUTTA

H.A.O. Hill

An Introduction to Spectroscopy for Biochemists. Edited by S.B. Brown. Pp.403. (Academic: 1980.) £18.40, $44.50.

THE avowed intent of the editor is to provide, in a single volume, a description of spectroscopic techniques at an advanced level appropriate to the non-specialist biochemist or clinician. How closely do the individual contributors approach this estimable, if unrealistic, goal in their presentations of "non-mathematical yet rigorous" accounts of particular techniques?

The "Introduction to Spectroscopy" by the editor provides the nervous clinician with a gentle, and certainly non-mathematical, survey of the major techniques, though the physical basis of the methods could be rather better explained. The following description of ultraviolet and visible spectroscopy by Dr Brown is clear and lucid, though I would have preferred to have selection rules discussed in terms of the probability of transitions taking place. Most spectroscopic techniques are best taught by illustrating their applications, and the spectra of amino-acids, nucleosides, nucleic acids, carotenoids, flavinoids and tetrapyrroles are briefly, but adequately, presented. By far the best part of the chapter is that concerned with applications to the analysis of biological materials.

G.R. Penzer provides a near-perfect pedagogical exposition of the principles of fluorescence — the only flaw being the inadequate number of examples — and the chapter on vibrational spectroscopy by P. Gans is well-balanced with most emphasis being placed, quite correctly, on the application of Raman, especially resonance Raman, spectroscopy. P. Bayley's account of circular dichroism and optical rotation is both rigorous and non-mathematical, is well illustrated and uses many well-chosen examples, though twice or thrice as many would not have been excessive.

R. Jones continues with a description of magnetic resonance spectroscopies. These are the most difficult techniques to explain, especially the EPR spectroscopy of metalloproteins. The temptation is to adopt the simplest description even when it is wrong. Thus, though crystal field theory as an *explanation* of the consequences of introducing metal ions into a non-spherical ligand environment died 20 years ago (some would say it was stillborn), it still infiltrates otherwise respectable essays.

The book is rounded off with chapters by E.J. Wood on atomic absorption spectroscopy and by A.J. Geddes on mass spectrometry which should be valuable to those intending to apply these methods for the first time. In short, this is a book that seeks to attain an impossible goal yet with much that is good in it. □

H.A.O. Hill is a Lecturer in Inorganic Chemistry at the University of Oxford, and Fellow and Praelector in Chemistry, The Queen's College, Oxford.

Learning from nematodes

J. Hodgkin

Nematodes as Biological Models. Edited by Bert M. Zuckerman. Vol.1, *Behavioral and Developmental Models*, pp.321; Vol. 2, *Aging and Other Model Systems*, pp.306. (Academic: 1980.) Each volume $35, £19.60.

IN STUDYING any biological phenomenon, it is desirable to work on an organism which is simple, well characterized and amenable to experimental manipulation. For many purposes, nematodes satisfy these criteria, and consequently they have attracted much attention as model systems in which to examine a variety of problems in cell and developmental biology, neurobiology and ageing. One nematode species in particular, *Caenorhabditis elegans*, has been characterized in great detail over the past 15 years, and an enormous amount is now known about this animal. However, this information is scattered widely throughout the literature, or else remains unpublished, so a monograph reviewing research on *C. elegans* and related nematodes would be very valuable. These books only partly satisfy this need, although most of the first volume, and parts of the second, are devoted to work on the genus *Caenorhabditis*. Each of the 18

chapters has a different author or authors, and there appears to have been little overall editorial control, so the contributions vary considerably in quality, purpose and organization. Few of them convey anything of the excitement, novelty or potential of research in this area.

The particular advantages of *C. elegans* are its neuroanatomy, development and genetics. The review of genetic analysis is excellent, and there are also adequate chapters on developmental genetics, biochemical genetics and the molecular genetics of muscle. The section dealing with cell lineages and development is long and thorough, but needlessly turgid. Neuroanatomy is scarcely described at all (apart from a good general chapter on nematode sense organs), although the total anatomy and connectivity of most parts of the nervous system have been known for some time. This omission is especially unfortunate in view of the chapter on behaviour, and the admirable summary of work on *Ascaris* neurobiology. Thus there is still no opportunity of comparing the two species without going back to the original papers.

The second volume contains contributions on ageing and longevity, nutrition, respiration, osmoregulation, energy metabolism, and the structure of nematode cuticle and sense organs. Some of these chapters are accounts of nematological research, rather than the use of nematodes to investigate fundamental biological problems, and therefore seem inappropriate to these volumes. Nevertheless, there is a great deal of interesting material in the two books; they are up-to-date and Academic Press has done a good job on the reproduction of photographs. For the time being, these volumes provide a useful introduction to contemporary research using nematodes. □

J. Hodgkin is on the staff of the MRC Laboratory of Molecular Biology, Cambridge.

Genetics and plant populations

Donald A. Levin

Demography and Evolution in Plant Populations. Edited by Otto T. Solbrig. Pp.222. (Blackwell Scientific/University of California Press: 1980.) £15, $29.50.

DURING the past decade, the discipline of plant demography crystallized from many disparate elements of empirical and theoretical ecology, and reproductive biology scattered in the basic and agricultural sciences. This discipline focuses principally on the quantitative aspects of germination, growth, reproduction, dispersal and death in a population, and the implications of these processes on the dynamics of population numbers and on life-history strategies. Although it is apparent that many characteristics of individuals related to the demography of populations are under genetic control, and that the demographic properties of populations may manifestly influence the genetic structure and amount and mobilization of genetic variation, the genetic perspective remains somewhat alien to scientists interested in plant demography. *Demography and Evolution in Plant Populations* is a step toward a unification of the ecological and evolutionary genetic components of demography.

The primary objective of the editor, Otto Solbrig, in assembling this collection of eight papers was to achieve a greater understanding of the dynamics of populations in relation to the action of natural selection. Papers by Abrahamson, Cook, Sarukhan and White deal almost exclusively with the dynamics of numbers of growth. One by Solbrig and another by Lloyd are principally genetic in content. Only the paper by Snaydon broadly integrates genetic and numerical aspects of demography. The result is a volume about demography and about evolution, rather than about the reciprocal influences of numbers and genotypes in populations.

Although the volume does not provide a broad synthesis, it does contain informative treatments of some major topics in plant demography. The high points of the volume are the treatments of numbers and size in plants by White, and the genetic variable in demography by Snaydon. Both papers bring to light much agricultural information which ecologists and evolutionists are unlikely to encounter elsewhere. Sarukhan's contribution on demography in the tropics is also packed with new information and insight. In the other chapters, the biology of seeds in the soil is imaginatively reviewed by Cook; vegetative reproduction and the genet–ramet dichotomy are treated by Abrahamson; Lloyd discusses conditions favourable to self-fertilization in predominantly outbreeding species; and Solbrig reviews the genetic structure of populations, and highlights approaches which integrate demography and genetics.

Demography and Evolution in Plant Populations will be a useful and authoritative source of data and ideas about plant demography. Scientists interested in plant population dynamics, reproduction and growth will find the volume to be of considerable interest and value. □

Tanford number two

B.A. Pethica

The Hydrophobic Effect: Formation of Micelles and Biological Membranes. 2nd Edn. By Charles Tanford. Pp.233. (Wiley: 1980.) £10.50, $24.65.

THIS second edition of Dr Tanford's well-known book has been extensively rewritten to include recent advances in micelle studies, and contains a number of new chapters, most notably on serum lipoproteins and membrane proteins. It is not a review of recent results, but rather a synthesis or overview written in a lucid and occasionally magisterial style by a master of the subject.

The emphasis is on the phenomena of the hydrophobic effect, using thermodynamic arguments in a clear fashion which avoids pointless rigour. The accounts of light scattering, spectroscopic and similar methods are firm and uncluttered, and the recent rush of mathematical models receives sober treatment. The theme of the book reaches from simple solutions of amphipathic molecules to the structural basics of biomembranes, and in so slim a volume it would be difficult to please all readers with the choice of topics and facts. The omissions are almost as interesting as the inclusions. For example, bile salts are given short shrift, and the relation of dilute micellar solutions to the full phase diagrams is only touched upon. Wilkins *et al.* are quoted in support of the lipid bilayer model for erythrocytes, but Blaurock's reconsideration is not. Given that biomembranes are the sites of extensive chemical activity, the lack of reference to the now substantial body of work on micellar catalysis is a pity.

In the account of biomembranes it is good to see Robertson getting proper credit for his contribution to the bilayer membrane hypothesis. The now conventional view that biomembranes are fluid mosaics based on lipid bilayers is the one adopted by Dr Tanford, and to me the important last chapter (on membrane proteins) consequently has the air of skilful fitting of the hydrophobic proteins to a Procrustean bed. Perhaps when physicochemical data on the proteins are as extensive as for the lipids, the remarks of J.B.S. Haldane (quoted at the front of the book), which identify the membrane polymers as the key components, will be seen as truly prescient and the role of the lipids will be put into better perspective. Be that as it may, the hydrophobic effect will remain of major importance in the study of lipids and proteins alike, and this book will beneficially influence future research on membranes and other structures. We should hope for a third edition for the pleasure of reading Dr Tanford again. □

Who now believes in the neutron bomb?

The Reagan Administration, which has been promising clarity and decisiveness since it occupied Washington three weeks ago, has begun badly in its pronouncements on the neutron bomb. One day, there was Mr Caspar Weinberger, the Secretary of Defense, promising that plans to deploy what is called the neutron bomb in Europe would be dusted off and reconsidered. A few days later, last week, Mr Alexander Haig, conscious because of his long spell in Brussels of European susceptibilities on this point, was saying that no decision had yet been taken and that none would be without prior consultation with the European members of the North Atlantic Treaty Organization. People in Europe will recognize that they have been here before. It is only two years since President Carter twisted every arm in sight, persuaded most but not all members of the alliance to accept the notion that neutron bombs were a sensible part of the armoury of the West — and then backed down at a point at which the West German government was in the thick of persuading a sceptical Bundestag that Mr Carter's first thoughts were right. Mr Haig is right to have spotted so quickly that the same battle cannot be fought a second time without spilling somebody's blood; perhaps he will make a good Secretary of State. Mr Weinberger's ruminations are understandable — a new man in an old post, discredited by too much vacillation, anxious to give the new Caesar comfort. They are not so easily forgivable.

The issue of the neutron bomb is more than merely a problem in military technology, but the technology is not irrelevant. Neutron bombs, when first described in outline three years ago, were held to have special military advantages. They could, the argument went, kill the crews of tanks whatever the thickness of the armour protecting them from the effects of conventional explosives. In principle, the argument is credible. The assumption must be that it is possible to generate neutrons from fusion explosions (the energy of fission neutrons is too little) without generating too much of the encumbering mechanical and thermal energy. Neutrons between ten and twenty million electron volts constitute a penetrating form of nuclear radiation. There is a good chance that an impinging neutron will penetrate the few inches of armour plating around a tank. The people inside, however, are more vulnerable. Consisting (as they do) largely of water, people function much like the moderating materials in nuclear reactors. They decelerate neutrons more efficiently than armour plating, chiefly because they have lighter atomic nuclei, but only by generating within themselves fast-moving and potentially damaging protons. The result is that people who think themselves protected by the vehicles they ride in will often be exposed to a fatal dose of radiation. In the macabre nature of these happenings, however, they will not always be aware of what has hit them. The first nausea may not come over them for half an hour or so and by then, of course, they may be dead from other causes as people on battlefields often discover to their cost.

Technically, the neutron bomb is therefore an exceedingly specialized weapon. It cannot be used on a battlefield as such, for its effects would be too slow. It is not, however, a strategic weapon. Yet the effects of a neutron bomb must be largely local. A hundred metres of atmosphere would probably have a stopping power for the spectrum of neutrons from a thermonuclear mixture not very different from a thin skin of armour plating. Thus pure neutron bombs cannot be used to attack targets spanning more than a few hundred metres on the ground without losing much of their power to do damage. On the other hand, they cannot be detonated near the ground without generating fallout. This, no doubt, is why most speculation on the subject has been concerned with the use of neutron bombs against concentrations of tanks marshalled for conventional attacks on some nearby target. By that means, the argument goes, it might be possible to prevent the tanks from rolling without so polluting the neighbourhood that everybody would be hurt. The scenario is appealing but not persuasive. Will generals saddled with the responsibility for using neutron bombs be able to make the delicate calculations of optimum detonation height that nuclear physics will require of them or their assistants? Will their opposite numbers in command of the hypothetical hostile tanks, having read in the newspapers of neutron bombs, then calmly assemble their forces in the manner appropriate to the Second World War? And, given the difficulty of arranging for public demonstrations, will either side in some future conflict take these drawing-board weapons seriously?

What Mr Haig to his credit appreciates is that there are more immediate problems. With the passage of time, it becomes more apparent that each new weapon requires a separate negotiation within the alliance which is the chief permanent commitment of the United States outside its borders. The wish to site cruise missiles in European states is still being talked about, and in some places (the Netherlands) may yet be talked out. The case for siting neutron bombs (Carter-style) in Europe took almost as long to make before President Carter listened more attentively than he need have done to what Mr Brezhnev had to say on the subject. In reality, the United States need not have made an issue of the neutron bomb and, more to the point, should not have done so. Cruise missiles raise novel issues, but neutron bombs are covered by the agreement within the North Atlantic Treaty Organization on the deployment of tactical nuclear weapons. If, as seems likely, they have only a specialized role to play in defence planning, and if the consequences of their use are likely to be less and not more serious, no new principle seems to be involved. In short, the issue of the neutron bomb seems less a consequence of improved technology in nuclear weapons than of President Carter's wish to say something publicly that had not been said before. Mr Weinberger appears to have fallen into the same trap.

Mr Haig's proposed remedy makes the best of a bad job. He promises that there will not now be a decision to site neutron bombs in Europe without full consultation with Western European governments. Given the history of the past few years, he has no other diplomatic choice. Mr Brezhnev should be pleased, but will refrain from saying so, even if he knows that his complaints at President Carter for seeking to deploy neutron bombs were partly bluff. (Neutron cross-sections are the same in the Soviet Union and the United States.) Mr Haig will no doubt also be pleased; he will have etablished his authority over the Department of Defense early in the new administration. Yet the problem of Europe remains to haunt him. Only three months after being returned to power, the West German coalition government is now less able to face a political battle about novel kinds of weapons than it was before the election last November. Other members of the alliance, the Netherlands for example, appear to have given up the internal struggle. None of this implies that NATO is about to fall apart but only that many of its members have become aware of the reality of the risk of conflict, and of the upheavals that may yet follow what is happening in Poland. Mr Haig must want to bring Western Europe up to scratch. Paradoxically, he may find that the only way to do that is to dust off not the neutron bomb but the series of arms control negotiations between East and West that have been in limbo since last September.

New Reagan budget a mixed blessing

Social science and planetary missions cut

Washington

President Ronald Reagan's first budget proposals are likely to contain a mixed message for science when they are formally unveiled next Wednesday. The emphasis is likely to remain on long-range research of potential value to the economy, and basic research of less direct relevance — such as planetary exploration and the social sciences — seems likely to suffer hefty cuts.

These are the main themes of preliminary proposals being circulated by Mr David Stockman, director of the Office of Management and Budget, as part of an effort to boost the US economy by large-scale reductions in social spending.

As expected, most of these cuts will fall on social welfare programmes, for example reducing health benefits and support for education. This theme will be reflected in the budget of the National Science Foundation (NSF) where major cutbacks are being proposed not only in research funding in the social and economic sciences but also in science education and support for women and other minority scientists.

Whereas President Carter, for example, shortly before leaving office had proposed a 1982 budget for NSF that would have allocated $84 million for research financed through the Behavioral, Social and Economic Sciences Directorate — an increase of about 15 per cent over the 1981 figures — Mr Stockman has proposed that funding for social and economic sciences be reduced from $33.6 to $10 million, and for behavioural and neural sciences from $39.6 to $30 million. Similarly he is proposing to eliminate the Women in Science programme, introduced last year.

In contrast to these cuts, it is intended that former President Carter's proposals for increased spending in the so-called hard sciences, such as physics and chemistry, should remain intact. These increases had been justified as part of the Carter Administration's attempts to accelerate the pace of technological innovation. And since this is likely to be a top priority for the Reagan Administration, it could therefore become the chief function for NSF, which has in recent years seen different types of goals added to its original mandate.

So although Mr Stockman is asking for an overall cut of $240 million in NSF's budget from that suggested by Mr Carter, the proposed increases for the hard sciences would remain untouched, leaving the agency with a slight growth over the year.

It is likely to be different at the National Aeronautics and Space Administration (NASA), where budget office is proposing virtually to eliminate the planetary science programme in its efforts to cut the agency's budget while keeping the space shuttle — now scheduled for an April launch — on target.

In particular, Mr Stockman is proposing to eliminate the Galileo mission to Jupiter — already running into rescheduling problems because of the difficulties in the development of the inertial upper stage needed for launching from the space shuttle, and the resulting decision to use a Centaur launcher.

Budget cuts of this order would result in a long period in which the United States was not engaged in planetary exploration. They are likely therefore to be bitterly contested by the scientific community and its supporters in Congress.

The proposed cuts in NSF's programmes are also expected to meet fierce opposition. When President Richard Nixon tried to inflict similar cuts, his efforts were successfully resisted by Congress, although the then Democratic Senate was a much greater hurdle than its present Republican counterpart.

No nominations have yet been made by the Reagan Administration for top science posts, although the President's team would probably like to have some individuals in position before the budget cuts begin.

Favourite to become director of the Office of Science and Technology Policy — which Mr Reagan is said to have been persuaded to retain — is Dr Simon Ramo, co-founder of TRW Inc. and head of Mr Reagan's Science and Technology Task Force set up immediately after last November's election. If Dr Ramo rejects the offer said to have been made to him, the choice could be Dr Arthur Bueche, vice-president for research of General Electric.

At NASA, the present favourite for administrator is Dr Hans Mark, former head of NASA's Ames Research Center and Secretary of the Air Force under Mr Carter. Dr Mark is said to have impressed Mr Reagan's transition team, and would be a popular appointment at the agency.

David Dickson

European high-energy physics cuts

European high-energy physics is heading for trouble. The Deutsches Elektronen Synchrotron laboratory (DESY) in Hamburg faces the prospect of operating for only 4–5 months a year, and the European nuclear research laboratory (CERN) at Geneva is likely to find its plans for a new electron–positron machine postponed for at least 6 months.

In Germany, the research ministry appears to have decided that, after some years of growth, the DESY budget can be cut back. And in Sweden, the Ministry of Research and Education is "suspicious" of the haste at CERN to build the 30-km electron–positron storage rings, with an initial electron-beam energy of 50 GeV. One source of trouble is that many Swedish physicists at CERN work not on high-energy physics but on spin-off experiments with the low-energy accelerators that litter the CERN site. Although not glamorous, such experiments are extremely sophisticated, and in danger of being neglected.

The Swedish Ministry of Research and Education said this week that it was seeking information from CERN on the future of these activities. Acknowledging that Professor Herwig Schopper, director-general of CERN, would like a decision on the large electron–positron machine (LEP) at the next bi-annual CERN council meeting in June, a Swedish spokesman asked "Why are we in such a hurry?" The intention at CERN is that LEP would be built within the running budget of 610 million Swiss francs a year, but Schopper freely admits that this would entail running down some ancillary facilities.

Although the annual running cost would not be changed, Stockholm is alarmed that the usefulness of CERN to Swedish scientists will diminish. In any case, a commitment for 15 years or more to the construction and running of LEP would have to be ratified by the Swedish parliament, said the spokesman, and that was most unlikely before June.

Schopper's dilemma is to reconcile the interests of governments broadly willing to support LEP but at a smaller budget (SF590 million a year) such as France, Germany and the United Kingdom and those of the smaller nations wishing to keep less costly experiments going. one sop might be to squeeze another SF95 million or so from the budget to build the European Synchrotron Radiation Source, the machine proposed by a panel of the European Science Foundation. "That would be nice" said the Swedish spokesman.

At DESY, ranking second only to CERN in Europe, the federal government is proposing to slash the budget for 1981 to DM135 million, compared with DM145.4 million last year. The government has met DESY's salary bill but made no allowance for increases (5 per cent would be necessary for inflation); cut DESY's budget for consumables by 10 per cent in money terms, making no allowance for the doubling of Hamburg electricity prices last September; and cut DESY's provision for investment in detectors and accelerator improvement by 22 per cent.

The laboratory can cope with the

0028-0836/81/070524-02$01.00

electricity prices (caused by the Polish crisis, which has reduced Hamburg's supply of cheap coal to a trickle) by reducing its operating time to 4½ months (in 1980 it was 9 months). At present the laboratory is counting on a partial reprieve and working as if it will get 6 months. If it does not — the Bundestag will decide in the spring — it will be quiet in Hamburg later in the year. **Robert Walgate**

Soviet agriculture

Soil first

Dr Vladimir Borovskii, director of the Kazakh Institute of Soil Science, has strongly criticized the All-Union Academy of Agricultural Sciences for its neglect of soil problems. The academy, he said, has no long-term programmes for studying the nature of the soil and establishing the laws of soil formation.

Interviewed on Moscow radio last month, Dr Borovskii said that unless these shortcomings are put right, the development of Soviet agriculture will inevitably be retarded. The draft basic guidelines for the new Five Year Plan, which are to be presented to the Party Congress later this month, should, he urged, include a clause that soil research must be considerably expanded.

The weeks between the publication of the draft guidelines and the meeting of the Party Congress which will approve them is traditionally a time for constructive criticism. As always, the guidelines emphasized the needs of agriculture.

By 1985, it is planned that production of mineral fertilizers should reach at least 150 million tonnes annually, at least 115 million tonnes of which will go to Soviet agriculture. A further 3.4–3.6 million hectares of irrigated land and 3.7–3.9 million hectares of drained land are to be brought into use. Some 26–28 million hectares of pasture are to be reclaimed from desert, semi-arid or mountainous regions. There is to be a drive for more efficient use of irrigated or drained land, and improvement of the technical level of water conservancy. Improvements are also expected in reducing the salinity of agricultural water supplies and soil acidity.

Mr Brezhnev clearly had these measures in mind in his message to the All-Union Agronomists' Conference in Moscow last December. Soviet agriculture, he said, had "powerful levers for raising productivity — modern technology, chemical means, large areas of irrigated and drained land, the achievements of science and advanced experience". In a similar vein, Politburo Member Mikhail S. Gorbachev stressed the "profound learning, highly scientific spirit and professional competence of Soviet agronomists". It was when the advice of such experts was ignored, he told the conference, that things began to go wrong.

Gorbachev's main criticisms of Soviet agriculture related mainly to planning. What was needed, he said, was "a sharper turn of the whole economic, organizational and political work towards effective use of the material, labour and financial resources", the more rational use of land, substantial increases in the production of grain and fodder and "solution of the social problems of the countryside". **Vera Rich**

Solar power

Crimean costs

The Soviet Union's first solar power station will go into operation in 1985, according to a "round table" discussion on solar energy published last month in the Moscow weekly *Literaturnaya Gazeta*. This pilot station, to be built in the Crimea, will have a generating capacity of 5 MW, and will run at an estimated cost of 1.5–2 rubles per kWh.

The cost is high. According to the Soviet Ministry of Energy, in 1979 the production cost of 1 kWh was 0.752 kopeks at a conventional thermal station, 0.786 kopeks for nuclear power and 0.149 kopeks for hydroelectricity. Thus the generation cost of Crimean solar electricity will be almost two hundred times that of nuclear power and more than a thousand times that of hydroelectricity.

Nevertheless, the pilot station has an important place in the new Five-Year Plan, which calls for an increase of renewable energy use in the national economy. While maintaining that the Soviet Union runs no risk of a shortage of conventional fossil fuels, energy planners have for several years been insisting on the need to conserve them, stressing their irreplaceable role as feedstocks for industry.

A number of solar energy projects are already under way in the Crimea, which has an average of only 47 days a year without sunshine. These include the Alushta experimental centre, where a village of single-storey cottages is used to test solar-powered domestic heating/air-conditioning units, and an experimental metallurgy centre at Karsiveli where parabolic mirrors will be used to produce temperatures of 3,500°C, allowing metals to be smelted to a high degree of purity.

The intended solar power station will also use parabolic mirrors, heating water to drive steam generators. Long-term plans for solar energy will take more sophisticated forms. According to Academician Nikolai N. Semenov, academic secretary of the "scientific council for finding new ways of using solar energy", research is being concentrated on photoelectric conversion.

Chemical methods of dissociating water are also being explored, according to Semenov, whose contribution to the round table differed very little from what energy strategists elsewhere are accustomed to say. Semenov emphasized the need for continuing research at a basic level in the exploitation of solar energy. **Vera Rich**

Wildlife conservation

Keepers' charter

The new British Wildlife and Countryside Bill has accomplished one thing at least — it has attracted a record of 600 amendments for debate in the committee stage in the House of Lords. After two weeks, the number of amendments discussed by the end of last week was well below target. The government still has a long haul ahead.

Most of the amendments dealt with so far have been withdrawn for further consideration by the government, whose views will not be known until the bill emerges from the committee. The government has however agreed even at this early stage to include the red squirrel, now down to a handful of breeding colonies in England, on the list of protected species. Other amendments, which have aroused varying degrees of interest but as yet no firm government response, include protecting bats in private houses, banning the use of crossbows to kill wild animals and protecting badgers and red foxes from the hazards of snares.

The debate is likely to become more fierce later this week, when the House of Lords turns from debating the protection of wild animals and plants (the first part of the bill) to the conservation of the countryside and national parks. The bill includes a clause relating to sites of special scientific interest, designated as such by the Nature Conservancy Council. Voluntary conservation bodies and the council have condemned the draft clause which requires that the owners of only some specially selected sites will have a statutory obligation to give notice of operations that could alter the characteristics of the site.

They argue that all sites should have the same protection and that the singling out of some sites would lower the status of the others. The clause has provoked a spate of amendments, the more extreme of which ask that all agricultural practice should be subject to the planning laws. The strength of opinion is likely to persuade the government to cave in.

Many of the amendments now being tabled could change the status of the Nature Conservancy Council, statutorily responsible for conservation. Not only might the council be given more power in enforcing protection for sites of special scientific interest but, if the voluntary bodies have their way, it could be called upon to help enforce wildlife legislation generally.

The council's reaction to the voluntary bodies' enthusiasm for awarding it greater power is cautious — it says simply that it is primarily a scientific organization. Memories of the bruising battle with the Natural Environment Research Council a decade ago, from which the conservancy council emerged the loser, are still fresh. **Judy Redfearn**

0028-0836/81/070525-02$01.00

German nuclear power

Local difficulties

Hamburg

West German Chancellor Helmut Schmidt will need to do some political juggling in the next few weeks if he is to maintain the credibility of plans to expand West Germany's nuclear energy programme to lessen dependence on oil imports. The dilemma stems from a decision last week by local members of his own Social Democrat Party (SPD) in Hamburg that the city should not contribute 50 per cent of the costs of a new nuclear power station planned for Brokdorf, 40 miles away.

Despite support for the power station from several local and national trades union, the Hamburg SPD accepted the arguments of the city's mayor, Herr Hans Ulrich Klose, that it was more important to base future energy policy on energy conservation than to support significantly increased production of electricity by nuclear means.

The Brokdorf plant, which would be built and operated by the Hamburg Electrical Utility, has become something of a symbol for the German anti-nuclear movement. Two years ago it was the scene of the first of a series of violent demonstrations against nuclear power which culminated in the decision to withdraw plans for a major storage and reprocessing facility at Gorleben.

Chancellor Schmidt, in putting considerable political weight behind the Brokdorf proposal, seems to have been gambling on an apparent decline in popular anti-nuclear sentiment over the past two years. The link between growing economic problems and OPEC oil prices is increasing pressures to proceed with the construction of nine new nuclear power stations.

Mayor Klose's arguments against Brokdorf were expressed more in local than national terms. He pointed out, for example, that although the country as a whole at present relies on nuclear energy for only 10 per cent of its energy needs, the completion of the Brokdorf plant would increase Hamburg's dependence from 30 to 70 per cent.

"How can we encourage energy saving when we blindly push ahead with nuclear power that may well prove to be superfluous to our needs?" Herr Klose asked a meeting of the local SPD, in a debate which ended with a vote against the plans.

The decision is not yet final, since it will have to be taken formally by the Hamburg Senate, which meets this week to vote on the city's participation in Brokdorf. However, it is unlikely that the view of the ruling SPD will not prevail.

The Brokdorf situation has already become a major political embarrassment to Chancellor Schmidt, who has made a commitment to other European leaders that his nation will make a major effort to reduce its dependence on foreign oil.

The SPD's position is that, pending the resolution of the waste disposal issues, the construction of nuclear power plants already under way should continue, as long as an adequate form of temporary disposal has been agreed.

In Hamburg, a plan for dealing with waste has been produced that seems to meet the conditions laid down by local port authorities. But the local SPD's decision — which runs directly contrary to Herr Schmidt's plans — has already been described by Hamburg's Interior Minister as a possible precedent for other nuclear stations.

The political problems raised by Hamburg's actions have further exacerbated tensions at a national level, where Herr Schmidt needs a viable energy policy to maintain the SPD's coalition with the Free Democratic party, but is finding his position on nuclear energy out of line with that of a large proportion of his own party.

For example, in Hamburg's neighbouring state Schleswig Holstein, the national SPD feels it has a chance of defeating the ruling Christian Democrats in the next elections. However, as in Hamburg, the local SPD is also opposed to the Brokdorf plans.

Not surprisingly, the national SPD has been somewhat embarrassed by Herr Klose's firm anti-nuclear stance. Some local SPD members who do not support the mayor's position had been hoping that he would be replaced by Herr Hans Apel, currently Defence Minister in Bonn, who supports Chancellor Schmidt's position. However, other political pressures make it unlikely that Herr Schmidt would agree to such a weakening of his own cabinet.

David Dickson

EEC nuclear research

Reactor guarded

Brussels

The go-ahead on the European Community's light water reactor (LWR) experiment, the Super-Sara project, is expected to be given at a meeting in Brussels this week. The ten member states' permanent representatives to the Community (Coreper) will be deliberating on a report by the Council of Ministers' Working Group on Atomic Questions before deciding whether or not to release the main bulk of the funds for the three-year programme (1981–83).

In March last year, the Nine, on the insistence of the French, allocated an initial grant of 3.31 European Units of Account (EUA), or £1.7 million, for the exploratory stage of the project. During the previous six months, the member states had been deeply divided as to whether the research was really necessary or justified at the price. Initial estimates put the cost of the programme at 43.92 million EUA but inflation and salary increases have now increased this to 54.03 million EUA.

The project makes use of the Community's Essor experimental reactor at Ispra in Italy, which, having served its original purpose, would otherwise become redundant. Italy is unwilling to take over financial responsibility for Essor and through the Super-Sara project, drawn up in 1979 in the wake of the Three Mile Island accident, the Commission is willing to take this on. It aims to simulate as far as possible the complete gamut of accidents which might occur in light water reactors. More extensive than similar projects in West Germany (the Rebeka reactor), France (Phébus) and the United States (PBF and MRBT), the simulated accidents include loss of coolants from small and large cracks, the exposure and fusion of the core, the effect of the containment breaking up, the monitoring of events in and outside the core and the possibilities of recooling the core.

The real task of the Commission since the project was agreed in principle last March has been to define the areas where the Community could benefit. The report which formed the basis of the Commission's communication to the Group on Atomic Questions was drawn up by a task force composed of experts from the member states, and the decision taken at the Coreper meeting will reflect the extent to which the task force has been successful.

The United Kingdom's original position — that the project is a good idea but in practice would be too expensive — changed after the March meeting to one of acceptance provided that the project went ahead as soon as possible. At that time, other member states, Germany and the Netherlands in particular, proposed carrying out the research in two stages and withholding much of the money until Super-Sara had proved its value. But postponing the project for two years, argues the Commission, would cost an extra 32 million EUA. Moreover, a follow-up programme planned for 1983–86 might produce particularly valuable results. France and many other countries are more worried that the project's costs will rise more steeply than predicted, with the high temperatures at which the experiments take place. France also feels that its own experimental reactor, Phébus, although smaller, will produce similar results just as quickly. On the other hand, the United Kingdom may now be prepared to come to the programme's defence in view of the recent decision to build the first British pressurized water reactor in the face of strong public opposition, and because of the United Kingdom's lack of safety expertise with light water reactors.

The Commission has been at pains to emphasize that it will ensure "a particularly rigorous control" of the costs and timetable. Another possible line of attack for the programme's detractors is the lack of qualified staff. An estimated 70 temporary staff will be needed in addition to the 2,600 permanent staff. However, the Commission emphasizes that other nuclear safety programmes will not be robbed of their present staff.

The biggest arguments in Coreper are likely to revolve around the timing of the project. Work on the loop has already begun at Ispra and to keep Essor unoccupied now will only lose money. But while the Commission is urging that the project should start in earnest immediately, the nuclear safety programmes' consultative committee wants the project's first phase to be extended for 6–12 months so that more feasibility studies can be carried out. However, financial support from third parties may tip the balance in favour of an early start. Three United States organizations — the Department of Energy, the Nuclear Regulatory Commission and the Electric Power Research Institute — are all considering participation, as are Japan and Sweden.

Jasper Becker

Data protection laws

UK lags behind

The United Kingdom seems on the point of becoming a "data desert" following its decision not to sign the Council of Europe's convention on data protection and privacy. On 28 January, seven European states signed the convention, which requires them to enact legislation defining the rights of individuals over the formation and use of files concerning them. All these states except one (Turkey) already have such laws. When ratified by the parliaments of five signatories, the convention will pass into force.

Britain must establish a domestic policy first, said ministers questioned in Parliament last week. But the issue has been under debate in Britain for ten years, and it is two years since the Lindop committee on data protection produced its report and recommendations. Mr William Whitelaw, Secretary of State for the Home Office, last October promised a policy statement "shortly". But there is now little sign that a statement will be forthcoming in the present session of Parliament.

It is a matter of human rights, but also of commercial interest. Companies argue that contracts involving protected data from outside countries will be lost to the United Kingdom, as Britain will be seen as a potential information leak. And this information can concern companies as well as individuals: the Council of Europe convention is defined in terms of "legal persons", which may include registered businesses.

Already, according to International Computers Ltd, a number of small deals with Sweden — the first in Europe to enact data laws — have been affected. Austria is also beginning to pay close attention to the nature of the data that cross its borders. So far there has been no serious commercial effect; but the European laws are only just beginning to operate.

In the United Kingdom, bodies from IBM to the National Council for Civil Liberties (NCCL) support the spirit of the Lindop report — that there should be legislation within five (now three) years. Opposition stems from government departments whose data handling might be most affected by legislation: the Home Office and the Department of Health and Social Security. The Department of Industry backs the data industry's view that legislation is necessary, although the appointment last year of a junior minister for information industries (Mr Adam Butler) specifically excluded data protection from his portfolio.

Lindop recommended the establishment of an agency which would initially coordinate views and propose legislation to Parliament (thus by-passing departments and ministers). Later the body would register and license protected files and uses of files.

Such an authority is regarded by NCCL as a necessary democratic safeguard. But commercial interests, while recognizing the need for independence, are fearful of a centralized bureaucracy. IBM, involved in most countries, favours the decentralized German system. There, firms and government agencies holding sensitive files must appoint an ombudsman who then bears legal responsibility for ensuring that files are properly constituted and used. Costs are thereby distributed to the file owners, rather than being a matter for central government.

The system also avoids the danger — so IBM thinking goes — of a "Balkanization" of data transfers, which might occur when national protection agencies attempted to agree on this or that data flow between their countries. Another way out, however, would be the wide adoption of a convention such as that drawn up by the Council of Europe.

Broadly, the Council of Europe convention — which is open to states outside the European region — commits ratifying states to enact legislation requiring that personal data be lawfully obtained, accurate and relevant, and that its use be restricted to approved purposes. Any information recorded on race, politics, religion, health, sexual behaviour and criminality is subject to extra safeguards — although the convention may be over-ridden in extreme cases involving state security, public fraud and crime.

The signatories so far are Austria, Denmark, France, Germany, Luxembourg, Sweden and Turkey. Within Europe, Norway also has data protection legislation but has not yet signed the convention. Outside Europe, the United States and Canada have legislation. It is being considered at one level or another in most developed states. **Robert Walgate**

European astronomy

Winning ways

Hard on the heels of the race for the Space Telescope Institute, won by Johns Hopkins University last month, comes a similar competition in Europe. Four astrophysical institutes are competing for the European Coordinating Facility that will analyse and store space telescope data for European astronomers. The winner is expected to be announced by the European Space Agency (ESA) in June.

The competitors are the Royal Observatory, Edinburgh, the European Southern Observatory, Munich, the Observatoire de Paris and the Italian Institute for Astrophysics, Frascati. They have submitted bids to have thier own hardware used to store the data and develop programs for analysing them.

European astronomers will be allocated at least 15 per cent of the space telescope's observing time. Observers, who will only be a fraction of those wishing to use the telescope, will typically spend one or two weeks at Johns Hopkins and then return to Europe with their data for further analysis. Astronomers working at institutes with hardware compatible with that of the coordinating facility will be able to use its programs either by accessing them directly through computer links or by applying for tapes through the post.

Observers will have exclusive rights to their data for one year after which they will be available to the whole astrophysical community. The National Aeronautics and Space Administration and ESA have recently agreed that all space telescope data should be stored at the European facility as well as the Space Telescope Institute.

The European facility will most probably use a VAX 11/780 computer manufactured by the DS Digital Corporation. In an effort to increase the compatibility of hardware, several astrophysical institutes in Europe have decided to adopt this computer over the past year. Of the four competitors for the facility, the Royal Observatory, Edinburgh, with links to five other nodes in Britain, has the most highly developed system based on the VAX 11/780, making it perhaps the most likely winner. But the other competitors could catch up. There are plans to link Frascati's computer to other nodes in Italy and several computers compatible with VAX 11/780 are already linked in France.

Most of the cost of the coordinating facility will be met by the chosen institute. Although all candidates have suitable hardware, some could be required to expand their facilities more than others, involving them in considerable expense. ESA will provide only modest support: about £50,000 towards start up costs and thereafter £25,000 a year for incidental expenses plus seven staff salaries.

Selfish genes in race or politics

SIR — I hesitate before giving the National Front even a tiny bit more exposure in your pages: I imagine they welcome verbal denunciations, much as, on a larger and a physical scale, they presumably relish a "Smash the Front" march. But a public challenge from Steven Rose has just that touch of insinuation which makes me feel I would be unwise not to respond. He says (*Nature* 22 January, p.335): "May I suggest that it would be in the public interest that John Maynard Smith and Richard Dawkins should clearly dissociate themselves from the use of their names in support of this neo-Nazi balderdash".

Balderdash is a well chosen word. The extract from *New Nation* that he quotes is of course obvious balderdash, a travesty of science, in the service of an evil cause. Rose would have had every right to have added, "I told you so." He and his colleagues have long urged that "in due course racists would deploy sociobiology in support of their views". In my naive way, I never believed it possible that such a deployment could seem logical to even the most twisted mind, but perhaps I just lacked Rose's intimate knowledge of how science can be misused for political ends.

The equating of "kinship", in the sense of kin selection, with "ties of race" appears to result from an interesting variant of what I have called the fifth misunderstanding of kin selection[1].

Let me pass from this relatively esoteric point to concentrate on the central fallacy of the passage from *New Nation* that Rose quotes: ". . .our genes don't permit us to live in a Marxist–Rousseauesque egalitarian communist utopian World State of universal altruism. It was an inevitable result of the way evolution works that our genes would not permit us so to live."

The key to the error is to be found in the word "inevitable". I tried to make it clear in *The Selfish Gene* that ". . . it is a fallacy — incidentally a very common one — to suppose that genetically inherited traits are by definition fixed and unmodifiable. Our genes may instruct us to be selfish, but we are not necessarily compelled to obey them all our lives. It may just be more difficult to learn altruism than it would be if we were genetically programmed to be altruistic".

Insofar as my book has any political moral, it is conveyed by the closing sentence: "We, alone on earth, can rebel against the tyranny of the selfish replicators".

There is no evidence that racism is a naturally selected tendency, but just suppose some such evidence were to be discovered. What should be our response to it? The *New Nation* author presumably would say: Racism is the product of genetic evolution, therefore it is inevitable and desirable, and should be formalized in our political institutions. I would say: Racism is highly undesirable, and if it is indeed the product of genetic evolution this simply means that we should fight all the harder against it. There is a third position, untenable but, nevertheless, commonly held: Racism is highly undesirable, therefore we cannot allow it to be true that it is the product of genetic evolution. There must be something wrong with the evidence.

What is really wrong with the National Front quotation is not the suggestion that natural selection favoured the evolution of a tendency to be selfish and even racist. What I object to is the suggestion that if such tendencies had evolved they would be inevitable and ineradicable: the suggestion that we are stuck with our biological nature and can't change it. It is this that is the real balderdash, but where on earth did the myth of the inevitability of genetic effects come from? Is it just a layman's fallacy, or are there influential professional biologists putting it about?

Consider the following passage from Rose's[2] review of E.O. Wilson's *On Human Nature*: ". . . although he does not go as far as Richard Dawkins . . . in proposing sex-linked genes for "philandering", for Wilson human males have a genetic tendency towards polygyny, females towards constancy (don't blame your mates for sleeping around, ladies; it's not their fault they are genetically programmed)".

We may pass quickly over the somewhat free interpretation of my book. "Philanderer males" were not humans, they were hypothetical animals postulated as part of an elementary mathematical model, and in any case the computer simulation which I described ended up with the philanderers slightly outnumbered by "faithful" males.

The serious point I want to make arises out of Rose's amusing remark about ladies not blaming their mates. Just suppose it were shown that "human males have a genetic tendency towards polygyny, females towards constancy", what on earth would that have to do with concepts like "blame" and "fault"? Everybody knows that most healthy humans of both sexes have strong sexual desires which are not always strictly monogamous in aim, and many humans nevertheless enter into voluntary contracts of sexual fidelity, with some at least momentary intention of overcoming their polygamous tendencies. Many even succeed in this.

Depending on our philosophical position with respect to "free will", on the nature of the personal relationships concerned, and on the form of the contract entered into, words like "blame" and "fault" may or may not seem appropriate. But whether or not they are appropriate will not be altered one whit by anything that geneticists may ever discover. If sexual desire is strong or weak, it is so whether or not we label it genetically determined.

The same goes for racial prejudice. Whether it is eradicable or not is a serious question, but the consideration of whether it is "genetic" has no bearing on the matter. Rose may have forgotten the difference between "sex-linked" and "sex-limited" (see quotation above), but he will certainly recall that warhorse of the genetics textbooks, phenylketonuria.

This serious disease, caused by a single recessive gene, is easily cured by rearing the child on a special diet: an "environmental" cure for a genetic disease. If racism should turn out to be a genetically determined disease, I see no reason why it, too, should not be easily cured by suitable rearing conditions. And if it is not easily cured by educational means, exactly the same might be true of an acquired prejudice, say a prejudice that one has been taught during some critical years of early life. There is nothing particularly irrevocable about genetic effects on development, as compared with non-genetic effects.

How Steven Rose and the spokesmen of the National Front came to share their fatalistic views on the inevitability of genetic determination I cannot guess, unless it has something to do with the fact that "historical inevitability" is as dear to the Marxist heart as the related concept of "destiny" is to the Nazi one. In their biological manifestations, at least, the two concepts are as fatuous as each other.

But let me sound another note that may strike a chord in Rose's heart, a note of pure political expediency. If a scientific theory, X, about the nature of man, could have evil human consequences, we may hope that X will turn out to be false, but we would be unwise to take our stand purely on our hope that it is false. After all, it may just turn out to be true, and then we are left helpless and with our guard down. It is much wiser to say: "I don't think X is scientifically valid, but even if it *is*, so what?"

This message is nowhere more important than in our dealings with the other controversy mentioned in Rose's letter, the race/IQ controversy. As Stephen Jay Gould[3] puts it with his customary cogency: "I do not claim that intelligence, however defined, has no genetic basis — I regard it as trivially true, uninteresting, and unimportant that it does . . . It is just as likely that blacks have a genetic advantage over whites. And, either way, it doesn't matter a damn".

In the aftermath of Mrs Thatcher's electoral victory in 1979 Steven Rose wrote[4]:" . . . the switch in scientific fashion, if only from group to kin selection models in evolutionary theory, will come to be seen as part of the tide which has rolled the Thatcherites and their concept of a fixed, nineteenth century competitive and xenophobic human nature into power."

The theory of kin selection is logically entailed by the now virtually undisputed neo-Darwinian theory itself. It explains things that have been going on in the world for a thousand million years, and that will go on after our species is long extinct. Versions of it probably hold sway in uncountable islands of life all over the universe. It is annoying to find this elegant and important theory being dragged down to the ephemeral level of human politics, and parochial British politics at that. It seems that the National Front are not alone responsible for this.

NEWS AND VIEWS

Betty 15/2/82

A new measure of intelligence?

from N.J. Mackintosh

RECENT experiments by Christopher Brand at the University of Edinburgh have revealed an extremely high correlation between IQ and performance on a very simple task — that of judging which of two briefly presented lines is the longer. Subjects seated in front of a tachistoscope are shown, for example, two vertical lines side by side, one approximately 50 per cent longer than the other. Their task is simply to say whether the longer line is on the left or the right. If the lines are displayed for more than a few tenths of a second, the task is, of course, trivially easy. But errors can be induced by reducing the duration of exposure. 'Inspection time' can then be defined as the minimum exposure duration at which the subject can maintain a level of accuracy of, say, 95 per cent. A series of studies by Brand[1] and earlier work by Nettlebeck and Lally[2] at Adelaide show remarkable correlations, ranging up to -.92, and with an average of about -.80, between inspection time and various measures of IQ.

These correlations demand to be taken seriously. According to Brand, they suggest the possibility that intelligence is really a matter of quickness of apprehension. The quick child becomes the intelligent adult because he has been able to learn more, and more rapidly, from fleeting messages or briefly presented information.

Before considering these claims, some features of the data should be noted. None of the studies used very large or representative samples of subjects — the largest, a study by Nettlebeck and Lally[2], used 48 subjects and found a correlation of -.80. The Edinburgh studies have all been quite small and several have included mental retardates who may have contributed disproportionately to the correlations since it is difficult to find any psychological task on which they do not perform poorly. There is some disagreement about whether inspection time is more strongly related to verbal or performance IQ. One would like to see a study of a large, representative sample of the population with normal mean and distribution of IQ, which employed factor analysis on a number of different IQ tests in order to discover which component or components were most closely related to inspection time. These reservations are not trivial, but they are not significant enough to discredit what remains an intriguing and possibly very important finding. What does it mean?

One rationale for the search for simpler correlates of intelligence is the belief that they may reflect the basic psychological mechanisms underlying the diversity of intelligent behaviour. Such a belief antedates the development of IQ tests themselves. In the 1870s, some 25 years before Alfred Binet invented the intelligence test, the early exponents of the science of experimental psychology founded by Wilhelm Wundt at Leipzig studied such supposedly elementary processes as sensory thresholds, reaction times and digit spans. Some experimenters tried to demonstrate that differences in mental ability could be reduced to differences in these elementary processes.

They were not very successful. A celebrated study of students at Columbia University showed that these sorts of measures correlated neither with one another nor with such an obvious (albeit imperfect) criterion of intelligence as a student's grades. What was to be made of this? According to Binet, the answer was to abandon psychological theory and to take a more pragmatic approach. If we want to measure a child's intelligence then we should ask him to solve simple problems, answer questions about the meanings of words, or show that he has understood a passage of prose read out to him. No matter that we have no theory of the nature of the psychological processes involved in such tasks. What counted was that the tests worked: not only did they correlate with one another, but they also served to differentiate older children from younger ones and those judged more clever from those independently judged less able. The intelligence test, later to be called the IQ test, was born and flourished on this purely pragmatic basis. Items were selected for inclusion in IQ tests not on the basis of any theory of the mind, but because they discriminated between children of different ages or more simply because they agreed with other items, and because the new test agreed with the old.

This extraordinary absence of underlying theory has always been the Achilles' heel of IQ tests. No matter how well their tests predicted success in school, university or the world at large, no matter that factor analysis revealed that all tests were measuring a single underlying trait of general intelligence or '*g*', it was always possible to embarrass psychometricians by asking them just what was this general intelligence that they were measuring. The fact is that they had no idea, and no talk of 'innate general cognitive ability' by Burt, or of the 'eduction of correlates' by Spearman could disguise this fact. It is small wonder that many differential psychologists should have sought some more substantial psychological foundations on which to build their tests. Both Eysenck[3] and Jensen[4] revived the idea that differences in speed of decision-making, as evidenced in choice reaction times, may underly differences in intelligence. When a subject is presented, on each trial, with one of a set of possible stimuli and must respond appropriately, but as quickly as possible, it has long been known that his reaction time usually increases with the number of alternative stimuli. Correlations of between -.30 and -.50 have been reported between IQ and the slope of reaction time against number of alternatives.

But these correlations, although often significant, are not nearly as impressive as those reported by Brand and by Nettlebeck and Lally. It is possible, as Brand would argue, that reaction times measure other processes which serve only to obscure the fundamental relationship between intelligence and speed of perceptual processing.

Can intelligence really be reduced to such a basic process as this? Surely intelligence is too diverse to be captured thus simply. To this objection, differential psychologists have a ready answer. For all its apparent diversity, they argue, intelligence is a unitary trait, and IQ tests have revealed it to be so. As Clarke and Clarke[5] point out, "the most outstanding feature of all measures of intellectual ability in its broadest sense is that they show some degree of positive covariation". The simplest explanation of this covariation is that all IQ tests measure, with varying degrees of accuracy, this single trait of general intelligence or *g*. And the newly discovered correlation between IQ and inspection time reveals that *g* is a matter of speed of taking in perceptual information.

The next, marginally more sophisticated objection must be that the theory rests a great deal of weight on a set of correlations. The facts reported are consistent with the theory, but correlational data always admit a variety of explanations. That most tests of mental ability show marked positive correlations with one another is

0028-0836/81/070529-02$01.00

important and perhaps surprising (slightly less so when one remembers that one criterion for the inclusion of items in IQ tests is that they should correlate with other items already in the test). But it cannot prove that all items are measuring the same underlying trait. There might be a variety of independent traits, which happened to correlate with one another in the general population. There might be an indefinitely large number of traits, skills, strategies, or bits of knowledge possessed by the intelligent man, and different items in IQ tests might sample different subsets of the available pool. Positive correlations between different items or tests would reflect only the overlap between the subsets sampled by each. The postulation of *g* is only one of several possible explanations of the observed pattern of inter-correlations, which is why it may be important to provide independent validation for the construct. But is it not obvious that the discovery of some new characteristic, however simple, basic, or well defined, which correlated with IQ would achieve a great deal? A correlation between IQ and inspection time does not mean that IQ *is* mental speed, nor even that speed is one (of several) causes of IQ. The causal relationship might be very much less direct than this; it might even go in the reverse direction.

If we are to understand the relationship between IQ and inspection time, we shall need more help from theoretical psychology, in particular from workers in cognitive psychology and artificial intelligence. Unfortunately, psychometricians have looked to neurophysiology for the support they perceive is needed, and even more unfortunately to bad neurophysiology. Hendrickson and Hendrickson[6] for example, have claimed to show that IQ correlates with measures of average evoked potentials, and have proposed an implausible theory of cerebral function to explain the correlation. The implication of their argument is clear: here is a correlation where there can be no question about the direction of causality: differences in intelligence must depend on differences in the efficiency of neural activity. In a very general way, they may be right — somehow, no doubt, intelligence depends on the brain. But in our present ignorance of the neural mechanisms underlying any aspect of cognition, specific hypotheses are likely to seem naive, and the Hendricksons neurophysiology and neurochemistry will seem to most specialists something worse than this.

Differential psychologists have seen a second advantage to be gained from the discovery of a correlate of IQ such as inspection time, reaction time or evoked potentials. They are sensitive to the charge that IQ tests are biassed. Differences in IQ between middle and working classes and between whites and blacks in the United States are well established, but are widely seen as evidence only of the bias inherent in the tests. The charge may not be as strong as some critics would like to believe, but it will always seem plausible that tests of vocabulary, information, arithmetic, or even simple problem solving may discriminate unfairly against those whose background has made them less familiar with the material in question. But who could claim that a test which asked one to say which of two briefly exposed lines was the longer could be culturally biassed or loaded against minority groups? Here, at last, is the psychometrician's dream: a culture-free test of intelligence.

The argument may seem persuasive, but a moment's reflection should give one pause. For suppose that the results of such a test revealed as large a difference between North American blacks and whites as is revealed by current IQ tests. There is no reason to believe that this would persuade the critics of IQ tests that blacks really were, on average, less intelligent than whites. It would be just as likely to undermine the credibility of inspection time as a measure of intelligence. If, on the other hand, such a test revealed no average difference between blacks and whites, this would not prove that conventional IQ tests were biassed and that there really were no differences in intelligence, for that would only be true if we were willing to accept inspection time as the better measure of intelligence. And since, *ex hypothesi*, its correlation with IQ would now have been degraded, one might wonder how someone who puts great store by the importance of these correlations in the first place could reasonably advance such a proposition.

The discovery that IQ correlates very highly with performance on an apparently simple psychological task, although intriguing, probably important, and surely destined to instigate some valuable research, does not of itself resolve some of the psychometricians' problems. It does not justify Eysenck's assertion[7] that "intelligence can now be measured by the methods of natural science — it is not just a mythical or abstract thing". As Eysenck has often argued, measurement is theory based. The theory relating IQ and inspection time seems distinctly simple. It may be correct, but most cognitive psychologists would be inclined to agree with Seymour and Moir[8] that "qualitative variations in the executive programmes which schedule and call the subordinate routines are more important as cognitive determinants of intelligence than differences in the speeds of functioning of the individual routines." □

The source of enduring meteor train luminosity

from W. J. Baggaley

In the second issue of *Nature* (**1**, 58; 1869) the journal's founder Editor, Norman Lockyer, commenting on a first report of an hour-long luminous meteor train, hoped "... that advantage was taken of this almost unprecedented opportunity to bring the spectroscope to bear upon a meteor cloud ..." and expressed the wish that the mechanism of this enigmatic phenomenon be unravelled. More than a century later spectral observations of long-enduring meteor trains are still few and our understanding of the processes that produce the persistent luminosity is still incomplete. The recent measurement (Hapgood *Nature* **286**, 582; 1980) of emission in the near infra-red of a 32-minute train is therefore a substantial contribution to the meagre data.

The problem is that enduring trains are rare; the extensive survey of observations of both sunlit trains occurring at twilight and night time self-luminous trains compiled by C. P. Olivier (University of Pennsylvania) shows that trains longer than ten minutes occur in about one per 125,000 visual meteor events. The corresponding occurrence frequency for a single observer is therefore about 8×10^{-5} h^{-1}. Since a train may occur in any part of the sky and may have an unfavourable orientation, the problem of securing spectral records is clearly formidable. Spectroscopic observations of both the meteor primary (impact excitation) and the enduring emissions were undertaken in the last century using multi-prism direct-vision slitless instruments. The first observations of enduring trains, by Herschel in 1866, were of the Perseid shower. He and later workers reported the regular appearance in trains lasting minutes of yellow and green emissions identified as the Na D doublet at 5,893 Å and the Mg triplet at 5,183 Å as well as bands in the orange and red. The only other visual spectrum obtained appears to be the transmission grating observation reported by Fred Whipple (in *Rocket Exploration of the Upper Atmosphere* eds Boyd & Seaton, 1954) of an orange-red band

accompanied by a discrete red emission. Multiple-filter visual binocular studies (Hajdukova *Bull. astr. Insts Csl.* **18,** 187; 1967) demonstrated that for a non-shower sample of 114 trains radiation was predominantly longward of about 5,500 Å, a result in contrast to primary emission which is due mainly to features in the blue. Since primary spectra of meteors are dominated by short-wavelength iron transitions, the early orthochromatic emulsions were successful in white light photography. However, attempts to record enduring trains were largely unsuccessful until the use of panchromatic emulsions extended the spectral response to about 6,500 Å. More recent observations (Spalding & Hemenway *Astrophys. J.* **66,** 54; 1961) suggested the presence of a narrow spectral region in agreement with the photographic results (Bakharev *et al. Bull. Inst. Astrophys. Acad. Tadzik, SSR* **53,** 14; 1970) of 15-second trains which showed an absence of blue radiation with contributions predominantly between 5,000 and 6,000 Å.

Photograph of a meteor trail in close proximity to the Andromeda Galaxy M31. (Courtesy of Ondrejov Astrophysical Observatory, Czechoslovak Academy of Science.)

In the latest observation, Hapgood measured in the passband between 7,000 and 9,000 Å an emission rate per unit length of the meteor column of 2×10^{17} photon s^{-1} m^{-1} and attributed the emission to the excitation of 'forbidden' oxygen states O_2^* during the reduction of ground-state sodium monoxide in the cyclic mechanism

$$\mathrm{Na}+\mathrm{O}_3 \rightarrow \mathrm{NaO}+\mathrm{O}_2$$
$$\mathrm{NaO}+\mathrm{O} \rightarrow \mathrm{Na}+\mathrm{O}_2^*$$

The present picture therefore is that enduring trains radiate predominantly at wavelengths greater than about 5,000 Å and the evidence suggests that the process is mainly band emission. Indeed, for the abundant meteor species (Fe, Mg, Ca, O, Na) there are no strong low-energy allowed atomic transitions in the red and IR. In any reactant-consuming emission process resulting from an interaction between the species of a meteor column or between column species and atmospheric constituents, the emission rate will vary approximately inversely as the meteor column cross-sectional area. Hence under the action of diffusive (ambipolar or molecular) expansion such luminosity could not survive for more than a fraction of a minute. The production of train luminosity for tens of minutes requires a high photon yield process with regeneration of an active species, such as the sodium catalytic reaction cycle. This oxidation–reduction process invoked to explain enduring meteor trains has recently gained unequivocal support as a source of the sodium nightglow.

Hapgood proposes that excitation of the atmospheric system during the reducing step produces the IR emission. The formation of vibrational levels of the second excited electronic state of molecular oxygen $O_2(b^1\Sigma_g^+, v)$ by ground-state reactants NaO and O is not in violation of energy or spin conservation or of correlation rules and an appreciable fraction of reducing reactions might be expected (Bates & Ojha *Nature* **286,** 790; 1980) to yield O_2 in either the $b^1\Sigma_g^+$ or $a^1\Delta_g$ state. Unfortunately, any attempt to gain information by airglow studies on the channelling of reaction energy into the O_2 $(b^1\Sigma_g^+)$ state is not possible because oxygen atom recombination processes swamp any contribution from the Na catalytic mechanism.

While there is support for the oxidation–reduction cycle as the origin of the sodium nightglow and as a contributor to enduring train luminosity (the only other meteoric species for which the cyclic process is exothermic in the production of excited atoms is potassium with the possible yield of the 7,665 Å doublet), the role of the Atmospheric system must remain conjectural. Certainly the Atmospheric bands cannot account for the visual characteristics of trains — the green, red and orange emissions. This deficiency can be filled, however, by cyclic processes known to be exothermic involving metal and alkaline earth metals where regeneration of active species Fe, Al, Ca and Mg — atoms deposited during meteoroid ablation — may lead to high-yield monoxide band emissions and IR continua. In recent years laboratory studies of such chemiluminescent reactions have employed low-temperature flames and flow reactors using controlled atmospheres with various oxidizing and reducing agents as well as cross-beam techniques where processess under single collision conditions can be monitored. Such laboratory work has been complemented by photometric studies of chemiexcitation emissions resulting from rocket releases of various reagents into the thermosphere. Thus, excitation of diatomic FeO in chemiluminescent reactions with ozone oxidation producing the orange systems with strong emissions 5,500–6,500 Å has been studied in the laboratory while the bands have been observed in night-time atmospheric ejections of iron carbonyl, $Fe(CO)_5$. The blue-green system of AlO, has received much attention in the laboratory and numerous atmospheric releases of trimethyl-aluminium have been monitored: the reaction cycle excites strongly many sequences 4,500-5,000 Å as well as a broad IR system. Similar laboratory work has examined both the excitation in CaO of the red system yielding strong emission in the range 5,981–6,289 A together with the IR system at 7,712–9,229 Å; and also the excitation in MgO of the green system where the transition sequence yields strong emission from 4,900 to 5,020 Å. These chemiluminescent reactions exhibit photon yields of about 10 per cent and also produce IR continua due to the excitation of polyatomic intermediaries.

The spectral features of the oxide–reduction cycle emission involving meteoric atoms correlate well with luminous train characteristics: the absence of short-wavelength radiation, the narrow band emissions in the yellow, orange, red and green (where the 100 Å-wide MgO band could be confused with the Mg 5,183 Å triplet in a low-resolution spectroscope), and the IR bands and continua. Metal oxide excitation is therefore a strong candidate for the source of enduring train luminosity.

Image intensifier photon integration systems with their sensitivity to faint trains can alleviate the problem of the paucity of meteor events and play a valuable role in the provision of definitive spectral data. Such data should provide unequivocal evidence for the source of enduring train luminosity and fulfil the wishes of the first editor of *Nature.* □

Selection and induction in the development of autonomic neurones

from Miranda Robertson

ONE of the most important recent advances in the study of neural development has been the demonstration by biochemists, physiologists and electron microscopists at the Harvard Medical School that dissociated neurones from the sympathetic ganglia of newborn rats can be induced to switch their neurochemical character by manipulation of the conditions in which they are cultured[1]. Cultured neonatal cells at first synthesize and secrete noradrenaline, but can be induced to switch to the synthesis and secretion of acetylcholine by co-culture with non-neuronal cells such as heart, or by medium in which such non-neuronal cells have been grown. At the same time, N.M. Le Douarin and her colleagues at the CNRS laboratory in Nogent-sur-Marne have demonstrated neurochemical lability in avian sympathetic ganglion cells *in ovo*. They have been able to induce adrenergic function in cholinergic sympathetic ganglia of quails by back-transplanting them into the neural crest of earlier embryos at a site from which adrenergic ganglia normally develop[2]. These discoveries suggested that neurochemical phenotype might be determined after neuronal differentiation by tissues in the environment, and stabilized in the course of maturation[3].

In the light of more recent developments, however, it seems possible that neurochemical phenotype, at least in the autonomic nervous system, may never be irreversibly stabilized. This possibility was extensively discussed at a recent conference*, with two other closely related issues: what is the primordial phenotype of the autonomic neurone — adrenergic, cholinergic or dual-function; and are the switches reported *in vitro* and *in vivo* all due to induction, or may some of them actually reflect selection from an already heterogeneous population?

There is now evidence that although cultures of neonatal rat ganglion cells, at least in the hands of the Harvard team, express adrenergic characteristics, chick neural crest cells are already able to express the cholinergic enzyme choline acetyltransferase (CAT) at the point at which they begin to migrate to form the ganglia (Le Douarin). Unless there is a fundamental difference between chick and rat, therefore, the Harvard dissociated neonatal neurones may already have a cholinergic history.

Furthermore, some recent experiments by M. I. Johnson (Washington University) imply that they may never entirely abandon their cholinergic option. Dissociated neurones (though not, for unknown reasons, explants) even from adult rat superior cervical ganglion can be induced to express cholinergic functions in appropriate conditions *in vitro*. This important result lends weight to the view, held by several participants at the meeting, that autonomic neurones may remain inherently dual-function throughout life, their detectable phenotype depending on the balance of environmental factors.

The alternative view, that the apparent switch in neurotransmitter specificity may be due not to induction but to selection of already committed neural cells from a heterogeneous population, was persuasively put by D. Edgar, from Thoenen's laboratory at the Max-Planck-Institut, Martinsried. He and his colleagues have identified three factors — nerve growth factor (NGF) and factors from medium conditioned by heart cells or glial cells — which are required by different subpopulations of chick autonomic ganglion cells at different developmental ages for survival *in vitro*. They have now been able to show that the same subpopulations can also be distinguished by markers of adrenergic or cholinergic functions[4].

Does this mean that the actual effect of a change in culture conditions, at Harvard and St Louis as well as at Martinsried, is to enhance the growth of a separate subgroup of existing cholinergic cells at the expense of the adrenergic population, rather than to induce a switch? The answer to this question must be no. The Harvard team, represented at the meeting by D. Potter, has been able to show that single autonomic neurones in culture can, both on the physiological criterion of their ability to excite or inhibit cardiac contraction and on the ultrastructural criterion of vesicle morphology, switch from adrenergic to cholinergic. The St Louis team (in whose hands ganglion cells do not switch completely but remain dual-function) have been able to confirm immunocytochemically the expression of adrenergic traits in cells shown electrophysiologically to display cholinergic properties.

How, then, can the different results be reconciled? Edgar suggests that the explanation may lie in the relative efficiency of the culture techniques used in the different laboratories. Perhaps only some cells are capable of switching, and those cells are selected by the dissociation and plating procedures used at Harvard. This view is consistent with the fact that plating efficiency at Harvard is about 10% whereas at Martinsried it is about 90%. The implication is that the Martinsried cultures are more representative of the original cell population; but does it follow that their behaviour is representative of what actually happens *in vivo*? So far, with one possible exception, there are no data which can be unequivocally interpreted one way or the other. The exception is the investigation recently reported by Landis at Harvard on the sweat glands of the rat footpad, which seem to be innervated early in ontogeny with adrenergic nerves that subsequently become cholinergic[5].

Nonetheless, there can be no doubt that survival factors such as NGF play an important part in shaping the developing nervous system; and I. A. Hendry (Australian National University) has confirmed that NGF injected into the rat eye is transported back into the superior cervical ganglion and can reverse the effects of axotomy, which would normally cause the neurone to die. This implies that neurones depend for survival on factors retrogradely transported from their target tissues, although definitive evidence would of course require that the NGF be endogenous and not injected.

A more characteristically ambiguous discovery was reported by I. B. Black (Cornell University), who finds cells staining with catecholamine immunofluorescence in various ectopic sites in rat embryos treated *in utero* with NGF. This result can be interpreted either as induction of catecholaminergic characteristics in cells which would not otherwise express them (or would express them at levels too low to be detected by Black's technique); or as rescue of cells dependent on NGF and which would normally be deprived of it and die.

What are the limits on the ability of a ganglion cell to switch according to its environment? Le Douarin finds that although embryonic sensory glia can give rise to glia, neurones and endocrine cells of the autonomic nervous system, transplanted autonomic ganglion cells seem to be committed to an autonomic fate, and invariably migrate to autonomic ganglia, showing that the range of their developmental potential is narrower than that of neural crest or even sensory ganglion cells.

Furthermore, Potter pointed out that his experiments with Furshpan and Landis on single cultured neurones followed over time seem to show variation from one neurone to another in the extent of the adrenergic-to-cholinergic switch, some cholinergic neurones retaining catecholamine uptake and storage mechanisms while others seem to lose them. While some of the variation seems to be intrinsic to the individual neurone, Potter emphasized that the expression of different neurotransmitter-specific characteristics is

differentially sensitive to changes in the culture medium. Defining the properties of the medium, or the dosage of 'factors' responsible for the induction of the different traits is one of the most important aims of current research *in vitro*.

Participants at the meeting hoped that in the longer term, their research might elucidate diseases of the autonomic nervous system: for example, it seems possible that familial dysautonomia may be due to a deficiency in NGF, and that Hirschprung's disease may be due to the failure of ganglion cells to migrate into the hindgut. At this stage, it seems too much to hope that fundamental research will produce clear clinical answers; but there is no doubt that it is asking the relevant questions. ☐

Quasar alignments: chance or necessity?

from M. G. Edmunds

EVEN the staunchest believers in the interpretation of quasar redshifts as indicating their extreme distances from us, must be experiencing some disquiet at the apparently extraordinary configuration of quasars recently reported by H. Arp and C. Hazard (*Astrophys. J.* **240**, 726; 1980).

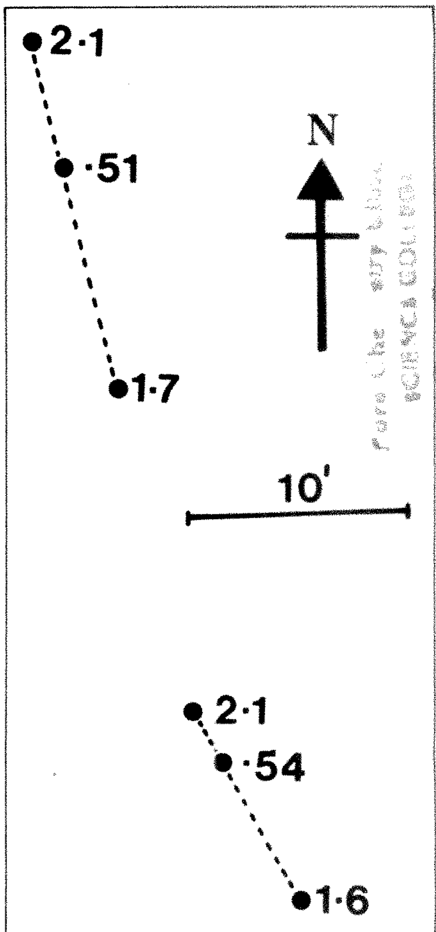
What Arp and Hazard have found is shown schematically in the accompanying figure. Two triplets of quasars are quite close together on the sky, with each triplet lying in a straight line which is exact to within the image sizes (about 2 seconds of arc) despite overall quasar separations of some 600 seconds for one triplet and nearly 1,000 seconds for the other. The confirmation of the identification of the objects as quasars, and the determination of their redshifts, have been accomplished by spectroscopic observations. The quasars are not unduly faint, all being brighter than about twentieth magnitude in visible light. Recent surveys of the density of quasars on the sky (see, for example, A. Savage and J. G. Bolton *Mon. Not. R. astr. Soc.* **188**, 599; 1979) imply that roughly five to ten quasars would be expected down to this magnitude per square degree of sky, so this peculiar configuration would seem, at first sight, to be highly unlikely to occur by a chance positioning of the individual objects in the sky.

The obvious implication is of association of the objects in the triplets, although the differences in redshift rule out any kind of gravitational lensing of a single object. But a kinematical explanation can be proposed, where the outer quasars in a triplet have been thrown out in opposite directions at relativistic speeds by the central object. This is not a new idea, but it has been unpopular as an explanation for quasars since it would be expected that some objects should be thrown out towards Earth giving Doppler blueshift, and blueshifted quasars are never observed. A novel mechanism for suppressing blueshifts has been suggested by Sir Fred Hoyle in a recent preprint (erroneously titled *The Quasar Controversy Resolved,* since it is bound to provoke even more discussion!). By assuming that the quasars ejected from the central object only radiate backwards in their rest frames into a cone around the line defined by the motion of the ejected object through a stationary intergalactic medium, then the so-called relativistic 'headlight' effect can cause this radiation to beam forwards towards an observer on Earth, while the transverse Doppler effect will cause it to be redshifted. Provided the cone of emission has suitable angle, blueshifts need never be observed. Unfortunately Sir Fred does not apply the model in detail to Arp and Hazard's triplets, and it is difficult to judge immediately just how artifical the parameters might have to be to give the observed configuration.

The idea of ejection of energetic objects from galactic (or quasar) nuclei is not in itself particularly heretical. The classic twin-lobe structure of giant radio sources, frequently observed to have a galaxy or quasar at the centre, certainly implies the symmetric ejection of something, although it could be just radiation. It is interesting that searches for optical objects at the regions of highest emission in the radio lobes, the very place you might expect ejected objects, has not found anything looking like a bright quasar. Some optically emitting regions have been found (see W. C. Saslaw, J. A. Tyson and P. Crane *Astrophys. J.* **222**, 435; 1978) but they are far too faint for reliable spectroscopic examination.

Is it possible that there are two kinds of quasar — one set composed of very active galactic nuclei, extremely energetic and at cosmological distances, and another kind composed of intergalactic ballistic missiles? This is a problem which is not new to the pages of *Nature* (M. Rowan-Robinson, **262**, 97; 1976; G. Burbidge **282**, 451; 1979), and it would be difficult not to concede that at least a proportion of quasars are at cosmological distances. Perhaps the most compelling arguments for this are the apparent continuity of spectral and energetic properties between Seyfert galaxies and quasars, and the observation of quasars which are apparently members of clusters of galaxies with the same redshift, implying a common (large) distance.

If some quasars are indeed distant, then there exists a theoretical problem in explaining the generation of their high luminosities in what must be (on the basis of observed variability) a comparatively small emitting region. Considerable progress has been made in recent years in considering accretion of material onto a massive black hole as a power source. Apart from the triplet alignment problem, the only real advantage in a ballistic quasar theory was that the objects could be in the local region near our own Galaxy and hence not require large energy outputs. Since the energy problem must be faced for



Schematic diagram of the configuration of quasars found by Arp and Hazard. The figures indicate the redshifts of the quasars, and it will be noticed that the two triplets have curiously similar values. The horizontal bar indicates the scale of ten minutes of arc on the sky.

M. G. Edmunds is in the Department of Applied Mathematics and Astronomy, University College, Cardiff.

the first type of quasar, it is of doubtful theoretical value to have a second type for which these problems can be sidestepped. Also, the overall similarity of spectral properties of quasars suggests a single kind of object. It is therefore tempting to apply Occam's razor and propose that there are only cosmological-redshift quasars, and that ballistic quasars do not exist. How could Arp and Hazard's alignments then be explained?

The answer could be that such associations are not as unlikely by chance as it might seem at first sight — perhaps the right statistics have not yet been done — it is anyway very difficult to apply *a posteriori* statistics once a peculiar pattern has been found. At least this point can, and should, be investigated more carefully by proponents of both quasar models.

It is perhaps surprising that the distances of quasars remain uncertain almost twenty years since their high redshifts were recognized, but a glance at the history of the debate over the nature of spiral nebulae should be enough to convince anyone that important questions sometimes take a long time to settle. Whatever their explanation, Arp and Hazard's fascinating triplets surely deserve a constellation name — Cosmology's Damocles or Hoyle's Banderillas perhaps? □

Antimatter back to front

from C.H. Llewellyn Smith

BEFORE 1956 it was taken for granted that parity is conserved — in other words, that the laws of nature do not distinguish between left and right. The shock produced by the discovery of parity violation was alleviated by Landau's observation that symmetry under the combined operation of 'charge conjugation' (C), which turns particles into antiparticles, and parity (P) could remain exact, that is, that there could be symmetry between left-handed matter and right-handed antimatter. If this CP invariance holds, then according to Landau "space remains completely symmetrical" and an asymmetry which "in view of the isotropy of space (conservation of momentum) would be more than strange" could be avoided. This view was generally accepted and CP invariance came to seem almost self evident. The discovery of CP violation by Christenson, Cronin, Fitch and Turley in 1964, for which they received the Nobel prize in 1980, was therefore almost as great a shock as the discovery of parity violation.

The existence of P and CP violation makes it possible to tell from watching a film of submicroscopic processes whether they involve matter or antimatter and whether the film is being projected correctly or has been loaded back to front. In contrast, if CP were conserved it would be impossible to distinguish a correctly shown film of matter from a back-to-front film of antimatter. If both C and P were conserved we could distinguish neither a film of matter from one of antimatter nor whether it had been loaded back to front.

Up to now CP violation has only been observed in the decays of neutral K mesons. The particles have fascinating properties which directly demonstrate fundamental aspects of quantum mechanics. In energetic collisions of strongly interacting particles, such as protons, either a K°, which contains an antistrange quark, or its antiparticle $\bar{K}^\circ$, which contains a strange quark, can be produced. However, strange quarks are unstable and decay into non-strange quarks. This allows K° and $\bar{K}^\circ$ to decay into identical products (either two or three pi mesons). It also allows a K° to turn into a $\bar{K}^\circ$ and vice versa. Consequently it is possible to make coherent quantum mechanical superimpositions or mixtures of K° and $\bar{K}^\circ$. Two particular mixtures behave as particles with definite masses and lifetimes. One, called K_S, is relatively short lived and decays predominantly into two pi mesons. The other, K_L, is longer lived and decays mainly into three pi mesons. A K° or $\bar{K}^\circ$ produced in a proton collision can be regarded as a mixture of K_S and K_L; the K_S component decays relatively quickly leaving pure K_L.

If CP symmetry were exact, the decay of K_L to two pi mesons would be completely forbidden, because K_S and the two-pion state into which Ks can decay would be symmetric under CP symmetry whereas K_L would be antisymmetric. The Cronin and Fitch experiment was designed to look for the CP violating decay $K_L \to \pi^+\pi^-$ and convincingly showed that it accounts for about two K_L decays in every thousand. A more direct manifestation of CP violation was provided by the later observation that the rates for the decays $K_L \to \pi^+ e^- \nu_e$ and $K_L \to \pi^- e^+ \bar{\nu}_e$ differ by about half a per cent; exact CP symmetry would turn K_L into itself, π^+ into π^-, e^- into e^+ and ν_e into $\bar{\nu}_e$ and require the rates to be equal.

Immediately after Christenson *et al.* announced their result in 1964, various ingenious ways to reconcile it with CP symmetry were proposed. Perhaps the most interesting was the idea of a long-range force which couples to K° and $\bar{K}^\circ$ and to other forms of matter and antimatter with opposite signs. Such a force would generate apparent CP violation due to the predominance of matter over antimatter in the Universe. However, it would also give rise to an apparent violation of lorentzian invariance causing the fraction of decays of K_L to $\pi^+\pi^-$ to depend on velocity. This was quickly ruled out.

It soon became apparent that not only CP but also time reversal invariance (T) is violated or, in other words, that the laws of nature depend on the arrow of time. This makes it possible to tell whether a film of certain submicroscopic processes is being run forwards or backwards. The possibility of T violation was immediately obvious because it was known that any theory which respects lorentzian invariance and the general principles of quantum mechanics is necessarily symmetric under the combined operation CPT. This CPT symmetry makes it impossible to distinguish a correctly projected film of matter run forwards from a back-to-front film of antimatter run backwards. If CPT is unbroken, then CP violation necessarily requires T violation. However T violation can be demonstrated directly without invoking CPT symmetry. Further study of the neutral K system showed that the quantum mechanical probability amplitude for K° to turn into $\bar{K}^\circ$ differs from the amplitude for $\bar{K}^\circ$ to turn into K° by about one per cent — a direct manifestation of T noninvariance. However, the amplitudes for K° and $\bar{K}^\circ$ to remain themselves, which must be the same if CPT symmetry holds, are equal to better than one part in 10^{17}.

It is hardly surprising that the origin of CP violation was mysterious in the 1960s since the nature of the weak interactions was not understood then. The advent of unified electroweak theories did not help at first since the simplest model which fitted the known facts did not allow CP violation. However, in 1973 Kobayashi and Maskawa pointed out that if there were more than four quarks CP violation would be almost unavoidable. Since the discovery of the fifth quark in 1977, CP violation has therefore seemed very natural. In fact, available unified models give rise to CP violation of the observed order of magnitude, although the precise strength of the effect can not be predicted at present. According to these models the only other likely observations of CP violation in the near future will be in the decays of mesons which contain the fifth quark and possibly also in neutrino oscillations, if they really occur, which are similar to K°- $\bar{K}^\circ$ oscillations.

This relatively happy situation has been jolted by the discovery that quantum chromodynamics (QCD), an extremely elegant and plausible candidate theory of the strong force, can give rise to CP violating effects, which are potentially much too large. Ironically one of the arguments for taking QCD seriously in the first place was that it could never generate strong CP violation. However, although this argument is true to all orders if the theory is treated perturbatively, it turns out that non-perturbative effects (called

---

C. H. Llewellyn Smith is a Reader in Theoretical Physics at the University of Oxford.

0028-0836/81/070534-02$01.00

'instantons') generate T and P violating effects which involve a new parameter called θ. Although θ could have any value, it would seem natural for it to be of order one. However, the experimental upper limit on the T and P violating electric dipole moment of the neutron requires $\theta < 10^{-8}$. No good reason why θ should be so small is known.

Thus there are still some mysteries surrounding CP violation. Indeed, it is still not clear whether C, P and T are intrinsically broken. It is possible to construct electroweak theories in which the underlying equations are completely symmetrical but the solutions are asymmetrical. Recently interest in the nature of CP violation has been greatly increased by the discovery that it may be a key element in explaining the large excess of matter over antimatter in the Universe. Attempts to unify the strong with the electroweak interactions suggest that baryon number is not conserved. Indeed, they predict that the proton decays with a lifetime of about 10^{30} years, and experiments designed to search for proton decay are now under construction. In this case, as originally discussed by Sakharov, a universe containing mostly matter can develop from a state of equilibrium between matter and antimatter because of the asymmetry due to CP violation. Furthermore, this picture is capable of explaining the observed ratio of about 10^8 between the number of photons and baryons in the Universe. If baryon number is conserved, it is necessary to invoke an initial asymmetry of one part in 10^8 to explain this ratio. If these cosmological speculations hold up they will put severe constraints on the fundamental mechanism responsible for CP violation.

The discovery of CP violation completed the conceptual revolution begun by the discovery of parity violation. This revolution has led to a healthy scepticism about other old shibboleths such as baryon conservation. Current theory can naturally accommodate CP violation. It is true that its magnitude cannot be predicted at present but this problem is on the same footing as other unanswered questions, such as how to predict the masses of quarks, if we leave aside the θ problem. The asymmetry between matter and antimatter which previously seemed "more than strange" now seems natural and perhaps even inevitable. But without it the Universe might be quite different. □

Genetic engineering and foot and mouth disease vaccines

from J. B. Brooksby

WHEN genetic engineering was first discussed in relation to foot and mouth disease vaccines, conventional virologists were sceptical of a practical outcome in less than perhaps ten or fifteen years. Enough was known of the viral genome to suggest that appropriate information might be incorporated into plasmids but a pessimistic view was taken of the possibility of expression of this information to provide the antigenic moiety of the virus in active form. The paper by Kupper and his co-authors on p.555 of this issue shows that the obstacle of expression has been surmounted and a milestone has been passed on the road to production of antigens for vaccine.

Although this is not the first report of the production of a viral antigen in this way, it is a happy circumstance that a foot and mouth disease product is early in the field, not perhaps because the agent was the first animal pathogen discovered to be a virus, but because of the importance of foot and mouth disease vaccine in controlling what is still one of the most serious diseases of animals throughout the world. More foot and mouth disease vaccine is produced than any other vaccine, but more is yet needed to begin campaigns in countries where the disease continues to spread. Compulsory regular vaccination in Western European countries over the past 25 years covering more than 60 million cattle has reduced the incidence of the disease to vanishing point — indeed, most recent outbreaks have been linked, at least circumstantially, to vaccine containing residual live virus. In South America, which has a long-standing problem, at least 500 million doses of polyvalent vaccine are produced annually. These figures indicate the importance of the disease to the animal industry, through its debilitating effects, lowering of milk production and interference, because of its remarkable spreading power, with trade in animals, meat and other products.

Present vaccines are produced from virus cultivated either in surviving tongue epithelial tissue collected from animals slaughtered for meat, or in cell lines grown in suspension in large (2,000 litres or more) vessels. Problems arise in the production of sufficient viral antigen, especially with some strains of virus, and the multiplicity of types (there are seven) and sub-types (over 60) necessitates either expensive polyvalent vaccines or vaccines appropriate to particular areas which may have to be changed rapidly to meet new strains arising in the field. Thus, although much has been achieved with available vaccines, as the experience of European countries shows, there is still a real need for alternative methods for producing viral antigen.

The application of genetic engineering may offer such a method and the work reported, together with other studies proceeding in the UK (at the Animal Virus Research Institute and Wellcome Foundation Ltd) and in the US (at the Plum Island Animal Disease Center and Genentech — see *Nature* **288**, 663; 1979), indeed give promise for the future.

The advantages of a vaccine based on an antigen consisting of the appropriate viral protein, prepared in a way that does not involve infective material at any subsequent stage after isolation of the viral RNA and which allows the production of greater quantities than from natural sources, are obvious. Kupper *et al.* have concentrated on the preparation of VP1, the coat protein responsible for the production of the antibody response to foot and mouth disease virus. Laporte and Bachrach and their colleagues in France and the US showed that purified VP1 from disrupted virus stimulates an antibody response, albeit weak, in guinea pigs and swine, and large doses will protect swine against subsequent infection.

In the present experiments, VP1 produced in the bacterial cell has been identified by its reaction with specific VP1 antibody and from the serological reaction it is estimated that at least 1,000 VP1 molecules are synthesized per cell. This is a signal achievement which is not diminished by the question — what remains to be done? Clearly, the new VP1 must be shown to immunize animals. The quantitative aspect is important, for the earlier work suggested that at least 1,000 times more antigen was required when the VP1 had been isolated than when it was carried on the intact, but inactivated virus particle. Yields from bacterial culture can probably be raised above those from mammalian cell culture and the factor by which this is possible will be critical for the success of the method. The quality of the antigen is also fundamental. It may be that, in order to preserve VP1 from degradation, it will be advantageous to synthesize the precursor which cleaves to form all four capsid proteins.

A new and exciting prospect is the possibility of overcoming some of the difficulties created by virus variation in the field. It may well be practicable to tailor strains to stimulate immunity to a wider antigenic spectrum than that given by naturally occurring viruses. There is no doubt that the progress reported will lead to a redoubled effort by the various groups and the prospects for new foot and mouth disease vaccines are indeed bright.

J. B. Brooksby is a former Director of the Animal Virus Research Centre, Pirbright, UK.

Well-groomed predecessors

from R. D. Martin

RECONSTRUCTIONS of mammalian phylogeny have depended heavily on dental evidence, since teeth are preferentially preserved in the fossil record. As a rule anterior teeth (especially incisors) are easily lost in fossilization and most weight has been placed on the characteristics of cheek teeth (premolars and molars). However, there are some striking modifications of the lower anterior teeth among living mammals and these provide not only useful diagnostic features but also valuable functional clues. A good example is the 'tooth-comb' formed by the procumbent lower front teeth in mammal groups such as the tree-shrews, strepsirhine primates (lemurs and lorises) and 'flying lemurs' (which actually are not lemurs and do not fly — they are unusual gliding mammals relegated to their own order, Dermoptera). The tooth-comb of lemurs and lorises is particularly unusual in that the lower canines are incorporated along with the incisors, and it is now widely accepted that a unique six-tooth comb (two canines and four incisors) was probably an ancestral feature of lemurs and lorises.[1,2] In tree-shrews, by contrast, the tooth-comb is formed by some or all of the six lower incisors without involvement of the canine teeth, and in flying lemurs the four lower incisors all have crenulated tips and act as individual combs. These are doubtless convergent developments.

The tooth-comb has often been seen as an adaptation for grooming of the fur. Indeed, virtually all tree-shrew, lemur and loris species have been seen using the tooth-comb in a characteristic rake-and-lift action to groom the fur, though no such use of the lower incisors has been recorded for the flying lemur. Despite some past claims to the contrary[3,4] there is now no doubt that the tooth-comb serves a valuable grooming function in tree-shrews and in strepsirhine primates. Nevertheless, in recent years evidence has accumulated that all of these species also use their anterior lower teeth for feeding. For instance, soft fruit pulp may be scooped out with the tooth-comb and detailed field observations of nocturnal lemurs and lorises [5] have revealed that many species feed upon gums (natural polysaccharide exudates from trees). For one species — the lesser bushbaby (*Galago senegalensis*) — clear evidence of the use of the tooth-comb in gum-feeding has been collected[6]. Further, the greatest development of the tooth-comb (once body size has been taken into account) is found in two species which feed predominantly on gums, the needle-clawed bushbaby (*Galago elegantulus*) and the fork-crowned lemur (*Phaner furcifer*). It has been claimed[7] that the tooth-comb in small-bodied lemurs and lorises is too fragile to allow for its use in feeding, but fruit pulp provides no great resistance and gums are usually collected in a semi-liquid state. It is therefore a moot point whether grooming or feeding was the primary function of the tooth comb in lemurs and lorises, but it is certain that both functions are served in extant species.

Our understanding of the origin of tooth-comb grooming has now been considerably advanced by the report by Rose, Walker and Jacobs (see this issue of *Nature* p583) that wear patterns produced by repeated passage of hairs between the lower anterior teeth can be clearly recognised with the scanning electron microscope (SEM). SEM photographs of the lower anterior dentitions of extant strepsirhine primates, such as *Galago crassicaudatus*, reveal fine vertical grooves on the sides of the teeth. Similar grooves are found on the lower incisors of certain tree-shrew species, but no such wear patterns are found on the comb-like lower incisors of the flying lemur, suggesting that their function is restricted to feeding. This new evidence is particularly valuable because the findings can be extended back through the fossil record. A tooth-comb consisting of six lower incisors has been reported[8] for early Tertiary (Palaeocene/Eocene) arctocyonid condylarths and Rose *et al.* have demonstrated that the lower incisors of these early placental mammals bear grooves closely resembling those found on the comb-teeth of modern lemurs, lorises and tree-shrews. This neatly confirms the proposal made by Gingerich and Rose that the lower incisors of these condylarths were used for grooming. This would seem to be the earliest direct fossil evidence of a mammalian behaviour pattern, and it would certainly appear to be the most reliable demonstration that mammalian hair was definitely in existence over 55 million years ago! Significantly, the earliest (mid-Palaeocene) condylarth species examined by Rose *et al.* also exhibited wear on the tips of the comb-teeth, indicating a combined grooming and feeding function.

Reconstruction of the evolutionary history of the tooth-comb in lemurs is hampered by the poor fossil record. Until recently, the only reliable early fossil forms were early Miocene lorisids from East Africa (approx. 18-20 million years old). On the basis of indirect evidence, all three recognised East African lorisid genera from the Miocene (*Komba*; *Progalago*; *Mioeuoticus*) are thought to have possessed tooth-combs like their modern relatives, but no anterior tooth crowns are known[9]. Now Jacobs (see this issue of *Nature* p585) has reported new fossil finds from the late Miocene Siwalik deposits of Pakistan (some 7-10 million years old) assigned to the lorisid species *Nycticeboides simpsoni*. This newly-discovered species definitely had a tooth-comb, and Rose *et al.* have applied their SEM procedure to the crowns of one canine and two incisors. These teeth closely resemble their counterparts in modern lorisids and SEM examination revealed the fine vertical grooves characteristic of use in grooming. Thus, the use of the lorisid tooth-comb in grooming can be definitely traced back at least 7 million years. Unfortunately, though, feeding on gum or soft fruit pulp is not known to leave characteristic wear patterns on the tooth-comb, so possible dietary function remains untested.

Jacobs regards *Nycticebodies simpsoni* as belonging to the subfamily Lorisinae (including the slow-moving pottos and their relatives), rather than to the Galaginae (the agile, saltatory bushbabies). It is true that *Nycticeboides* shares with modern lorisines specific characters such as simple rear premolars, relatively weak development of the fourth cusp (hypocone) on the upper molars, and poor development of the ectepicondylar flange on the humerus. However, such characters only indicate a phylogenetic link between *Nycticeboides* and lorisines if they emerged *after* the divergence between galagines and lorisines (that is, if they are not primitive features of the lorisids), and this remains to be demonstrated. But if Jacobs is right, the presence of *Nycticeboides* in the Siwalik deposits could have a wider significance, since *Ramapithecus* (regarded by many palaeontologists as an early relative of man) also occurs in the Siwaliks. All modern lorisine species, unlike some bushbabies, are confined to relatively dense forests with virtually continuous arboreal pathways. Modern tree-shrews are similarly confined to forested regions and fossil tree-shrews have already been reported from these same Siwalik deposits[10,11]. The combined evidence of forest conditions provided by fossil lorisines and tree-shrews in the Siwaliks raises the possibility that *Ramapithecus* was also at least partly a forest-living primate. If *Ramapithecus* does lie close to the origin of the hominid line, as many authorities believe, confirmation of a forest background for this Miocene genus would be of great value, if only in ruling out some of the speculative suggestions which have been made in the past. □

REVIEW ARTICLE

Dendritic release of dopamine in the substantia nigra

A. Cheramy, V. Leviel & J. Glowinski

Groupe NB—INSERM U 114, Collège de France, 11, place Marcelin Berthelot, 75231 Paris Cedex 05, France

Dopamine can be released in the substantia nigra from the dendrites of nigrostriatal dopaminergic neurones, to be involved there in the self-regulation of the dopaminergic cells, to control the release of neurotransmitters from nigral afferent fibres and to influence the activity of nigral non-dopaminergic cells.

IT is still widely considered that the transfer of information is unidirectional in neurones which communicate through chemical synapses. Messages travelling from dendrites, through somata and down axons finally reach the nerve terminals from which the neurotransmitter is released. By interacting with postsynaptic receptors located on somata or dendrites, the neurotransmitter will then modify the activity of the target neurones. Several years ago, however, it was suggested that molecules could also be released from dendrites to influence surrounding cells or nerve terminals[1-5]. In this article, we review the accumulating evidence which indicates that dopamine (DA) is released from dendrites of the nigro-striatal dopaminergic neurones and contributes to the processing of signals in the substantia nigra (SN). Complementary anatomical, electrophysiological and biochemical studies show that DA is released from dendrites to regulate not only the release of neurotransmitters from some nigral afferent fibres, but also the activity of the dopaminergic neurones and of other nigral efferent neuronal pathways. Consequently, by acting in the striatum and the SN, the dopaminergic neurones may influence the messages delivered to the striatum by the cortico- and thalamo-striatal fibres and those emerging from the SN through projections innervating the thalamus and the pontine nuclei.

Substantia nigra as a site for study of dendritic release of DA

Nigro-striatal dopaminergic neurones are particularly well suited to the study of neurotransmitter release from dendrites in the central nervous system. Their cell bodies are mainly concentrated in the pars compacta and their long, ramified and varicose dendrites extend throughout the pars reticulata of the SN[1]. Their fibres, in contrast to those of non-dopaminergic cells of the pars reticulata, do not emit collaterals within the SN[6]. Intraventricular or locally injected radioactive catecholamines readily label the cell bodies and the dentrites of the dopaminergic neurones whilst showing the virtual absence of catecholaminergic nerve terminals[7-10]. Furthermore, few if any nigral boutons degenerate after intraventricular or nigral injections of 6-hydroxydopamine[11,12], a neurotoxin which selectively destroys catecholaminergic fibres. The SN is also an appropriate site for the study of the dendritic release of DA because there is good evidence not only that DA can be synthesized[13-18] and stored[1,10,19,20,21,22] in dopaminergic dendrites, but that it can also be inactivated. However, it should be noted that the mechanism of DA re-uptake in dendrites may differ from that in nerve terminals[1]. Furthermore, little is yet known about the mechanisms of DA storage in dendrites. Although a few large or small dense core vesicles are seen to be scattered in some thin distal dendrites using 5-hydroxydopamine as a marker of monoamine storage sites[23], no specialized vesicles are seen in dopaminergic dendrites identified by the autoradiographic method[7,10]. It has been suggested that DA is stored in smooth endoplasmic reticulum[10,17,22].

DA metabolism in the SN

A guide to the metabolism of DA is commonly provided by measurement of its metabolites, methoxytyramine (3-MT), dihydroxyphenylacetic (DOPAC) and homovanillic (HVA) acids. This approach has also been applied to the rat SN to investigate DA metabolism in dendrites in various experimental conditions and to compare the results with those obtained in the striatum.

Korf *et al.*[24,25] observed an enhanced accumulation of DOPAC and HVA not only in the striatum but also in the SN shortly after the electrical stimulation of the middle forebrain bundle through which dopaminergic fibres run towards the striatum. The changes in the levels of nigral DA metabolites led

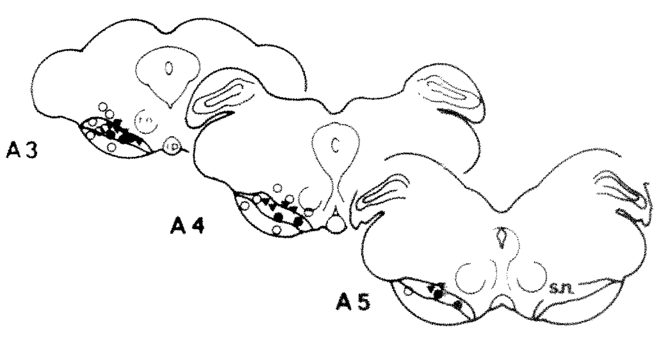

Fig. 1 *In vivo* spontaneous release of newly formed ^{3}H-DA in the cat SN. Halothane-anaesthetized cats were implanted with a push–pull cannula in the left. ^{3}H-tyrosine (50 Ci mmol^{-1}, 50 μCi ml^{-1}) was delivered continuously in the push–pull cannula (2 ml h^{-1}) and ^{3}H-DA was estimated in 10-min superfusate fractions 1 h after onset of superfusion, at a time when the spontaneous release of the ^{3}H-transmitter reached a steady state. In each case, the mean spontaneous release of ^{3}H-DA was estimated on the basis of results obtained in five successive fractions and the localization of the tip of the push–pull cannula was determined. The spontaneous release of ^{3}H-DA was much higher when the tip of the cannula was in the SN (●, >0.5 nCi per 10 min; ▲, 0.1–0.5 nCi per 10 min) than when it was in the lateral part or outside of the SN (○, <0.1 nCi per 10 min). them to suggest that DA was released from dendrites as a result of antidromic activation of the dopaminergic neurones.

Various drugs acutely influence the nigral DA metabolism, sometimes in a manner different from that in the striatum. For example, amphetamine reduces DOPAC formation in both structures whilst increasing 3-MT levels only in the striatum[26], whereas reserpine, which depletes striatal and nigral levels of DA[27], increases the levels of DOPAC and 3-MT in the striatum, but not in the SN[26–28]. In addition, γ-hydroxybutyrate, a general anaesthetic which enhances striatal DA levels and synthesis, induces opposite effects in the SN[29,30]. These and other[27,28,31,32] discrepancies also indicate that changes in nigral DA metabolism reflect events occurring in dendrites and not in axon collaterals.

Dendritic release of DA *in vitro*

Using slices of the rat SN, Geffen *et al.*[21] demonstrated a calcium-dependent release of ^{3}H-DA from dendrites with potassium depolarization. Similar observations were made with slices of pars compacta or pars reticulata or by measuring the release of endogenous DA[10]. A veratridine-evoked release of ^{3}H-DA sensitive to tetrodotoxin was also shown, indicating that dopaminergic dendrites have fast sodium channels[33] (Table 1). Gentle homogenization of nigral dopaminergic dendrites can produce particles which behave like synaptosomes on density gradient centrifugation[34,35]. These dendrosomes take up ^{3}H-DA which can be released by potassium depolarization[36] (Table 1). Amphetamine, a potent releasing agent of DA from nerve terminals, stimulated the release of DA from SN slices or dendrosomes[35,37,38] (Table 1). Other studies indicated that transmitters present in large amounts in the SN could also influence the dendritic release of DA (Table 1). γ-aminobutyric acid (GABA), which did not affect the spontaneous release of ^{3}H-DA newly taken up from SN slices, potentiated the potassium-induced release of the ^{3}H-amine and this effect was blocked by picrotoxin[38]. Substance P[39] and glycine[40,41] stimulated spontaneous efflux of ^{3}H-DA from rat nigral slices, the latter effect being antagonized by strychnine[40] (Table 1).

Dendritic release of DA *in vivo*

Our method for demonstrating the *in vivo* dendritic release of DA makes use of a push–pull cannula to superfuse continuously the SN of halothane-anaesthetized cats with a physiological medium containing ^{3}H-tyrosine, the precursor of ^{3}H-DA[42]. This method ensures specificity because tyrosine hydroxylase is only located in dopaminergic neurones in the SN. In fact, ^{3}H-DA represented >90% of the total content of ^{3}H-catecholamines recovered in superfusates. Furthermore, the spontaneous release of ^{3}H-DA was only substantial when the push–pull cannula was within the SN (Fig. 1). ^{3}H-DA release was reduced in the absence of calcium and markedly increased during a pulse application of potassium. Tetrodotoxin, which reduces the spontaneous release of ^{3}H-DA from nerve terminals in the caudate nucleus, induced the opposite effect when applied in the SN[42]. This effect excludes a nigral release of ^{3}H-DA from nerve terminals and suggests that some nigral afferent fibres inhibit the spontaneous dendritic release of DA. Furthermore, the inability of tetrodotoxin to reduce the spontaneous release of ^{3}H-DA from dendrites could indicate that fast sodium

Experiments were performed in cats implanted with push–pull cannulae as described in Fig. 2 legend. Changes in ^{3}H DA release are expressed as per cent of the mean spontaneous release estimated during the hour preceding the treatments. They were estimated during the first 10-min (amphetamine, potassium) or the third 10-min (other cases) fraction after the start of treatment, and are the mean of data obtained with groups of 4–7 animals compared with results from untreated cats. Data corresponding to the local effects are not indicated (—). Drug treatments: *d*-amphetamine (10^{-6} M); α-M-*p*-T (α-methylparatyrosine, 10^{-4} M); diazepam (10^{-5} M); K^+ (potassium, 30 mM).
*$P \leq 0.05$ using Student's *t*-test.

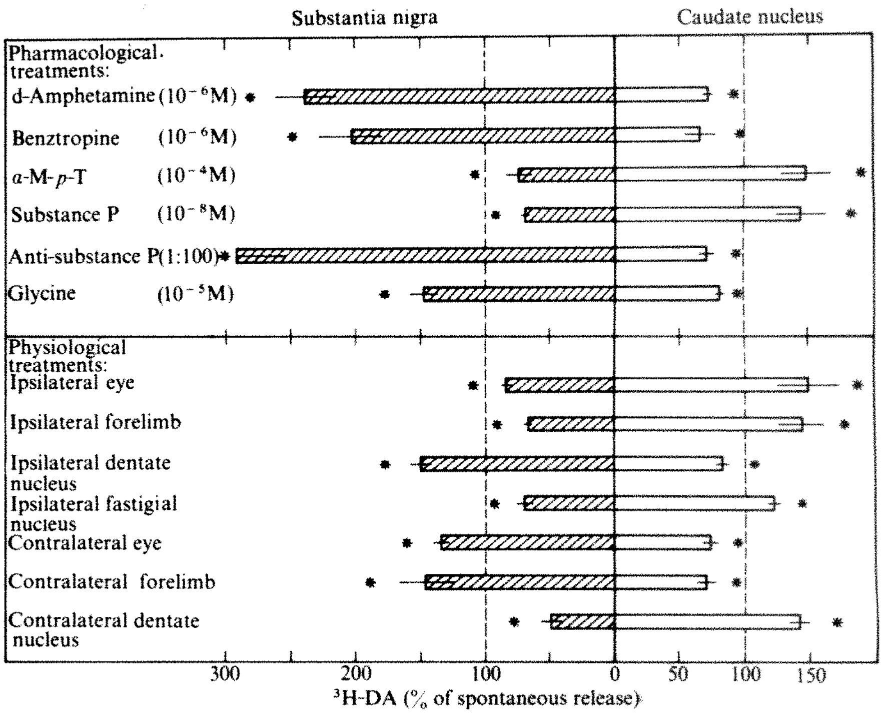

Fig. 2 Examples of treatments which induced opposite changes in the release of ^{3}H-DA from dendrites in the SN and from nerve terminals in the ipsilateral caudate nucleus. The effects of the unilateral nigral application of dopaminergic drugs, substances affecting substance P transmission, glycine or unilateral physiological stimuli on the release of newly formed ^{3}H-DA in the SN and the corresponding caudate nucleus were examined in halothane-anaesthetized cats implanted with push–pull cannulae. ^{3}H-DA was estimated in successive 10-min fractions during the continuous delivery of ^{3}H-tyrosine to each cannula. *d*-Amphetamine, benztropine, α-M-*p*-T, substance P, substance P antibody or glycine were introduced for 10–60 min into the superfusing medium delivered to the SN 3 h after the start of the experiments. The physiological stimuli comprised the delivery of light flashes applied for 10 min to the ipsilateral or contralateral eye, the electrical stimulation of the ipsilateral or contralateral forelimb (10 min), the electrical stimulation of the ipsilateral or contralateral dentate nuclei of the cerebellum (10 min) or the ipsilateral cerebellar fastigial nucleus (10 min). The results are expressed as per cent of the mean spontaneous release of ^{3}H-DA estimated during the hour preceding the treatments and correspond to changes observed during the first 10-min application of amphetamine, benztropine and glycine, or during the third 10-min fraction after the start of application of other treatments. They are the mean of data obtained with groups of 3–7 animals, compared with results from untreated cats. Statistical analysis was done using Student's *t*-test; *, $P \leq 0.05$.

channels are not involved in this process, in contrast to that observed in the caudate nucleus. In fact, dendritic spikes resistant to the neurotoxin have already been described[43–45].

Several neurotransmitters present in the SN influence the dendritic release of ^{3}H-DA. A stimulation of ^{3}H-DA release was induced by glycine (Fig. 2), acetylcholine and serotonin but substance P induced the opposite effect[46,47] (Fig. 2). Although GABA was ineffective, the GABA agonist muscimol enhanced the dendritic release of ^{3}H-DA[48] whereas the reverse was seen with diazepam, a benzodiazepine known to facilitate GABAergic transmission.

One critical step in our *in vivo* studies has been the demonstration that changes in the activity of neurones with functional connections to the SN, or involved in sensory motor processes, affected the dendritic release of DA. Thus, ^{3}H-DA release was altered by electrical stimulation of the motor or visual cortices[49] (Table 2) and of the fastigial and dentate cerebellar nuclei[50] (Table 2, Fig. 2), as well as by local pharmacological interruption, or facilitation of dopaminergic transmission in the ipsilateral caudate nucleus or in the contralateral SN[51] (Table 2, Fig. 3). Further evidence that messages originating in one SN could influence the dendritic release of DA in the contralateral structure came from the local nigral application of potassium[52] or diazepam (Table 2). Marked changes in the dendritic release of ^{3}H-DA were also induced by delivery of sensory stimuli[53] (Table 2, Fig. 2). Sometimes, the changes in ^{3}H-DA release remained for up to 1 h after treatment, suggesting the involvement of long-term regulatory processes which have still to be elucidated. These *in vivo* experiments indicate that the dendritic release of DA from the nigro-striatal dopaminergic neurones is a physiological event which must contribute to the local transfer of information.

Dendritic DA can influence the activity of ipsilateral dopaminergic neurones

Several years ago, Bunney and Aghajanian[54] suggested the presence of dopaminergic receptors on dopaminergic cell bodies or dendrites in the rat SN. They observed that the microiontophoretic application of DA or of apomorphine reduced the firing rate of the dopaminergic cells and that this effect was prevented or reversed by neuroleptics[55]. Groves *et al.*[56] reported that amphetamine (a drug which releases DA) inhibited the firing rate of pars compacta neurones after its local application and that this effect was prevented by peripheral injection of α-methylparatyrosine[57], the inhibitor of catecholamine synthesis. Because these authors also observed that the local application of haloperidol enhanced the firing rate of pars compacta neurones, they suggested that DA could be released from dendrites and was involved in a self- or lateral-inhibition of the nigral dopaminergic neurones[56]. The presence of dopaminergic autoreceptors in the rat SN has since been confirmed by binding studies with labelled spiroperidol[58–60] or apomorphine[61] after selective degeneration of the dopaminergic neurones.

To confirm the changes in the firing rate of dopaminergic cells seen in electrophysiological studies, we have measured changes in DA release from nerve terminals during pharmacological modification of the nigral dopaminergic transmission. The nigral application of DA by a push–pull cannula reduced the spontaneous release of ^{3}H-DA in the ipsilateral caudate nucleus of the cat[62] and similar results were obtained when the dendritic release of ^{3}H-DA was enhanced by the local application of amphetamine or benztropine[63] (Fig. 2). Conversely, the release of ^{3}H-DA increased in the caudate nucleus during the nigral application of α-methylparatyrosine[51] (Figs 2, 3) or of dopaminergic blockers[63], indicating that DA released from dendrites tonically inhibits the activity of the nigral dopaminergic cells. Opposite changes in the dendritic release of ^{3}H-DA and the release of the ^{3}H-transmitter from nerve terminals were also seen during modifications of glycinergic and substance P-ergic transmission in the SN (Fig. 2). The simplest hypothesis is that DA released from dendrites exerts its inhibitory effect through dopaminergic autoreceptors situated on dopaminergic cell bodies or dendrites.

We have also obtained evidence to support earlier biochemical[64,65] and electrophysiological[66] data consistent with the hypothesis of a neuronal feedback loop involved in the control of the activity of the nigro-striatal dopaminergic neurones[67]. Thus, when amphetamine was applied to the caudate nucleus, it not only increased local dopaminergic transmission, but also

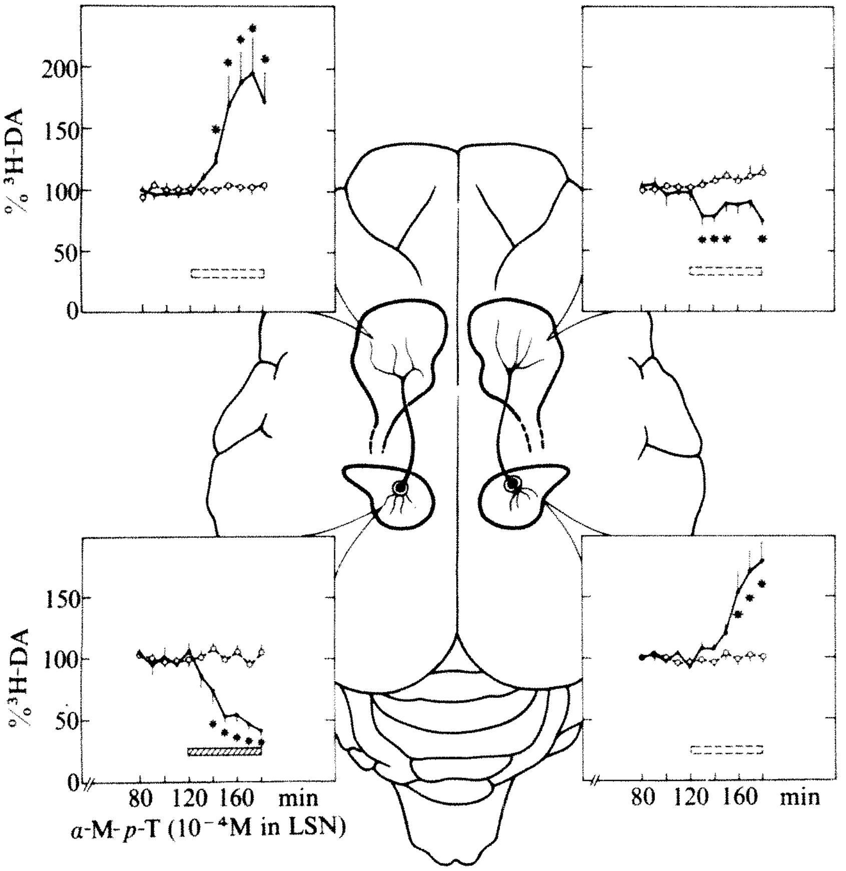

Fig. 3 Effects of α-M-p-T application into the left SN on the release of ^{3}H-DA from the two caudate nuclei and the two SN. Four push-pull cannulae were simultaneously implanted in halothane-anaesthetized cats to measure the release of ^{3}H-DA formed from ^{3}H-tyrosine (50 μCi ml^{-1}) in both SNs and both caudate nuclei. α-M-p-T was introduced for 60 min into the artificial cerebrospinal fluid superfusing the left SN (LSN) (hatched bar). In each animal and for each cannula, ^{3}H-DA in each successive fraction was expressed as per cent of an average spontaneous release calculated from the five fractions collected before treatment. Data are the mean ± s.e.m. of results obtained with five animals (●). *, $P \leq 0.05$ when compared with corresponding control values obtained in five untreated animals (○).

stimulated the dendritic release of ^{3}H-DA in the SN; α-methylparatyrosine induced the opposite effects[51] (Table 2). Therefore any changes in the dopaminergic transmission in the caudate nucleus may in turn affect the activity of the nigral dopaminergic cells through the influence of striato-nigral fibres on dopaminergic dendrites. The identity of the neurones involved in the activation or the inhibition of the dopaminergic cells has yet to be conclusively determined although substance P neurones may be responsible for activation[46,47,62,68] (Fig. 2) and GABA neurones for inhibition[69,70].

Because the modulation of the activity of dopaminergic cells by nigral afferent neurones can be mediated by their influence on the dendritic release of DA, a decreased release of DA from SN dendrites accompanied by an increased release of DA from nerve terminals in the ipsilateral caudate nucleus, and vice versa, should also be observed in physiological conditions. This pattern of responses was observed after unilateral electrical stimulation of the dentate or fastigial cerebellar nuclei[50], which send monosynaptic projections to the SN, or with the unilateral delivery of visual or somatic stimuli[53] (Fig. 2). It is not yet known whether inhibitory signals mediated by DA release from dendrites are always involved in the regulation of the activity of the dopaminergic neurones.

It will also be important to establish how DA reaches the dopaminergic autoreceptors located on parent or other dopaminergic neurones in the SN. Are there functional dendro-dendritic synapses[22] or appositions[10] as suggested by some authors or are the dendrites always separated by glial elements connected by multiple gap functions as claimed by other workers[71]? The latter features could subserve a modulatory role of DA in the SN which would explain the long-term changes in activity of the dopaminergic neurones seen in several of our *in vivo* experiments.

Dendritic DA can control nigral afferent and efferent pathways

The presence of dopaminergic receptors on nigral afferent fibres and on non-dopaminergic efferent neurones already suggests a role for dendritic DA in the presynaptic regulation of the release of other nigral neurotransmitters or in the control of the activity of non-dopaminergic cells. That postsynaptic dopaminergic receptors are associated with nigral afferent fibres is shown in the rat by the unchanged nigral DA-sensitive adenylate cyclase activity after degeneration of the nigral dopaminergic cells compared with the decrease after destruction of striato-nigral neurones[72–74].

As ^{3}H-spiroperidol binding sites not coupled to the DA-sensitive adenylate cyclase are still detectable after destruction of the dopaminergic cells, some dopaminergic receptors also seem to be located on non-dopaminergic cells in the SN[58–60]. In fact, cells in the pars reticulata have been shown to be sensitive to the microiontophoretic application of DA[75]. More recently, Ruffieux and Schulz[76] have observed that ~40% of the pars reticulata cells were excited by DA in the rat and that this effect was antagonized by fluphenazine. Furthermore, half of these cells identified by antidromic activation corresponded to the nigro-thalamic neurones. It it thus highly probable that numerous nigral non-dopaminergic neurones can be influenced by DA released from the dendrites of the dopaminergic neurones—this is also supported by recent autoradiographic studies which indicate that both apomorphine[77] and amphetamine[78] enhance glucose utilization in the pars reticulata of the SN and that the apomorphine effect is reversed by neuroleptics.

Reubi *et al.*[79] obtained the first evidence for a role of DA in the presynaptic regulation of a neurotransmitter release from nigral afferent fibres when they observed that DA and amphetamine stimulated the release of ^{3}H-GABA previously taken up in slices of the rat SN, and that these effects were blocked by neuroleptics. More recently, Van der Heyden *et al.*[80] have obtained comparable results *in vivo* although GABA release was either enhanced or decreased depending on the concentration of DA or apomorphine used. These results suggest that dopaminergic receptors coupled to the DA-sensitive adenylate cyclase are located on GABA striato-nigral fibres. In contrast, the striato-nigral substance P afferent fibres seem to lack dopaminergic receptors because the release of substance P from rat SN slices was not influenced by DA or dopaminergic agonists[81].

A series of experiments in which we investigated the mechanisms involved in the reciprocal regulation of the two nigro-striatal dopaminergic pathways demonstrated that DA released from dendrites influences the activity of non-dopaminergic nigral cells. Cats implanted with one push–pull cannula in each SN and caudate nucleus allowed us to investigate the effects of unilateral nigral facilitation or interruption of dopaminergic transmission not only on the activity of the ipsilateral dopaminergic neurones but also on the release of DA from terminals and dendrites of the contralateral dopaminergic neurones. Amphetamine, which when applied to one SN facilitated the local release of ^{3}H-DA and reduced the ^{3}H-transmitter release in the ipsilateral caudate nucleus (Fig. 2)[51,63], induced opposite affects in the contralateral SN (decreasing ^{3}H-DA release) (Table 2) and caudate nucleus (increasing ^{3}H-DA release)[51]. The unilateral nigral application of α-methylparatyrosine produced the opposite results (Fig. 3) and other experiments revealed that these contralateral effects were mediated by DA released from dendrites but not from terminals of the ipsilateral dopaminergic neurones[51]. Thus DA released from dendrites in one SN influences non-dopaminergic nigral cells involved in the regulation of the activity of the contralateral dopaminergic neurones. As no direct connections have been described between the two SN, a polysynaptic neuronal loop projecting to the contralateral SN must be involved. The nigro-thalamic neurones which can be excited by DA[76] could contribute to this neuronal loop. In fact, the contralateral effects induced by amphetamine of α-methylparatyrosine are suppressed after lesion of the thalamic massa intermedia[82]. The nigro-thalamic neurones are not the only ones to be influenced by dendritic DA—indirect evidence suggests that this is also the case for the nigral neurones projecting to the dorsal raphe. Indeed, in cats implanted with push–pull cannulae, the application of DA or α-methylparatyrosine in one SN induced changes in serotonin release in both caudate nuclei, which could reflect modifications of the activity of dorsal raphe serotoninergic neurones[83]. These results emphasize the role of dendritic DA in the control of signals leaving the SN through non-dopaminergic cells.

Unfortunately, there is as yet no firm morphological evidence for the dendro–axonic synapses suggested by biochemical data which indicate that dendritic DA is involved in the regulation of transmitter release from some nigral afferent fibres. However, Reubi and Sandri[71] have observed large special symmetrical junctions in the pars reticulata between dendrites and axons and Hattori *et al.*[17] have suggested that dendro–axonic transmission occurs in some axo–dendritic synapses in which vesicle-like structures are seen to be attached to the post-synaptic membrane. However, some of the dendro-dendritic synapses[22] or appositions[10] observed in the pars reticulata could correspond to sites by which dendritic DA influences non-dopaminergic nigral cells, as indicated by electrophysiological and biochemical studies.

Conclusions

Our knowledge concerning nigral dopaminergic transmission is now as broad as that acquired for dopaminergic transmission intervening at the level of nerve terminals in the striatum. The dendrites of the nigro-striatal dopaminergic neurones have the capacity to synthesize, store and release DA. However, the dendrites seem to differ from the nerve terminals as they contain very few vesicles and the smooth endoplasmic reticulum seems to be the storage site of the transmitter; furthermore, it is very unlikely that fast sodium channels are to be involved in the dendritic release process occurring in physiological states. Several neuronal pathways which project to the SN influence directly or indirectly, through local microcircuits, the release of DA from dendrites. As shown in Fig. 4, by acting on various types of dopaminergic receptors, only some of which are coupled to a DA-sensitive adenylate cyclase, DA released from dendrites exerts several functions. One of the most paradoxical effects of the dendritic DA is to inhibit tonically the activity of the nigro-striatal dopaminergic neurones by self- or lateral-inhibition; dopaminergic autoreceptors are involved in this phenomenon (Fig. 4:1). There is already some evidence that DA released from dendrites regulates the presynaptic release of GABA from terminals of the striato-nigral GABAergic neurones; dopaminergic receptors associated with a DA-sensitive adenylate cyclase mediate this effect (Fig. 4;2). Other dopaminergic receptors are located on some nigral neurones mainly distributed in the pars reticulata of the SN; these non-dopaminergic neurones could be interneurones involved in microcircuits (Fig. 4;3) or nigral efferent neurones (Fig. 4;3). We already know that DA exerts an excitatory effect on the nigro-thalamic neurones which contribute to a polysynaptic neuronal loop by which dendritic DA in one SN influences the activity of the contralateral nigro-striatal dopaminergic neurones. As contact between dopaminergic dendrites and glial cells[71] and capillaries[10] have been described (Fig. 4;4), the role of the dendritic DA may not be restricted to the transfer of information between neurones.

Further morphological studies at the electronmicroscopic level are required to define more precisely the relationships between dopaminergic dendrites and target cells. It also remains to be established whether or not DA released from dendrites acts at a distance from its release sites. Present biochemical techniques do not permit the monitoring of the *in vivo* release of transmitters on a time scale familiar to electrophysiologists. Therefore, the role of the dendritic release of DA during fast changes in activity of the nigral dopaminergic cells is not yet known. However, we already know that the changes in the dendritic release of DA are generally of long duration, even when they are induced by physiological treatments such as sensory stimuli. Such a phenomenon explains the prolonged modification of the activity of the dopaminergic cells observed in several situations. This time dimension is another peculiar feature of the signals mediated by dendritic DA and provides further evidence for a modulatory role of the nigro-striatal dopaminergic neurones in the transfer of information in the SN and the striatum.

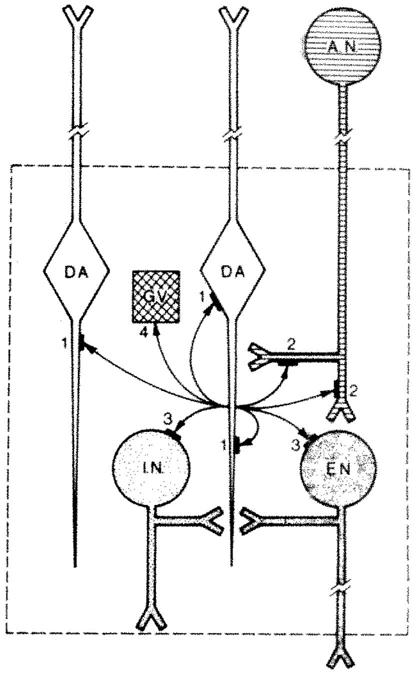

Fig. 4 Schematic representation of the various sites of action of DA in the SN: (1) dopaminergic autoreceptors; (2) dopaminergic receptors located on nerve terminals of striatonigral pathways (AN, afferent neurones); (3) dopaminergic receptors which could be located on nigral interneurones (IN) or on nigral non-dopaminergic efferent neurones (EN); (4) interactions with glial or vascular elements (GV).

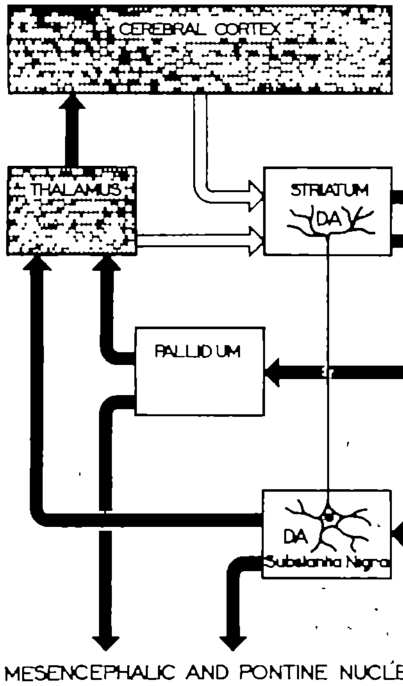

Fig. 5 Schematic diagram of some extrapyramidal circuits illustrating the role of nigro-striatal dopaminergic neurones in filtering messages travelling through the striatum and the substantia nigra. Open arrows: main inputs to the striatum; hatched arrows: main outputs from the striatum; black arrows: main outputs from the basal ganglia. DA: release of dopamine from nerve terminals and dendrites of the nigro-striatal dopaminergic neurones

Shepherd's proposal that a single neurone consists of several functional units[5] may apply to the nigro-striatal dopaminergic neurones which display functional properties both in the striatum and the SN (Fig. 5). Thus, at one level, DA released from the terminals of these nerves contributes to the fitering of messages delivered to the striatum by various afferent fibres, including the cortico- and thalamo-striatal fibres, and by influencing the activity of large populations of striatal cells it modulates the transit of signals converging on the pallidum and the pars reticulata of the SN. At another level, DA released dendritically within the SN is involved in the processing of information passing through the nigral pars reticulata in the direction of the thalamus, the subthalamic nucleus and various mesencephalic or pontine nuclei. It is thus not surprising that the nigro-striatal dopaminergic neurones have a critical role in the coordination of sensory motor processes.

One important question is to determine whether or not all central neurones share the capacity to release their transmitter from dendrites. In most cases, studies similar to those carried out on the dendrites of the nigro-striatal dopaminergic neurones are impaired by the co-existence of dendrites, nerve collaterals or nerve terminals of the same type of neurones in a given brain nucleus. However, it has already been suggested that GABA could be released from dendrites in the olfactory bulb[84], and DA released from amacrine cells in the retina[85] could originate from dendrites because this type of interneurone has no axon. Using sophisticated electrophysiological analysis, dendro-dendritic excitatory and inhibitory synapses have been particularly investigated in the olfactory bulb[5]. Furthermore, synaptic circuits through dendrites have now been found in several brain areas including the retina, the cerebral cortex, the basal ganglia, the thalamus and the suprachiasmatic and trigemenal nuclei[5]. Therefore, there is little doubt that the chemical transfer of information through dendrites is not a feature unique to the nigro-striatal dopaminergic neurones.

Macroscopic quantum electrodynamic effects in a superconducting ring containing a Josephson weak link

R. J. Prance, A. P. Long, T. D. Clark, A. Widom*, J. E. Mutton, J. Sacco*, M. W. Potts, G. Megaloudis* & F. Goodall*

School of Mathematical and Physical Sciences, University of Sussex, Brighton, Sussex BN1 9QH, UK

The problem of coherent flux tunnelling across a Josephson weak link enclosed by a thick superconducting ('SQUID') ring in terms of quantum electrodynamics is considered. We show that for a low effective noise temperature ($\simeq$few K) in the SQUID ring and with the weak link capacitance $\lesssim 3\times10^{-15}$, such a process should be observable. Experimental evidence is given to justify this claim.

IN the usual treatment of a superconducting ring containing a Josephson weak link (a 'SQUID'—superconducting quantum interference device) the total flux Φ in the ring is assumed to be a classical quantity[1]. This article investigates the behaviour of such a SQUID when this assumption is no longer valid—in what we shall term the 'quantum limit', where voltage and magnetic flux measurements on the SQUID ring interfere. In this limit, we compare the predicted quantum electrodynamic behaviour with the actual experimental properties of a SQUID ring, biased at 430 MHz, in the temperature range 4.2–1.8 K.

Properties of the SQUID ring

With Φ classical, the following thermodynamic arguments macroscopically describe the properties of a SQUID ring containing one weak link. The condensed matter hamiltonian depends on Φ nonlinearly. The resulting condensed matter free energy, periodic in the flux quantum $\Phi_0=(\pi\hbar/e)$, is given by[2]

$$F(\Phi+\Phi_0, T)=F(\Phi, T) \qquad (1)$$

where the temperature of the ring is T and Φ_0 is determined by the electric charge by virtue of the gauge breaking Landau–Ginzburg electron pair wave function[3].

The free energy can be expressed in terms of the Josephson critical current $I_c(T)$ as

$$F(\Phi, T)=F(0, T)+[\Phi_0 I_c(T)/2\pi][1-\cos(2\pi\Phi/\Phi_0)] \qquad (2)$$

If an external flux Φ_x is applied to the ring (self-inductance L), then the thermal equilibrium total flux can be obtained by the minimum free energy principle

$$A(\Phi_x, T)=\min_{\Phi}\,[F(\Phi, T)+(\Phi-\Phi_x)^2/2L] \qquad (3)$$

Equations (2) and (3) imply, for equilibrium flux, that

$$\Phi+LI_c(T)\sin(2\pi\Phi/\Phi_0)=\Phi_x \qquad (4)$$

For $I_c(T)>\Phi_0/2\pi L$, equation (4) describes the hysteretic behaviour in Φ versus Φ_x of a SQUID ring[1,2]. This behaviour forms the basis of operation of the r.f.-biased, so-called 'hysteretic' SQUID magnetometer[1] and reflects the existence of local metastable free energy minima.

As a measurement device, the hysteretic SQUID depends on long lifetimes for the metastable free energy states referred to above. We now consider how quantum electrodynamic (QE) effects may considerably shorten the lifetime of such a metastable state. In QE circuits one adds both electric field energy (capacitively) and magnetic field energy (inductively) to the microscopic condensed matter hamiltonian

$$\mathcal{H}(\Phi_x)=H(\Phi)-(\hbar^2/2C)(\partial/\partial\Phi)^2+(\Phi-\Phi_x)^2/2L \qquad (5)$$

where C is the weak link capacitance and, for simplicity, we have included only the dominant LC–photon oscillator mode at an unrenormalized frequency $\omega_0^2=(1/LC)$. The stable free energy of the SQUID is now (in principle) calculated from statistical thermodynamics

$$A(\Phi_x, T)=k_BT\ln Tr\exp-(\mathcal{H}(\Phi_x)/k_BT) \qquad (6)$$

The main difference between the classical (equation (3)) and QE (equation (6)) picture is in the dynamic lifetimes of metastable states in $F(\Phi, T)$ which participate in hysteretic modes of dynamical behaviour.

Dynamical dissipative modes

Classically, the SQUID ring admittance $Y(\Phi, \zeta)$, at fixed Φ and complex frequency ζ, has been discussed by Tinkham[4]. In general, $Y(\Phi, \zeta)$ contains dissipative current fluctuation modes which obey the oscillator strength sum rule

$$\left(\frac{2}{\pi}\right)\int_0^\infty Re\,Y(\Phi, \omega+i0^+)\,d\omega=\left(\frac{1}{L_\infty}\right) \qquad (7)$$

where the kinetic inductance[5] L_∞ depends on the geometry of the ring and local electronic plasma frequencies. In the superconducting phase, the SQUID ring admittance has the Tinkham form

$$Y(\Phi, \zeta)=(\partial^2F/\partial\Phi^2)_T(i/\zeta)+1/Z(\Phi, \zeta) \qquad (8)$$

where the frequency pole is due to the supercurrent $J=(\partial F/\partial\Phi)_T$ response and the normal current weak link shunt impedance $Z(\Phi, \zeta)$ describes the dissipative part of the current response. For superconductors, equation (7) reads

$$\left(\frac{1}{L_\infty}\right)=\left(\frac{\partial J}{\partial\Phi}\right)_T+\left(\frac{2}{\pi}\right)\int_0^\infty d\omega\,Re\,Z^{-1}(\Phi, \omega+i0^+) \qquad (9)$$

with

$$(\partial J/\partial\Phi)_T=(2\pi I_c(T)/\Phi_0)\cos(2\pi\Phi/\Phi_0) \qquad (10)$$

for the free energy parameterization of equation (2).

The growth of $I_c(T)$ as T is reduced implies that dissipation current fluctuation modes in $Z(\Phi, \zeta)$ are subtracted so as to keep

---

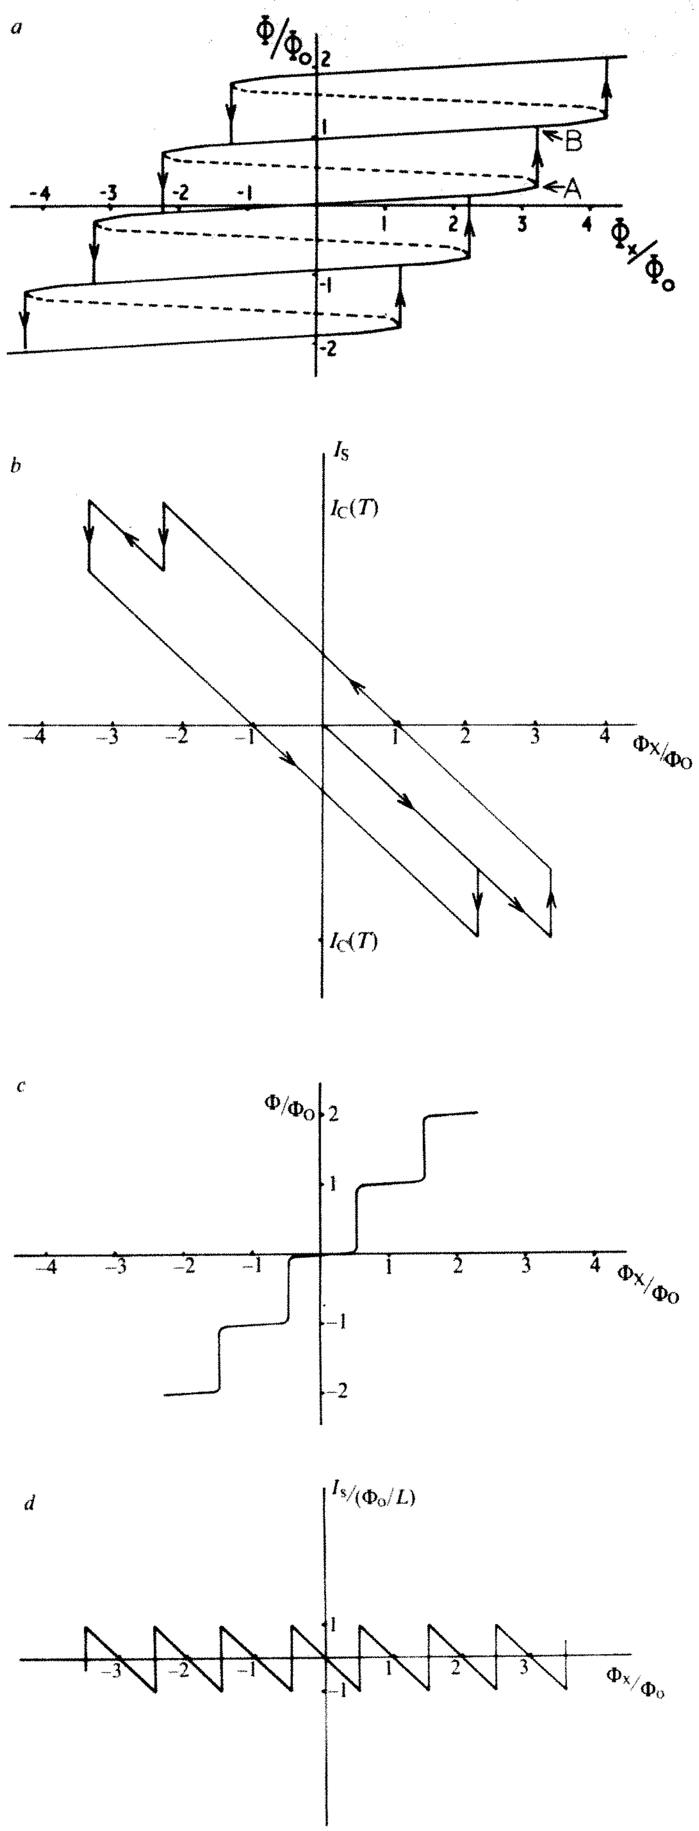

Fig. 1 *a* and *b*, Classically metastable Φ versus Φ_x and I_s versus Φ_x curves for $2\pi LI_c(T)/\Phi_0>1$; *c* and *d* Φ and I_s versus Φ_x with coherent flux tunnelling as the dominant process—again $2\pi LI_c(T)/\Phi_0>1$.

the total oscillator strength L_∞^{-1} in equation (9) constant. Tinkham has also argued, on the basis of equation (9), that the normal current dissipation in the SQUID is greatest in the region of relative maxima in $F(\Phi, T)$ and least in the region of relative minima. This allows for long lived metastability near free energy relative minima in the classical theory where Φ is treated as a classical quantity.

In QE circuits, the operator current commutators, whose average value determines the admittance, now describe, through LSZ quantum field theory, inelastic photon scattering processes[6]. Transition matrix elements are determined by an operator admittance, as discussed previously[7]. For example, an off-energy shell photon scattering amplitude, determined by $Y(\Phi, \zeta)$ considered as an operator, has the form

$$M_{\rm fi} \approx -{\rm i}\omega_{\rm fi}\int {\rm d}\Phi\cdot\Phi\chi_{\rm f}^*(\Phi)\,Y(\Phi, \omega_{\rm fi}+{\rm i}0^+)\Phi\chi_{\rm i}(\Phi) \qquad (11)$$

where the initial and final photon wave functions, $\chi_{\rm i}$ and $\chi_{\rm f}$, in the representation implicit in equation (5), describe the localization in Φ-space of the photon states. In the elastic on-energy shell limit ($\omega_{\rm fi}\to 0$) the ζ-pole in the Tinkham admittance in equation (8) dominates the lifetime of the photon states near metastable free energy minima.

The Josephson critical current $I=I_c(T)\sin(2\pi\Phi/\Phi_0)$ reflects the maximum frequency $\nu(T)$ with which coherent electron pairs can pass through a weak link contact, through $I_c(T)=2e\nu(T)$. The current matrix elements, which classically yield dissipative heating in the SQUID weak link, can, from a QE view, pass Faraday flux lines across the link. Such coherent flux tunnelling, with flux Φ_0 passing across the link, constitutes a truly macroscopic quantum phenomenon as it requires the flux Φ in the SQUID ring to be treated quantum electrodynamically. The passage of flux, in discrete units of Φ_0 across a weak link, together with an associated phase change of 2π along the link, is known generally as the phase slip process[8]. There is a critical voltage law[9,10] for coherent flux tunnelling which is directly analogous to the critical current law $\{I_c(T)=2e\nu(T)\}$ for the electron pair tunnelling. The critical voltage is $V=V_c(T)\sin(2\pi Q/q)$, where Q is the electric charge on the weak link capacitor, $V_c(T)=\Phi_0\Omega(T)$ reflects the maximum frequency $\{\Omega(T)\}$ with which flux quanta can pass across the link and $q=2e$.

Quantum electrodynamically, the main hindrance to coherent flux tunnelling arises from the small overlap of the photon wave functions $\chi_{\rm i}(\Phi)$ and $\chi_{\rm f}(\Phi)$ localized about points in Φ-space displaced by a flux quantum Φ_0. The elastic photon amplitude is determined (on-energy shell) by the supercurrent part of the SQUID admittance operator. If the noise in the capacitor charge operator $Q\to i\hbar\partial/\partial\Phi$ (which generates flux quantum displacements via $\exp({\rm i}\Phi_0 Q/\hbar)$ is gaussian, then $\Omega(T)$ and $\nu(T)$ are related by

$$\Omega(T)=\beta\pi^2\nu(T)\exp-(\Phi_0^2\langle\Delta Q^2\rangle/2\hbar^2) \qquad (12)$$

where β is a coefficient of order unity which depends on the phase slip amplitude in the flux tunnelling process.

Let us suppose that the charge fluctuation (equation (12)) is determined by an effective quantum noise temperature, T^*, defined by the 'equipartition' rule

$$\langle\Delta Q^2\rangle = Ck_{\rm B}T^* \qquad (13)$$

For a classical capacitor in thermal equilibrium $T^*=T$. Equations (12) and (13) then relate the critical voltage to the critical current by

$$V_c(T)=\beta(\pi^3/2)(\hbar/e^2)I_c(T)\exp[-\pi^2(Ck_{\rm B}T^*/2e^2)] \qquad (14)$$

For comparison the critical current for coherent pair tunnelling is given by

$$I_c(T)\simeq I_c(0)\exp[-q^2\langle\Delta\Phi^2\rangle/2\hbar^2] \qquad (15)$$

with $q=2e$ and $\langle\Delta\Phi^2\rangle\simeq k_{\rm B}TL$ by the 'equipartition' rule.

The exponential fall in $V_c(T)$ with noise temperature T^* is similar to the decay in $I_c(T)$ with increasing temperature T. With

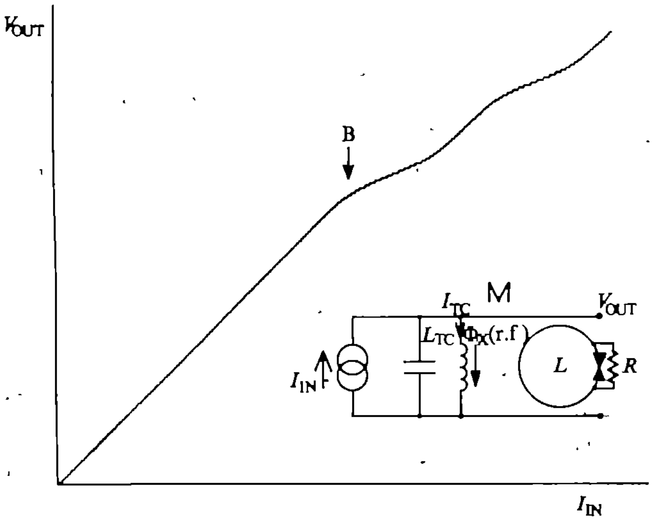

Fig. 2 V_{OUT} versus I_{IN} characteristic of a 'hysteretic' SQUID magnetometer biased at 430 MHz; $T=4.2$ K; post-detection bandwidth $=1$ Hz; $\Phi_{XDC}=n\Phi_0$(n integer); point B denotes critical current breakpoint; V_{OUT}(break)$/G=1.3$ mV, where G is the system gain.

$V_c(T)$ large compared with the total noise voltage in the SQUID, QE flux tunnelling will render the metastable free energy states (equation (4)) too short lived for the SQUID to operate in a hysteretic mode. In the other extreme, in which the SQUID noise voltage is large compared with $V_c(T)$, direct flux tunnelling will not be observed, and the SQUID ring will operate in the usual classically metastable manner. The maximum phase coherent coupling energy associated with electron pair tunnelling is $\Phi_0 I_c(T)=h\nu(T)$. Josephson effects become apparent when the weak link phase locks against thermal fluctuations, that is when $\Phi_0 I_c(T)>k_B T$. Similarly, we expect coherent flux tunnelling to be observable when the conjugate flux tunnelling phase coherent coupling energy $qV_c(T)=\hbar\Omega(T)$ becomes larger than $k_B T^*$.

Discussion

The behaviour of a classically 'hysteretic' SQUID ring (and hence that of hysteretic r.f. SQUID magnetometers[1]) can be analysed conveniently in terms of the screening supercurrent I_s circulating in the ring in response to an externally applied flux Φ_x. Figure 1*a* and *b* show, respectively, Φ plotted against Φ_x and I_s plotted against Φ_x for $I_c(T)>\Phi_0/2\pi L$. The classical metastability is apparent. In this regime, the 'fluxoid' states (A and B in Fig. 1*a*) are well defined[1]. This metastability is reduced considerably if coherent flux tunnelling becomes important. To calculate $I_s(\Phi_x)$ in this QE regime we consider the amplitude (D_n) for the SQUID ring to contain n flux quanta and look for the ground state energy $E(\Phi_x)$ of the equation

$$\{(n\Phi_0-\Phi_x)^2/2L\}D_n-(\hbar\Omega/2)(D_{n+1}+D_{n-1})=ED_n \quad (16)$$

Here, the energy stored in the ring inductor (L) is $(n\Phi_0-\Phi_x)^2/2L$, $\hbar\Omega/2$ is the flux tunnelling matrix element linking states of the ring different in flux by $\pm\Phi_0$ and, for simplicity, we take $T=0$.

Equation (16) generates macroscopic band spectra for the SQUID ring such that $E(\Phi_x+\Phi_0)=E(\Phi_x)$. As we have shown previously[11], the stable screening current is given by

$$I_s(\Phi_x)=-\mathrm{d}E(\Phi_x)/\mathrm{d}\Phi_x=\sum_{n=1}^{\infty} I_n \sin\left(\frac{2\pi n\Phi_x}{\Phi_0}\right) \quad (17)$$

Figure 1*c* and *d* show, respectively, Φ plotted against Φ_x and I_s plotted against Φ_x in the regime $I_c(T)>\Phi_0/2\pi L$ but with coherent flux tunnelling as the dominant process. In this situation all classical metastability disappears and both Φ and I_s versus Φ_x follow what we term stable, thermal curves[2].

The practical r.f.-biased SQUID magnetometer consists of a SQUID ring inductively coupled to a parallel LC tank circuit, as shown inset in Fig. 2. The coupled tank circuit–SQUID ring combination is excited at, or close to, resonance by means of an external r.f. current source (I_{IN} in Fig. 2). The tank circuit inductance is L_{TC}. The mutual inductance between this coil and the SQUID ring is M, the ring inductance is L and the weak link is represented by a supercurrent channel ($I_c(T)\sin(2\pi\Phi/\Phi_0)$, shaded double triangle) in parallel with a shunt resistor R. This parallel combination is usually referred to as the resistively shunted junction (RSJ) model[12] of a weak link. The external flux Φ_x in this system is the a.c. flux in the tank circuit inductor. In terms of this equivalent circuit we wish to determine the system response V_{OUT}, across the tank circuit, as a function of I_{IN} which we can control externally. In operation, weak coupling is maintained between the tank circuit and SQUID ring. The loaded quality ('Q') factor of the tank circuit is usually in the range 50–100.

For classically metastable behaviour (Fig. 1*a*, *b*) the SQUID ring–tank circuit combination has a linear V_{OUT}–I_{IN} characteristic up to a critical flux $\pm\Phi_{XC}$(r.f.) in the tank circuit coil. At these values of flux, and in the absence of fluctuations[13,14], almost discontinuous transitions take place between adjacent fluxoid states of the SQUID ring. The energy required to drive the SQUID ring through the hysteresis loops in Φ(r.f.), or I_s(r.f.), versus Φ_x(r.f.) is drawn from the tank circuit. This forces the SQUID ring–tank circuit into a relaxation oscillation mode[1]. With the r.f. current source amplitude $|I_{IN}|$ increasing linearly with time these oscillations lead to the well known, almost constant voltage, current steps in V_{OUT} versus I_{IN} (ref. 1). The current change along each step corresponds to the energy required to compensate for the losses in the hysteresis loops in Φ(r.f.) versus Φ_x(r.f.). The noise, either external or intrinsically generated in the SQUID ring junction 'shunt resistor', increases the slope $\mathrm{d}V_{OUT}/\mathrm{d}I_{IN}$ on the steps. In certain conditions the so-called 'step slope' α is proportional to the intrinsically generated noise flux $\langle\Delta\Phi^2_{INT}\rangle^{1/2}/\mathrm{Hz}^{1/2}$ in the ring.

Figure 2 shows a V_{OUT}–I_{IN} characteristic of an ultra-low noise SQUID magnetometer developed in our laboratory[15]. The bias frequency is 430 MHz, the temperature T of the SQUID ring and tank circuit is 4.2 K, and the post-detection bandwidth for this plot is ~1 Hz. The d.c. flux Φ_{XDC} on the SQUID ring has

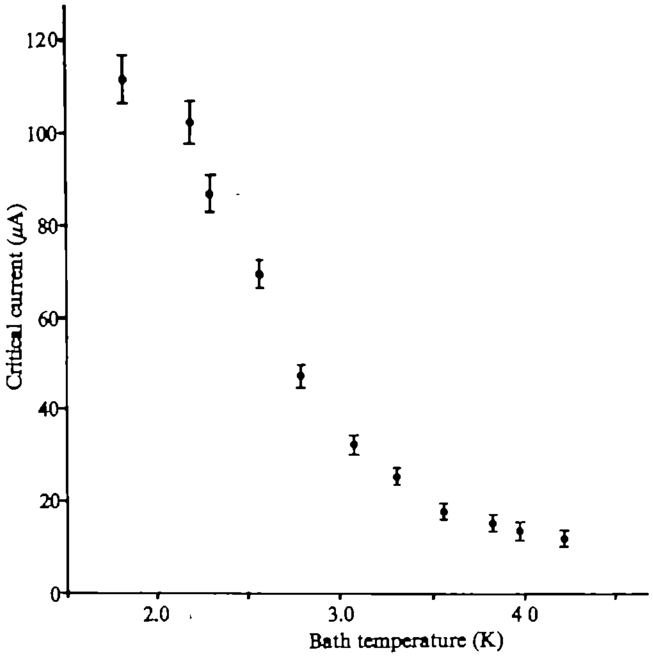

Fig. 3 Critical current $I_c(T)$ of 430 MHz magnetometer SQUID ring weak link versus temperature T of low temperature section (SQUID + tank circuit + GaAs FET preamplifier).

been set at $n\Phi_0$ (n integer). The distinctive features of this magnetometer are: (1) a liquid helium cooled GaAs FET preamplifier; (2) *in situ* (4.2 K) tuning of the GaAs FET Amp and tank circuit with GaAs varactor diodes; (3) very low noise room temperature SQUID electronics and; (4) very extensive shielding of the SQUID electronics subsystems, both at 4.2 K and at room temperature.

This magnetometer uses a two-hole 'Zimmerman' SQUID[16] consisting of a SQUID block and two screws to make the point contact weak link. The block and screws are machined from niobium, as are the lock nuts used to stabilize mechanically the point contact[17]. The point contacts are adjusted (and stabilized) at 4.2 K (ref. 15). Before the contact is made, the post (flat-ended) screw is oxidized in air at 200 °C until a light brown oxide has formed on the flat[15].

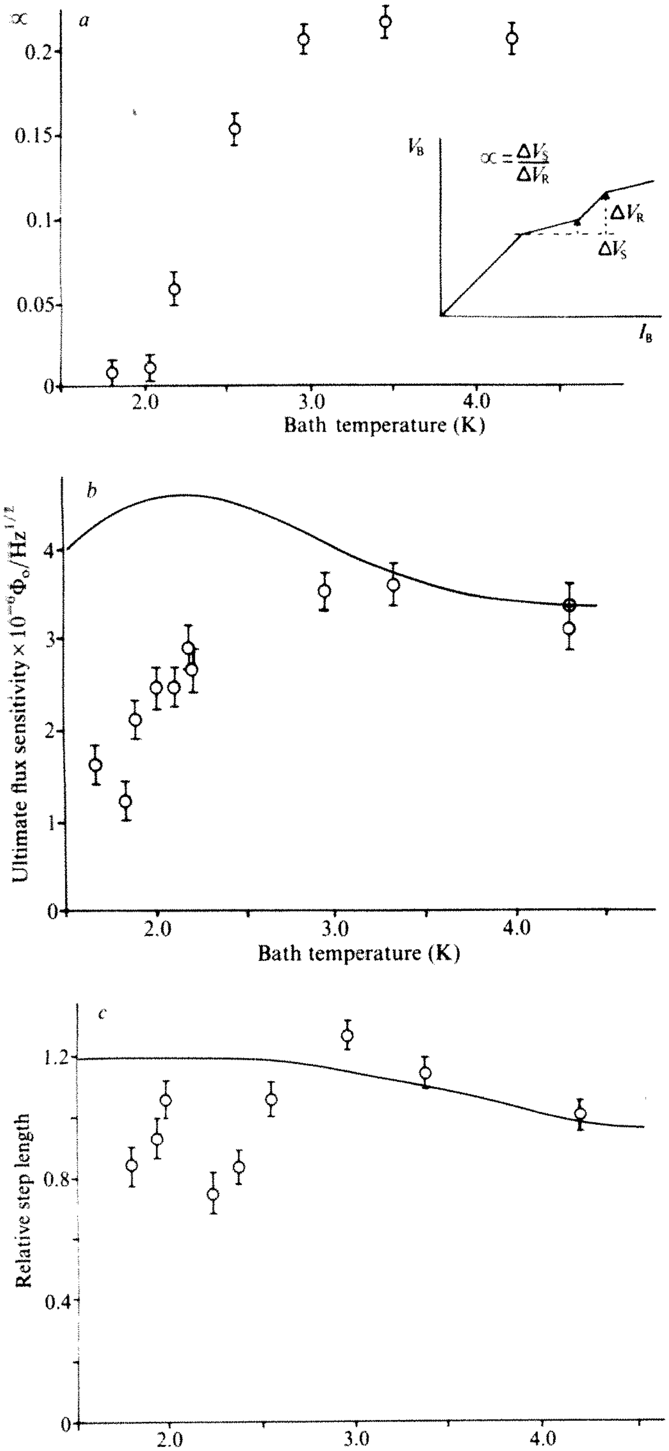

Fig. 4 *a*, Plot of 'step slope' parameter α (definition inset) versus T. *b*, Dependence of total magnetometer system flux noise on T; full line $\langle\Delta\Phi^2_{\rm NTOT}\rangle^{1/2}$ calculated from the classical theory of SQUID magnetometers. *c*, Plot of current length of first CM step versus T; full line α versus T calculated from classical theory of SQUID magnetometers.

The output of both single and two-hole SQUID magnetometers varies periodically as the input signal flux is changed, with period Φ_0. (J. E. Zimmerman, personal communication). For this periodicity the flux sensitivity (flux signal/noise ~ 1) of our 430 MHz system $\leq 4\times10^{-6}\Phi_0/\text{Hz}^{1/2}$ (conservatively) at $T = 4.2$ K, close to the value estimated from classical SQUID theory[1].

In this magnetometer the tank circuit inductance $L_{\rm TC} = 4\times10^{-8}$H, the mutual inductance (tank circuit/SQUID ring) $M = 5\times10^{-10}$H, the ring inductance $L = 5\times10^{-10}$H, $K^2Q = 0.62$ where K is the tank circuit–ring coupling coefficient, and Q(loaded) $\simeq 50$. The seven-turn tank circuit coil is constructed from either lead-plated copper or niobium foil. The GaAs FET preamplifier, with 50 Ω input impedance, is matched capacitively to the resonant tank circuit. The noise temperature $T_{\rm NA}$ of this amplifier has been measured in the Sussex and Appleton laboratories in several different ways[15]—hot/cold noise source comparisons, noise tube calibrations and direct measurement of the output noise voltage on a real-time oscilloscope. We find $T_{\rm NA}$(hot/cold) ≤ 13 K(Sussex), <10 K(Appleton); $T_{\rm NA}$(noise tube) < 10 K(Appleton) and $T_{\rm NA}$(direct) < 6 K(Sussex).

The 'break' in the slope of the $V_{\rm OUT}$–$I_{\rm IN}$ characteristic at the start (point B) of the first current step in Fig. 2 can be used to estimate $I_{\rm C}(T)$ of the SQUID ring weak link. Thus, the critical current can be estimated directly from the voltage $V_{\rm OUT}$(break) because classically[1,18]

$$V_{\rm OUT}(\text{break}) = (2\pi\nu_0 I_{\rm C}(T)L_{\rm TC}L)/M \qquad (18)$$

Alternatively, $I_{\rm C}(T)$ can be calculated from the measured change in $V_{\rm OUT}$(break) as the d.c. signal flux on the ring is changed by $\Phi_0/2$ (ref. 18). Point B in Fig. 2 is the 'break point'. In the classically metastable model of SQUID behaviour (Fig. 1*a*, *b*) no structure should be observed in the $V_{\rm OUT}$–$I_{\rm IN}$ characteristic below the breakpoint voltage $V_{\rm OUT}$(break).

We have estimated the shunt resistance R and capacitance C of the SQUID ring junction in several different ways. First, in our magnetometer there is no sign of the splitting of the current steps in $V_{\rm OUT}$–$I_{\rm IN}$ which is known, experimentally[19] and by simulation[20], to occur when $\nu_0 = \omega_0/2\pi > R/L$. There is also no obvious deterioration in the step pattern up to at least the twentieth step at $T = 4.2$ K. From these observations we conclude that $\nu_0(= 430\text{ MHz}) \ll R/L$ and $R \geqslant 10\ \Omega$ for $I_{\rm C}$(4.2 K) in the range 5–10 μA. We have also constructed a niobium 'SQUID' ring essentially identical to our usual magnetometer rings except that the post screw is electrically insulated from the SQUID block. The point contact is again adjusted at 4.2 K and stabilized mechanically with lock nuts. This arrangement enables four-terminal d.c. current–voltage measurements to be made on niobium point contact junctions prepared in the same manner as those used in our SQUID magnetometer. We find that for the post flats oxidized thermally to a light brown colour, junction resistances $\simeq 10\ \Omega$ correspond to $I_{\rm C}$ values in the range 5–10 μA at 4.2 K. This is the typical critical current range for properly adjusted r.f.-biased hysteretic SQUID magnetometers.

The RSJ model of a weak link places an upper bound on the value of C. In this model, and for constant current feed, the inclusion of a parallel capacitance across the weak link leads to a hysteretic d.c. current–voltage characteristic[12]. The current can take on one of two values at low voltages. The so-called 'McCumber' parameter $2\pi I_{\rm C}(T)CR^2/\Phi_0$ is a function of the lower and upper values of the current at zero time-averaged voltage. The lowest temperature we can reach in our cryostat is 1.8 K, at which temperature well prepared thermally oxidized point contacts with $R \simeq 10\ \Omega$ display no hysteresis. We find that

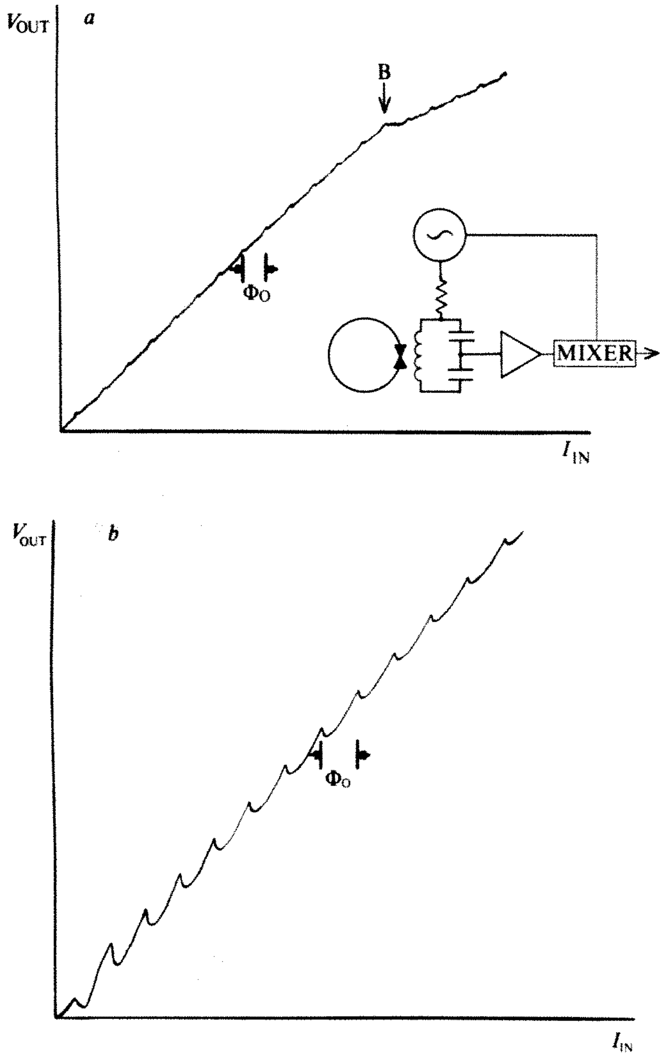

Fig. 5 *a*, Experimental V_{OUT} versus I_{IN} characteristic of the 430 MHz magnetometer of Fig. 2 at $T = 1.8$ K; post-detection bandwidth $\simeq 1$ Hz; $\Phi_{XDC} = n\Phi_0$ (n integer); point B denotes CM critical current breakpoint; $V_{OUT}(\text{break})/G = 12.3$ mV; noise in this figure and in Fig. 2 due to digitizing error on output of signal analyser used to record these curves. *b*, Theoretical V_{OUT} versus I_{IN} characteristic calculated using the coherent flux tunnelling model; $\Phi_{XDC} = n\Phi_0$(n integer).

$I_C(T)$ increases from 5–10 μA at 4.2 K to 50–100 μA at 1.8 K. This behaviour is characteristic of superconductor–normal metal–superconductor weak links[21]. For $I_C(1.8\text{ K}) \simeq 100$ μA, $R \simeq 10\ \Omega$ and taking the recorder linewidth as the maximum degree of hysteresis, we find that $C < 5 \times 10^{-15}$ F (ref. 22).

Another estimate of C can be obtained from the shape of the weak link resistance transition. For sufficiently small systems (here, the weak link) mean field fluctuations can lead to a partial suppression of the resistance of the system above the apparent critical temperature T_C (refs 23, 24). The dimensionality of the system can be obtained from the shape of the resistance transition and estimates can be made of the actual size of the fluctuating region. The thermally oxidized (light brown) point contacts studied so far appear to show two-dimensional behaviour. Treated as S/N/S junctions with a relative permitivity $\varepsilon_N \sim 1$ and current densities in the weak link $\sim 10^5$ to 10^6 A cm^{-2} (ref. 25), we estimate N-layer thicknesses ~10 Å, weak link dimensions ~1,000 Å square and C in the range 10^{-15}–10^{-16} F.

Although our UHF system behaves perfectly well as a classically metastable magnetometer at $T = 4.2$ K, changes in behaviour occur as the low temperature section (SQUID ring, tank circuit and GaAs FET Amp) is cooled from 4.2 to 1.8 K. Our main findings are:

(1) $I_C(T)$, estimated from $V_{OUT}(\text{break})$, increases rapidly as the temperature is lowered below 4.2 K. Figure 3 shows $I_C(T)$ plotted against T. $I_C(T)$ tends towards saturation at the lowest attained temperature (1.8 K).

(2) Below 3 K the 'classical metastability' (CM) current steps in V_{OUT} versus I_{IN} begin to smear out and at 1.8 K essentially all the CM steps except the first have disappeared.

(3) Between 4.2 and 1.8 K the step slope of the remaining first CM current step in V_{OUT} versus I_{IN} goes essentially to zero. A plot of this 'step slope' parameter α as a function of temperature is shown in Fig. 4*a*. The conventional definition of α is shown inset. According to the theory for CM SQUID magnetometers the intrinsic flux noise $\langle\Delta\Phi_{INT}^2\rangle^{1/2}$ is related to α by the expression[1]

$$\alpha \simeq 1.4\nu_0^{1/2}\langle\Delta\Phi_{INT}^2\rangle^{1/2}/\Phi_0\ \text{Hz}^{1/2} \qquad (19)$$

From the value of α at 1.8 K in Fig. 4*a* we calculate that $\langle\Delta\Phi_{INT}^2\rangle^{1/2} \simeq 3 \times 10^{-7}\Phi_0/\text{Hz}^{1/2}$ at 1.8 K. This is comparable with the estimate[26] of the 'quantum-limited' noise flux in the SQUID ring at finite frequency $\langle\Delta\Phi_{NO}^2\rangle^{1/2} \sim [h \times 1 \times 2L]^{1/2} \simeq 3.9 \times 10^{-7}\Phi_0/\text{Hz}^{1/2}$ for $L = 5 \times 10^{-10}$H.

(4) The total system flux noise (that is the flux noise/Hz$^{1/2}$ measured at the output of the magnetometer) decreases rapidly as the temperature is reduced below 3 K and $\simeq 1 \times 10^{-6}\Phi_0/\text{Hz}^{1/2}$ at 1.8 K. This dependence is shown in Fig. 4*b*. The full curve is the sum of the contributions from the intrinsic, preamplifier and tank circuit noise calculated using the theory for CM SQUID magnetometers[1]. Here, we take $L = M = 5 \times 10^{-10}$H, $L_{TC} = 40$ nH, $K^2Q = 0.62$, $Q \simeq 40$ and $T_{NA} \simeq 6$ K (ref. 15). Since the tank circuit is essentially power matched to the GaAs FET preamplifier we set the tank circuit noise temperature $T_{NTC} = T_{NA}$. The measurement of the system flux noise is made on the first CM SQUID current step. Both the signal and the noise are decreasing between 3 and 1.8 K.

(5) According to the theory of CM SQUID magnetometers multiple fluxoid transitions should set in when the SQUID ring damping parameter[1]

$$\gamma = \left[\frac{(2\pi I_C(T))}{\Phi_0}\right]^{1/2} RC^{1/2} \gtrsim 1 \qquad (20)$$

Taking $I_C(T) = 114$ μA at 1.8 K, $R \simeq 10\ \Omega$ and $C \leq 5 \times 10^{-15}$ F we find $\gamma = 0.4$.

In the usual interpretation of CM SQUID magnetometer behaviour[1] the length of the current step(s) should increase once multiple fluxoid transitions become possible. Figure 4*c* shows the current length of the first CM step, relative to its value at 4.2 K, as a function of temperature. The full curve is the expected CM SQUID behaviour. These data presumably eliminate the possibility of the onset of multiple fluxoid transitions providing an explanation for the observed behaviour of the SQUID magnetometer. It has been suggested (A. J. Leggett, personal communication) that heating effects in the point contact might be responsible for the decrease in step slope (α) and SQUID magnetometer signal between 3 and 1.8 K. However, theoretical studies[27] suggest that heating is not important in Nb contacts with relatively low critical currents ($\simeq 100$ μA) at temperatures $\simeq 2$ K.

(6) At temperatures $T < 3$ K weak structure appears below $V_{OUT}(\text{break})$ in the V_{OUT} versus I_{IN} characteristic. Figure 5*a* shows this characteristic taken at 1.8 K in a post-detection bandwidth of ~1 Hz. The low temperature and UHF phase sensitive detection circuits of this magnetometer are shown inset in Fig. 5*a*. The UHF phase of V_{OUT} with respect to I_{IN} has been adjusted to maximize the rounded cusp structure in the characteristic. These cusps are periodic in I_{IN} with a half period

between the first cusp and the origin. The V_{OUT} versus I_{IN} characteristic retains two CM features—the breakpoint and the remnants of the first current step following this breakpoint. In Fig. 5*a* the d.c. flux Φ_{XDC} has been adjusted to follow the upper extremum of the first current step—conventionally[1] this would correspond to $\Phi_{XDC} = n\Phi_0$ (n integer). From the measured $I_C = 114\ \mu A$ at 1.8 K the screening flux in the SQUID ring (LI_C) is $13.5\Phi_0$. No structure of any kind is observed below the breakpoint at temperatures $T > 3$ K, at least within the limits of resolution of the detection system—approximately two orders of magnitude greater than that displayed in Fig. 5*a*.

Conclusions

We believe that the above changes in the properties of the 430 MHz magnetometer are caused by the onset of QE behaviour in the SQUID ring. As we have outlined, with QE flux tunnelling dominant all classical metastability disappears and both Φ and I_S versus Φ_x follow the stable thermal curves shown in Fig. 1*c*, *d*. In terms of the classical model of SQUID the transition from metastable (Fig. 1*a*, *b*) to stable (Fig. 1*c*, *d*) behaviour corresponds to a change from r.f. 'hysteretic' to r.f. inductive 'operation' of the SQUID magnetometer. The latter, inductive mode requires that $2\pi LI_C(T)/\Phi_0 < 1$. Clearly, this is not the case, even at 4.2 K where $I_C \simeq 10\ \mu A$ and $2\pi LI_C(T)/\Phi_0 \simeq 15$. For this parameter to be <1, $I_C(T)$ must be $<0.66\ \mu A$. Good quality, thermally oxidized niobium point contact junctions with high resistances ($\gtrsim$few Ω) and low critical currents ($\lesssim$few μA) display sinusoidal current–phase (I–ϕ) relations[28]. Such a sinusoidal I–ϕ relation generates a slow sinusoidal modulation, periodic in Φ_0, on a linearly rising background in V_{OUT} versus I_{IN} (ref. 29). The rounded cusp behaviour in Fig. 5*a* would require a highly nonlinear I–ϕ relation, which seems inconsistent with the known properties of niobium point contacts.

Most of the features of Fig. 5*a* can be generated from the QE flux tunnelling model of a SQUID ring and the equivalent circuit of a SQUID magnetometer shown inset in Fig. 2. The stable QE screening current of equation (17) contains higher Josephson harmonics which affect the impedance of the SQUID ring–tank circuit in a characteristic way. We have made a computer simulation of this circuit to generate V_{OUT} in terms of I_{IN}. For a high 'Q' tank circuit (that is, $Q \simeq 50$) we assume that the dominant contribution to the output (V_{OUT}) oscillates at the input current drive frequency, that is $V_{OUT}(t) = |V_{OUT}(\omega)| \cos(\omega t + \phi_V)$, where ϕ_V is the relative phase between the output UHF voltage and the input UHF current I_{IN}. We can then calculate I_{IN} in terms of the normalized flux $B = [MI_{TC}(\omega)]/\Phi_0$ coupled into the SQUID ring. From Kirchoff's and Ohm's laws applied to the circuit in Fig. 2 we find that

$$\mathrm{Im}\, V_{OUT}(\omega) = \left(\frac{\omega_0^2}{\omega} \cdot \frac{L_{TC}}{M} \cdot \Phi\right)[B \cos \phi_{IN} - |\tilde{I}_{IN}|] \qquad (21)$$

where $\tilde{I}_{IN} = (M/\Phi_0)I_{IN}$ and ϕ_{IN} is the phase of the input current I_{IN}.

Figure 5*b* shows the numerical solution of equation (21) for $I_{TC} = 4 \times 10^{-8}$H, $L = M = 5 \times 10^{-10}$H, and $\Phi_{XDC} = n\Phi_0$ (n integer). In this calculation R (taken $= 2\Omega$) represents dissipation in the SQUID ring–tank circuit system. Dissipation is built into the equivalent circuit for this system (Fig. 5*a*, inset) as the GaAs FET preamplifier, with a real 50 Ω input impedance, is power matched to the tank circuit. There is also a small amount of dissipation in the tank circuit itself. The solution consists of a linear ramp with cusps periodic in Φ_0. The first cusp occurs at a half period from the origin. Each cusp in V_{OUT} versus I_{IN} corresponds to a pair of jump discontinuities (one each side of the origin) in the stable UHF screening current curve $I_S(\Phi_x)$ versus Φ_x (Fig. 1*d*). There is no breakpoint in the V_{OUT} versus I_{IN} characteristic because, by definition, in this model flux periodically tunnels into (or out of) the ring to prevent the screening current building up to $I_C(T)$ (see Fig. 1*d*). However, the similarity between the experimental characteristic below the breakpoint in Fig. 5*a* and the theoretical QE flux tunnelling characteristic in Fig. 5*b* is obvious.

The relatively sharp transition from CM to QE SQUID behaviour (Figs 4*a*, *b* and 5*a*) can be explained in terms of equation (14) for the coherent flux tunnelling critical voltage $V_C(T)$ and Fig. 3 for $I_C(T)$ versus T. In this magnetometer the preamplifier (and hence the tank circuit) noise temperature T_{NA} is so low that only the intrinsic flux noise contribution is important[15], at least within the range of validity of the RSJ model. We consider that the shunt resistance R in the RSJ model is, in fact, a non-equilibrium manifestation of classical metastability[4]. As flux tunnelling begins to dominate so the real phase or flux slip processes[8] in the SQUID ring junction become progressively weaker until the classical shunt resistance in the RSJ model disappears. The classical intrinsic flux noise $\langle\Delta\Phi_{INT}^2\rangle^{1/2}$ will also then disappear provided the effective noise voltage coupled into the SQUID ring from other noise sources is less than $V_C(T)$. The only remaining source of noise is the GaAs FET amplifier. We estimate that the r.m.s. noise voltage $\langle V_{NAS}^2\rangle^{1/2}$ coupled into the SQUID ring from this amplifier through the tank circuit $\simeq 0.5\ \mu V$, for $\nu_0 = 430$ MHz, $Q \simeq 50$ and a seven-turn tank circuit coil. If we take $T^* = 2$ K (the approximate temperature T of the SQUID ring) in equation (14), $C \simeq 3 \times 10^{-15}$F, $I_C(1.8\ K) = 114\ \mu A$ and $\beta \simeq 1$ we calculate $V_C(T) = 0.9\ \mu V$. To a first approximation we expect the SQUID ring to phase-lock for coherent flux tunnelling when $\langle V_{NAS}^2\rangle^{1/2} < V_C(T)\rangle$. For $C = 3 \times 10^{-15}$F and $T^* = T$, $\langle V_{NAS}^2\rangle^{1/2} = V_C(T)$ when $T = 2.6$ K and $I_C(T) \simeq 84\ \mu A$. In the flux tunnelling model the sudden change in SQUID behaviour arises simply because of the very rapid rise in $I_C(T)$ between 3 and 2 K.

The critical voltage is defined as $V_C(T) = \Phi_0\Omega(T)$ so for $V_C(1.8\ K) = 0.9\ \mu V$ the coherent flux tunnelling frequency $\Omega(1.8\ K) \simeq 430$ MHz. The noise voltage $\langle V_{NAS}^2\rangle^{1/2}$ in the SQUID ring due to the GaAs FET Amplifier is a time-averaged quantity. There will be mean, occasionally, noise voltage excursions large compared with $\langle V_C(T)$. This may provide an explanation for the remnants of classical behaviour in V_{OUT}–I_{IN} at 1.8 K. This characteristic is a time-average in a 1-Hz bandwidth over a very large number ($\sim 10^{10}$) of sweeps in $I_S\{\Phi_x(UHF)\}$ versus $\Phi_x(UHF)$. Given our estimate of $\sim 0.5\ V_C(1.8\ K)$ for the noise voltage, we expect noise fluctuations to be large enough on some sweeps to destroy the phase coherence of the flux tunnelling process. By definition, $V_{OUT}(CM)$ must be phase-incoherent with respect to $V_{OUT}(QE)$ so in the flux tunnelling model $(V_{OUT}$–$I_{IN})_{observed}$ will be a superposition of $(V_{OUT}$–$I_{IN})_{CM}$ and $(V_{OUT}$–$I_{IN})_{QE}$. Each current step in $(V_{OUT}$–$I_{IN})_{CM}$ requires four classically metastable fluxoid transitions (two hysteresis loops for $\Phi_{XDC} = n\Phi_0$). If QE flux tunnelling dominates over classical thermally activated fluxoid transitions, successive steps in V_{OUT} versus I_{IN} will become qualitatively more and more improbable. Thus, we would expect higher order steps in V_{OUT} versus I_{IN} to be very weak and this is what we observe experimentally. From this viewpoint the magnetometer signal will be reduced either because very few full hysteresis loops are traversed per second or because QE flux tunnelling processes narrow the width of these hysteresis loops dramatically. The observed reduction in noise in the magnetometer between 3 and 1.8 K will, in this model, be due to the disappearance of the intrinsic flux noise $\langle\Delta\Phi_{INT^2}\rangle^{1/2}$. The residual flux noise, which is derived from the preamplifier, is in this magnetometer[15], comparable with $[h \times 1 \times L]^{1/2}(\mathrm{Hz})^{-1/2}$.

We conclude, therefore, that if the noise injected into a SQUID ring from external sources is reduced sufficiently so that $T^* \simeq$ few K, QE behaviour will be observed at $T = 2$ K provided the SQUID weak link capacitance $C \leqslant 3 \times 10^{-15}$F.

We thank Professor A. J. Leggett for interesting discussions on the subject of macroscopic quantum effects in superconductors and to Professor D. F. Brewer for his invaluable support, also C. Trubridge, M. Moore and R. Askew for technical assistance.

Monoclonal antibodies distinguish identifiable neurones in the leech

Birgit Zipser & Ronald McKay
Cold Spring Harbor Laboratory, PO Box 100, Cold Spring Harbor, New York 11724

Monoclonal antibodies were isolated by screening 475 hybridomas obtained from mice immunized with whole leech nerve cords. The majority (about 300) reacted with leech nervous tissue, but only about 40 made antibodies that identified single kinds or small sets of cells. Twenty of the antibodies which react with specific neurones were studied in greater detail and are described here. They include antibodies against identified sensory neurones and motor neurones as well as against numerous unidentified cells.

THE ability of a nervous system to generate coherent behaviour is dependent on a vast number of precise connections between neurones. Virtually nothing is known about the molecular mechanisms which generate these connections, but all tenable hypotheses ultimately postulate the existence of molecules, differing in kind or quantity from cell to cell, which mediate the necessary recognition. The problem of neural specificity becomes apparent when one considers that neurones typically receive inputs from and send outputs to whole sets of other cells each of which in turn has its own extremely complex characteristic connection pattern. Connections are established during development but the degree to which marker molecules may be present in adults is unknown, although regeneration studies in adults[1] imply long-term persistence of at least some molecular specificity. It has long been known that there are many chemical differences between neurones, involving such functions as transmitter synthesis. Recent studies on the identification and localization of neuronal peptides[2] have greatly widened the scope of detectable molecular variation among nerve cells. The relationship of this chemical variation to the mechanism of connection is still unknown. Progress in this area will require the development of ways of relating chemical specificity to unique connectivity. Because, by hypothesis, the markers of interest will differ in each neurone with different connections, these molecules must somehow be identified in structured material where the same neurone can be easily identified in repeated experiments. Such a simple system is required not only for the identification of specific neuronal markers but also for analysing the rules which establish neuronal connections.

As a step towards this goal, we have investigated whether individual cells and sub-networks of the relatively simple leech nervous system could be distinguished by specific antibodies. As the putative antigens could not, in principle, be purified *a priori,* we used the technique of hybridoma formation[3], which allows the isolation of lymphocyte clones secreting antibodies specific for individual molecules even though a complex mixture of antigens was used for immunization. Monoclonal antibodies were obtained from lymphocytes of mice immunized with the entire isolated nervous system of the leech and screened on intact ganglia. The results of our study, reported here, give a clear answer to the question of the existence of chemical markers in individual cells and sub-networks. These specific markers are surprisingly abundant, and extrapolation from our initial sample makes it feasible that every cell has one or more chemical markers shared by only small subsets of neurones. Although we know little about the exact cellular locations of these markers, many are present in all parts of the cell, including long axonal projections and neural terminals. Indeed, the situation seems quite analogous to a colour-coded electric cable

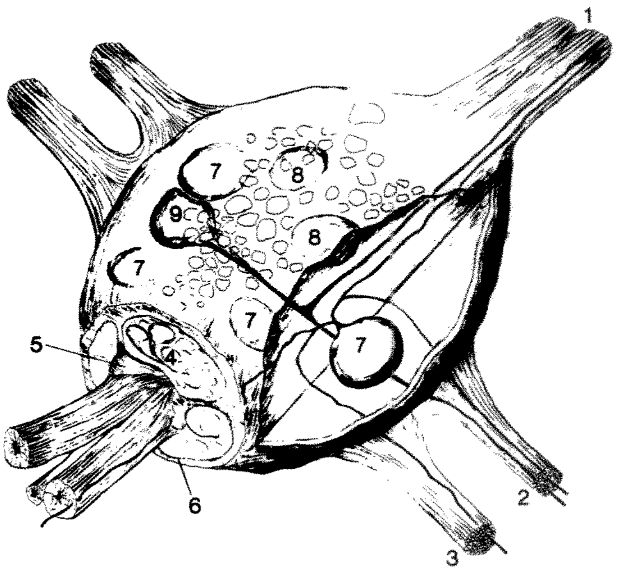

Fig. 1 Diagram of a midbody ganglion. (1) Connective, (2) anterior root, (3) posterior root, (4) neuronal cell bodies in glial packages, (5) the beginning of the neuropile where synapses occur, (6) capsule, (7) two pairs of bilaterally symmetrical pressure cells, (8) the pair of large Retzius cells are shown in the background of several hundred neuronal cell bodies, (9) one of the two lateral penile evertor cells (the other has been dissected away). Each cell body has a characteristic location and number of axons. Note that the penile evertor motor neurone projects into contralateral roots and the sensory pressure cell has ipsilateral projections.

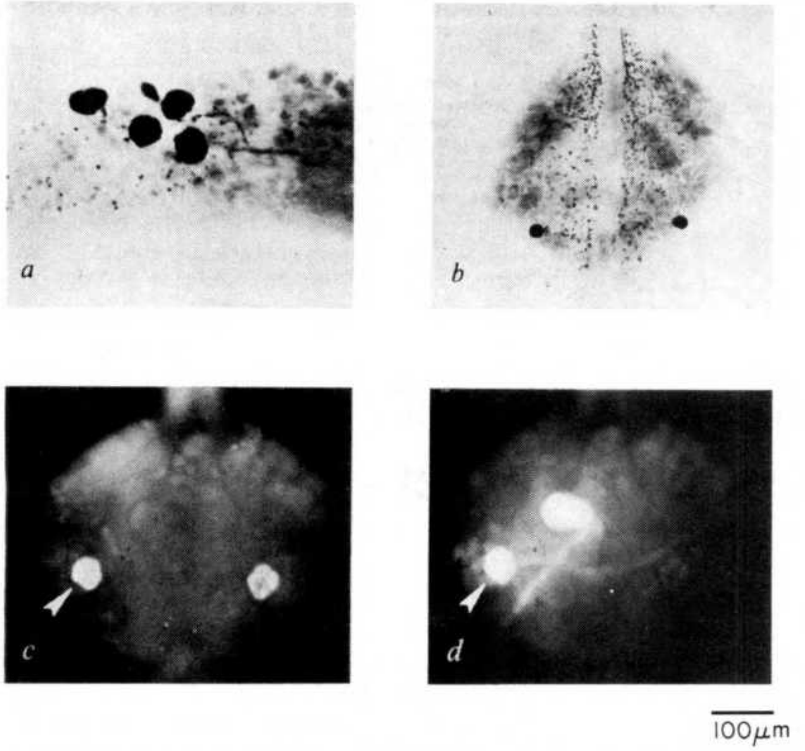

Fig. 2 Specific staining with Lan3-1. The monoclonal antibody was visualized immunocytochemically using peroxidase-conjugated (*a*, *b*) or rhodamine-conjugated (*c*) second antibody. *a* Shows cell bodies in the right supraoesophageal ganglion stained with Lan3-1. *b* Shows a bilaterally symmetrical pair of reactive cell bodies in a typical midbody ganglion. In addition to the two deeply stained cell bodies the neuropile contains a large number of stained beaded processes (varicosities) which extend into one or more axons in the connective. *c* Shows two larger cell bodies which reproducibly occur in the fifth and sixth ganglia stained with a rhodamine-conjugated second antibody. The two smaller cell bodies are also present but lie in a different focal plane. *d* Shows the same ganglion as *c* but viewed under FITC optics which reveals the presence of microinjected fluorescent dye lucifer yellow. The left lateral PE cell (marked by an arrow) was identified by a unique synaptic relationship to the morphologically and physiologically identifiable rostral penile evertor cell. The other cell labelled by lucifer yellow as a control is the Retzius cell.

containing many wires, where each wire has its own unique molecule (dye) to facilitate proper recognition and connection at terminals. The existence of specific markers is far from sufficient to explain the mechanism of neural connection specificity, but it does give us a handle by which the problem can be attacked at a previously inaccessible level. In addition to their usefulness in elucidating the mechanism of connectivity, these monoclonal antibodies will be of value in broadening our understanding of leech neurobiology, for they clearly identify whole systems of neurones together with their axonal patterns. In this article we present a survey of our initial results, together with detailed data on some of the monoclonal antibodies isolated.

The leech nervous system

The leech nervous system consists of a ganglionic chain which can be dissected out of the organism virtually intact and still electrophysiologically active. This chain has 34 copies of a basic 400-neurone ganglion in which most neurones are present as bilateral pairs. Each ganglion, in addition to containing unipolar nerve cell bodies on its outer surface, has a central neuropile where all the synaptic connections are made. The individual ganglia communicate with each other by means of a fibre tract called the 'connective' which contains thousands of fine nerve fibres. Input and output linking the ganglia to sensory, motor and secretory organs in the leech body pass through four fibre tracts called roots. A typical leech neurone has a spherical body of 10–90-μm diameter from which a stalk-like process runs a short distance into the central neuropile. Here it ramifies extensively, making many synaptic connections which are often associated with bulb-like varicosities of up to a few micrometres diameter. Many cell bodies also send processes through the connective to adjacent ganglia and to the periphery through one or more of the roots. The basic nervous system is modified by the addition of extra neurones to ganglia which have specialized functions such as reproduction, or by the fusion of ganglia to create the larger head and tail nuclei. In addition, there is a structure near the head which is of entirely different embryological origin[4]—the supraoesophageal ganglion, with many neurones some of which apparently have neurosecretory function[5]. Individual leech neurones can be reliably recognized by various features such as position, cell body diameter, electrical activity and axoneuritic pattern[1,6–8]. Many neurones, such as the sensory cells responding to pressure, touch and noxious mechanical stimulation, or the motor neurones innervating the well defined simple body wall musculature, can be visually identified through a dissecting microscope. Not only do the nerve cells occupy unique locations in the ganglia but the long axons they send into the connective occupy characteristic positions in its tightly packed bundles of fibres. A diagram illustrating a leech ganglion is given in Fig. 1. There are about 15 times more axons in the connective[9] than there are neurones in a typical midbody ganglion; the source of this large number of fibres is, in part, the cells in individual ganglia that send axons long distances down the connective, often all the way to the head and tail.

Generation and screening of antibodies

To obtain monoclonal antibodies, mice were immunized with homogenized material made from leech nerve cords (*Haemopis marmorata*) containing primarily neurones and glia, but with some muscle and connective tissue cells as well. Cells from the spleens of immunized mice were fused with myeloma cells and plated out at very low density in microtitre plates to obtain single clones. A total of three separate fusions yielded about 475 cell lines which supplied the hybridoma material for the work described here.

Previous work on enkephalin localization in the leech[10] had shown that a single neurone containing a unique antigen can be visualized in the whole, unsectioned ganglia by immunocytochemical staining techniques. These procedures served as a starting point for developing the immunocytochemistry necessary to visualize the distribution of antigens recognized by the monoclonal antibodies described here. Hybridoma growth medium was screened for the presence of interesting antibodies on segments of nerve cord containing several ganglia. The cytological staining procedure, described in detail in Table 1, legend involved dissecting out an entire ganglionic chain, mechanically breaking the capsule surrounding each ganglion, fixing the material and cutting it into segments of three or four ganglia, which were then reacted with antibody. After the appropriate washing steps this material was incubated with rabbit anti-mouse antisera to which either a fluorescent label or the enzyme horseradish peroxidase (HRP) had been conjugated. Of the 475 individual hybridomas screened, 3 came from a small preliminary test, 43 from one major fusion and 429

Table 1 Summary of staining patterns of 20 monoclonal antibodies staining specific features of leech nervous system

	No. of ganglia tested	Neurones in standard midbody ganglion	Extra neurones in specialized ganglia	Degree of generalized neuronal labelling	Processes in neuropile and fibretract

Generation of monoclonal antibodies: Female C3H mice (Jackson Laboratories) were immunized by intraperitoneal injection at various times with the entire nerve cord of four leeches. Four days before fusion mice were immunized by intravenous injection of the SDS-soluble material from four leech nerve cords. The fusion procedure was essentially that of Kohler and Milstein[3]. The two initial fusions were performed with the SP-2 myeloma cell line[15]. Antibodies from these fusions are numbered Lan1 and Lan2. The third fusion was carried out with the P3-X63 8Ag cell line and the derived clones numbered Lan3. The hybrid cells were plated into 1,500 microwells and grown in hypoxanthine–aminopterin–thymidine medium. The hybridoma supernatant could be tested directly or as a fluid derived from an ascites tumour. Of the 41 lines identified as staining selectively on the first screen the great majority were successfully grown up and frozen so that they could be recovered up to 5 months later. The hybrids with P3-X64 as a parent are best stored at −70 °C, not in liquid nitrogen. Of the 20 lines shown 13 were recloned in soft agar and shown to be monoclonal. All lines that were recloned gave the identical staining pattern to the original hybridoma supernatant. The cloning in soft agar gave >95% positive clones on the first round as a result of the high dilution of the initial plating. These two observations together with the low frequency of specific antibody-labelling pattern (5–10%) suggested that this is a good strategy for generating antibodies of interest. Staining of leech nerve cord: The leech nerve cords were dissected from alcohol-anaesthetized leeches stored at 10 °C and fixed in 4% paraformaldehyde, 0.1 M phosphate buffer, *p*H 7.4, for 30 min at room temperature for the antibodies Lan2-3 and Lan3-7. All the other antibodies shown were bound to ganglia fixed with Bouin's fixative for 4 h at room temperature. After washing in PBS (0.05 M phosphate buffer *p*H 7.4, 0.9% sodium chloride) the capsules were cut. Hybridoma supernatant containing 0.2% saponin was incubated with the fixed ganglia overnight. Before and after addition of the second antibody the ganglia were washed in three 10-min changes of PBS, 0.2% saponin. The second antibody was either HRP-conjugated or rhodamine-conjugated rabbit anti-mouse IgG (Cappel) diluted 1:30. The peroxidase substrate used was 3′,3-diaminobenzidine. In the case of the antibodies Lan3-10 and Lan3-6 protein A was used as a link in a modification of the peroxidase anti-peroxidase (PAP) procedure[16]. Protein A was bound to the monoclonal antibody for 1 h at 37 °C, after washing in PBS and rabbit PAP (Cappel) was added at a dilution of 1:200 for 30 min. The lucifer yellow dye used in microinjection was viewed under fluorescein optics as described previously[13]. The electrophysiological characteristics of the cells controlling penile eversion have been described in detail previously. Whole mounts of leech nerve cord stained with both rhodamine and peroxidase methods were analysed by microphotometry on the Leitz microscope attached microdensitometer. The cells stained by Lan3-1, Lan3-2 and Lan3-9 both gave approximately the same 5–10-fold signal over background in the whole mounts. Thin sections (1 μm) would be expected to reduce the background noise considerably. Thin sections of the peroxidase stained supraoesophageal cell bodies stained by Lan3-9 gave a signal 50-fold over the absorbance of adjoining tissue.

* Recloned in soft agar.

from another. Of these, 64% secreted antibodies that bound to the leech nervous system. Most showed no obvious preference for subsets of neurones but reacted with general nerve cell components. A few bound to interesting subcellular or extracellular structures, for example, to antigens specific for the axon hillock of leech neurones (Lan3-15). Two antibodies recognized muscle antigens and stained the large muscle fibre present in each ganglion. Of central concern to us here is the group 41, which reacted with restricted subsets of neurones or fibres.

Antigen distribution

Of the 41 antibodies that stained restricted sets of neurones, about half have been studied in some detail and are reported here. Table 1 summarizes our findings about each of these monoclonal antibodies. The data for Table 1 are based on the immunocytochemical staining patterns of each antibody. An example is illustrated in Fig. 2 showing Lan3-1, a monoclonal antibody which binds to a pair of small bilateral neurones in a midbody ganglion (Fig. 2*b*). The right and left cell bodies are located at homologous positions on the dorsal surface in each of the 21 midbody ganglia as shown diagrammatically in a schematic representation of the leech nerve cord (Fig. 3). In addition to labelling these cell bodies, the antibody binds to clouds of varicosities in the central ganglionic neuropiles as well as to specific axons in the connective, the fibre tract that links all ganglia in the 34-ganglion nerve cord. Because each monoclonal antibody seems to have its own optimal histochemical procedures, to obtain good staining patterns, it is necessary to test a spectrum of fixatives and secondary antibodies. For example, with Lan3-1, the small pair of cell bodies appeared during the initial screen using 4% paraformaldehyde fixation, but the fine axons and varicosities were only observed after switching to Bouin's fixation. The HRP-conjugated rabbit anti-mouse IgG heavy and light chains remained a good secondary antibody but peroxidase-conjugated μ chain-specific rabbit anti-mouse IgM

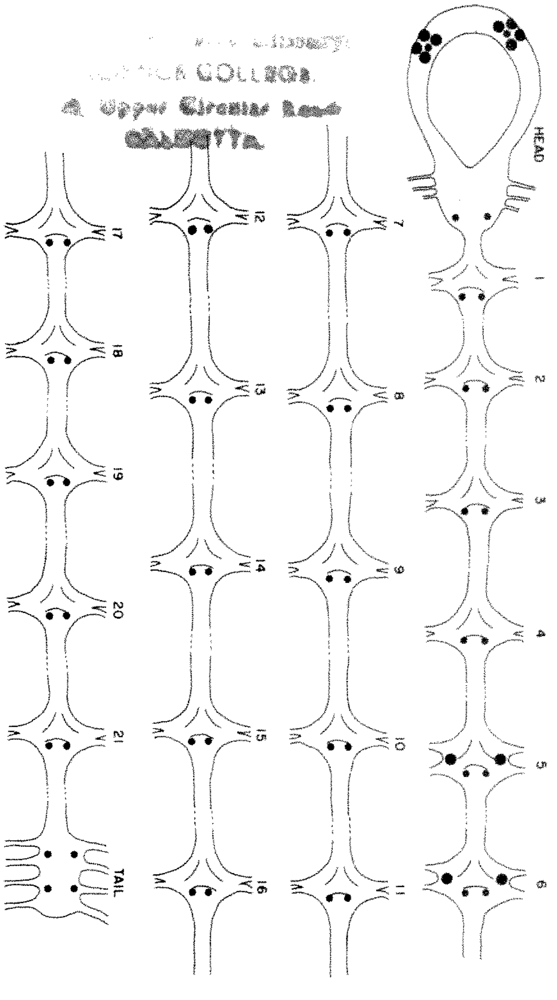

Fig. 3 This diagram illustrates the symmetry and repetitive organization of the nerve cord. The cell bodies stained by Lan3-1 in the 21 free midbody ganglia were verified in a large number of tests. The head and tail brains are more difficult to analyse and might contain additional neurones besides those indicated.

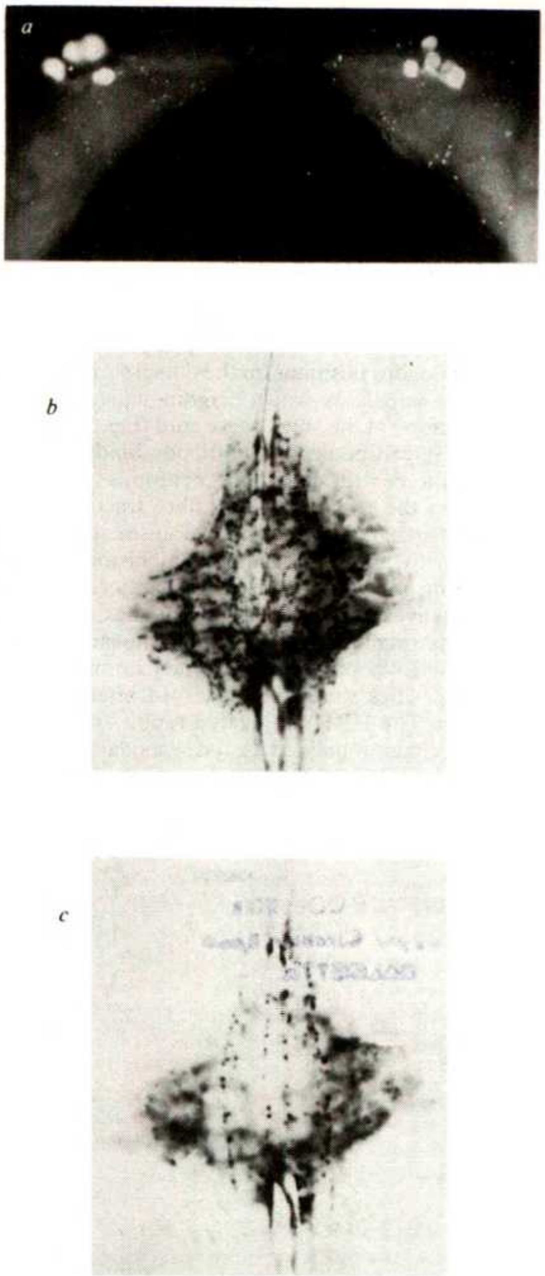

Fig. 4 Specific staining with Lan3-9. *a* Shows that this antibody also recognizes a bilateral set of five cell bodies in the supraoesophageal ganglion using rhodamine-conjugated second antibody. These differ from those stained by Lan3-1 (Fig. 2*a*). *b* And *c* show two focal planes through the same whole midbody ganglion stained by the PAP procedure (see Table 1 legend). No cell bodies can be seen here but several axons marked by discontinuous staining and a complex dense array of varicosities are visible.

also bound to Lan3-1, showing that this monoclonal antibody is an IgM.

All monoclonal antibodies were retested with fluorescently labelled secondary antibodies to confirm the staining pattern and detect features perhaps not visible with HRP. In the fluorescence procedure compromises have to be made between fixatives to achieve good labelling while maintaining low background. As the intact leech ganglion is 250-µm thick, an elevation in background fluoresence can critically impair the visibility of selectively stained features. Paraformaldehyde fixation has so far given the lowest background, making it possible to distinguish fine processes and varicosities at ×100 magnification. With Bouin's fixation, the background fluorescence tends to submerge fine processes buried in the neuropile while the visibility of superficial cell bodies remains excellent. However, with high power magnification the Lan3-1 varicosities can be seen with rhodamine-conjugated second antibody. In addition to Lan3-1, antibodies Lan3-3 and Lan3-4 recognize pairs of neurones in the midbody ganglion. Lan3-4 is specific for a pair of 40-µm cells situated between anterior and posterior roots, whereas Lan3-3 binds to a different pair closer to the anterior pole of the ganglion in the vicinity of the heart motor neurone.

Several antibodies that bind to homologous neurones in successive midbody ganglia bind to extra neurones in specialized ganglia, in the fused head ganglion or in the supraoesophageal ganglion. Ganglia 5 and 6 (G5, G6), containing almost twice as many neurones as the standard midbody ganglion, are specialized to subserve reproductive function and many of their supernumerary neurones innervate the genitalia. Lan3-1 recognizes pairs of large cells in G5 and G6 (Fig. 2*c*) in addition to the characteristic pairs of small cells (Fig. 2*b*). Previous studies[11] have shown that there is a pair of penile evertor motor neurones (PE) in G6 with the same position and axonal pattern as those stained by Lan3-1 in G6 and a homologous pair in G5 of unknown function. To demonstrate unequivocally that the large cells stained by Lan3-1 in G6 were the previously identified PE neurones, a double-labelling experiment using an injected dye was carried out. A cell body believed to be the left lateral PE cell was impaled with a microelectrode and its identity confirmed by its characteristic action potential (20 mV, non-overshooting) and its synaptic relationship with another major penile evertor cell, the rostral PE motor neurone[12]. Following electrophysiological identification, the fluorescent dye lucifer yellow[13] was injected through the recording electrode (Fig. 2*d*). To control for the effect of lucifer yellow on antibody staining, the left Retzius cell in the centre of the ganglion was also injected. After the ganglion had been fixed it was treated with hybridoma supernatant in the usual way and then treated with rhodamine-conjugated rabbit anti-mouse IgG. The results illustrated in Fig. 2*c* and *d* confirmed that the lateral PE cell contained the antigen to which the monoclonal antibody Lan3-1 binds. The same cell fluoresces yellow with the intrasomatically applied marker lucifer yellow (Fig. 2*d*) and red with the rhodamine-labelled mouse antibody (Fig. 2*c*). Of course, the monoclonal antibody bound to both the left injected lateral PE and the right uninjected cell. Under fluorescein isothiocyanate (FITC) optics, suitable for studying lucifer yellow fluorescence, a certain amount of rhodamine breakthrough is noticed in the right lateral PE cell. The lack of lucifer yellow interference with the antibody visualization is demonstrated by the absence of Retzius cell staining with rhodamine.

The subset of neurones labelled by Lan3-1 extends into the head and tail ganglion as well as into the supraoesophageal ganglion. The head and tail ganglia contain small pairs of neurones probably analogous to the small pair of cells that regularly repeat in the midbody ganglia. In addition, several large cells occur in the supraoesophageal ganglion. It is interesting that specific neurones in the supraoesophageal ganglion (Fig. 2*a*) with their separate embryological origin share an antigen with neurones in the rest of the nerve cord.

Of the 20 antibodies studied in detail, 2 bind to supernumerary neurones in the sex ganglia, G5 and G6. Like Lan3-1, the antibody Lan3-3 binds to extra neurones in G5 and G6 in addition to staining a pair of neurones which repeat in the midbody ganglia. The supernumerary cells labelled by Lan3-3 in the sex ganglia also lie between the anterior and posterior roots but on the dorsal surface whereas the lateral PE cell stained by Lan3-1 lies on the ventral surface. Axons and varicosities are not stained with Lan3-3.

Antibodies (for example, Lan3-12, 3-10, 3-9 and 3-11) were found that labelled cell bodies of neurones in the head, supraoesophageal ganglia or the anterior ganglia but not in any of the regularly repeating midbody ganglia. Lan3-12, 3-10 and 3-9 (Fig. 4*a*) all bind to neurones in the supraoesophageal ganglion. In addition, antigenically related processes occur throughout the nerve cord as fibres in the connective and nerve terminals in midbody ganglia are stained. As seen in Fig. 4*b* and *c* Lan3-9-

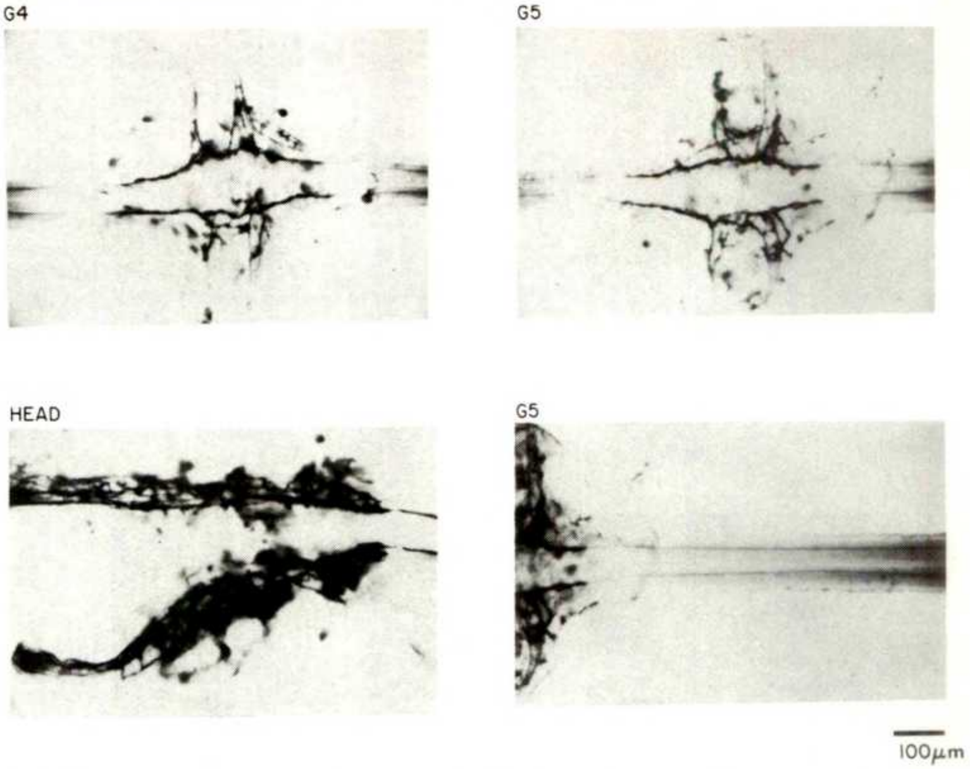

Fig. 5 The staining pattern of Lan2-3. Lan2-3 detects a single bilaterally symmetrical fibre system in each midbody ganglion. *a* and *b* show that major features of the fibre pattern repeat in adjacent ganglia. This uninterrupted staining of a branching fibre system contrasts with the punctate varicosities stained with both Lan3-1 (Fig. 2) and Lan3-9 (Fig. 4). The fibre system stained in the head ganglion is more complex (*c*). In *d* we show that a tight bundle of axons extends from a ganglion into the connective.

labelled axons run in the connective and similarly stained varicosities swamp the ganglionic neuropile.

Some antibodies stained only axons and neurites. Cell bodies have not yet been detected. An example is given in Fig. 5, where the staining pattern of Lan2-3 is seen to consist of relatively thick smooth fibres that pass through the connective (Fig. 5*d*) and ramify in the midbody ganglia (Fig. 5*a*, *b*) and head (Fig. 5*c*). This fibre system could have peripheral cell bodies, cell bodies in the tail ganglion or cell bodies devoid of antigen.

Nine monoclonal antibodies were isolated which stain more than one pair of neurones in a typical midbody ganglion. Six of these antibodies bind to mechanosensory neurones present in the typical 400-neurone midbody ganglion which selectively respond to touch, pressure and pain in clearly defined receptive fields on the skin of the leech. The typical mechanosensory cell body sends its axons (1) into the ipsilateral roots to innervate its own ganglion's receptive field and (2) via the ipsilateral connective into neighbouring ganglia to innervate partial receptive fields in adjacent body segments. These neurones have been extensively characterized electrophysiologically and through intracellular marker injections[1,6,7].

The four neurones responding to noxious mechanical stimuli (the nociceptive cells) all share a common antigen recognized by the monoclonal antibody Lan3-2 (Fig. 6*d*). This antigen is present in the cell body and all along the axonic and neuritic processes. It labels the ipsilateral projections and highlights a dense railroad-track-like pattern arising from the close packing of right and left axons running through the nerve cord. The nociceptive cells labelled by Lan3-2 and the pressure cells labelled by Lan3-5 (Fig. 6*c*) have been identified by double labelling (data not shown). The monoclonal antibody Lan3-5 labels the cell bodies and processes of three pairs of unidentified neurones and the two pairs of pressure cells. The pressure cells confine their axons to the ipsilateral ganglion and connective whereas the unidentified neurones cross to the contralateral side, allowing them the possible role of integrative interneurones. The antibody Lan3-6 binds to about 26 neurones in the typical posterior midbody ganglion including the pressure cells, possibly the touch cells and unidentified neurones (Fig. 6*b*). Additional antibodies that bind to pressure cells are Lan3-7 (Fig. 6*a*), Lan1-1 and Lan2-1 (not shown here). It is likely that these antibodies bind to different pressure cell antigenic determinants as they stain different sets of neurones.

Several antibodies show specific staining superimposed on a generalized uniform labelling. Examples are the brightly labelled roots of Lan3-5 (Fig. 6*c*) or the gradient of diaminobenzidine reaction product intensity of the Lan3-6-stained ganglion (Fig. 6*b*). Lan 3-6 reproducibly labels the constellation of neurones illustrated here, but in addition other cells, such as the Retzius cells, can be weakly labelled. Lan3-2 in Fig. 6*d* only binds to the four nociceptive cell bodies as visualized with the rhodamine-conjugated second antibody. If an HRP-conjugated second antibody is used, other cell bodies can show some degree of staining. Lan1-1 is an antibody that gives a somewhat higher degree of generalized staining in addition to binding to a definite constellation of ganglionic neurones. It also binds to many peripheral nerve bundles and cell bodies but not to muscle fibres or connective tissue. Specific cell staining is superimposed on the highest level of uniform cell body labelling with Lan3-8. This antibody is of special interest because it reproducibly stains the S-cell axon[1] as verified through double-labelling experiments. Occasionally, the S-cell body can be recognized but is generally submerged in the background. In contrast to Lan3-8, most of our antibodies that differentiate between specific nerve cells stain a small set of neurones. Of the 20 antibodies listed in Table 1, only 2 show strong general neuronal staining, 8 may give some general staining on which the reproducible specific staining is superimposed, but 10 show very high signal to noise labelling of only a few neurones. We have used a microphotometer to analyse the specificity of staining quantitatively. For example, in 1-µm thick sections of the supraoesophageal ganglion incubated with Lan3-9, the cell bodies similar to those shown in Fig. 4*a* had an optimal optical absorbance 50-fold greater than an adjoining unstained tissue. This makes us confident that we are detecting major differences in antigen concentration between neurones.

Discussion

We report here that monoclonal antibodies raised against the nervous system of the leech reveal an unexpectedly high level of antigenic diversity. Of the 475 hybridomas tested, approximately 300 bound to the leech nervous system. Of these, 41 different antibodies have been obtained which label specific subsets of neurones. Twenty of these antibodies have been analysed in detail and all give different staining patterns. These numbers suggest that many hybridomas secreting antibodies

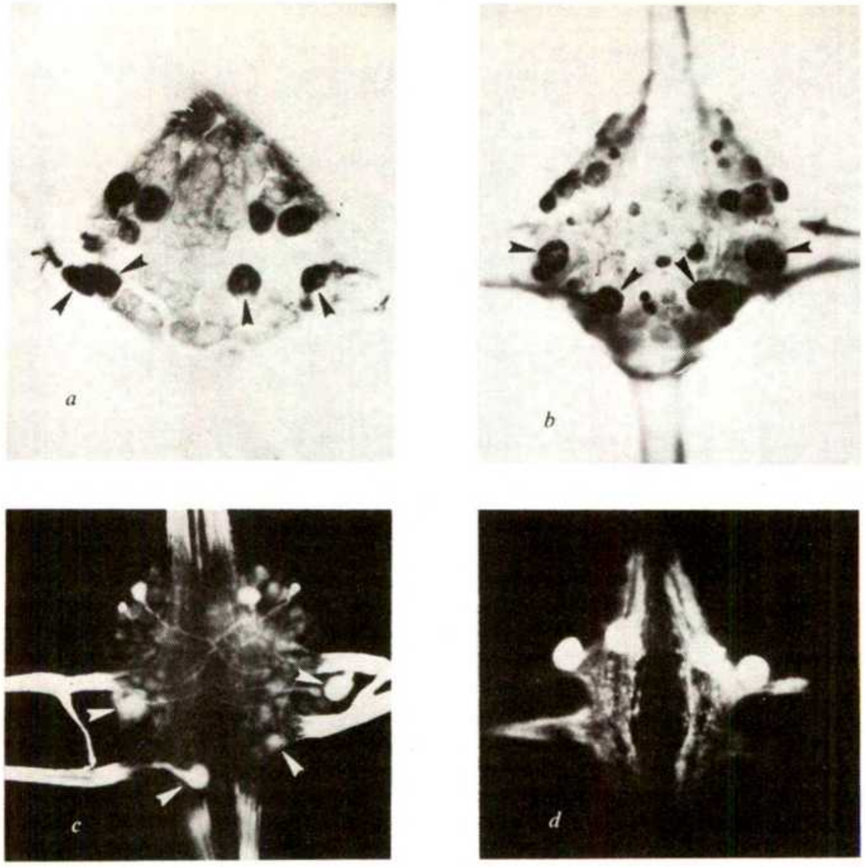

Fig. 6 Mechanosensory cells stained by four different antibodies. Three antibodies, Lan3-7 (*a*), Lan3-6(*b*) and Lan3-5 (*c*) stain the pressure cells (marked by arrows) as part of three distinct staining patterns. The pressure cells were identified by their morphology and in the case of Lan3-5 by double labelling with rhodamine-conjugated second antibody and lucifer yellow microinjection. In *d* the antibody Lan3-2 is shown staining the nociceptive cell bodies and processes.

against specific antigenic determinants have not yet been detected. The presence of large numbers of antigens restricted to small groups of neurones has implications for many aspects of neurobiology. Recent work on the rat retina has shown that monoclonal antibodies can distinguish between photoreceptors and glial cells[14]. The promise of this approach lies in the potential to identify molecules present in cells with a known electrophysiological function and neuroanatomical location. The chemical specificity of the antibodies then offers a bridge between electrophysiology, anatomy, the molecular nature and developmental behaviour of the antigen.

The potential of specific monoclonal antibodies as a tool in neurobiology can be seen, for example, in the antibody Lan3-1 that binds to a small group of cells in the leech nerve cord. The two large cells in the fifth and sixth midbody ganglia are known to be involved in the control of sexual behaviour. The cell in ganglion 6 was previously identified as one of the two major penile evertors, the lateral PE motor neurone[11,12]. The antibody staining technique has now confirmed the earlier impression that this type of neurone repeats in ganglia 5 and 6 but not in any other midbody ganglion. The obvious question raised by the staining pattern is the relationship between the large-diameter supernumary neurones in G5, G6 and the headbrains to the small-diameter neurones repeating in successive ganglia. Lan3-1 clearly does not code for general penile evertor function because it does not label the other major penile evertor cell, the rostral PE motorneurone, but it could still signify a sub-network controlling sexual function. Antibodies like Lan3-1 will serve as markers for studying leech development. By staining the nervous system at different developmental stages with Lan3-1 we may identify a particular sequence in which the cells express the antigen recognized by Lan3-1. In the case of Lan3-1, the special interest lies in relating these data to the sexual and hormonal development of the organism.

Considering the past work on the leech[6], it is of considerable importance that several antibodies were isolated that label the mechanosensory cells mediating the motor responses to the environmental stimuli touch, pressure and noxious mechanical stimulation. Such monoclonal antibodies will be helpful in extending the analysis of sensory systems in the leech where the detailed description of the first-order sensory neurones stands in contrast to our ignorance of higher-order sensory function. For example, Lan3-5 binds to all four pressure cells and to three other bilateral pairs of cells of so far unidentified function in the typical midbody ganglion. Conceivably, such immunocytochemical staining patterns could represent a network processing pressure sensation in which the nonidentified cells might be higher-order sensory neurones.

An integrated approach using many neurobiological techniques will be required to understand these staining patterns in detail. We have no experimental information on the molecular nature of the antigens showing restricted cellular distributions. It is clearly important to define molecules found in only a few neurones as we suppose that directly or indirectly they will lead us to the molecular mechanisms governing neuronal specificity.

We thank David Zipser for important contributions to this project and manuscript, Mike Ockler for drawing Fig. 1, David Lane for his help during our first fusion, Walter Stewart for the lucifer yellow dye, and James D. Watson for his encouragement. This work was supported by NSF grant BNS 78-248-72 and a Whitehall grant. During part of this project R. McK. was supported by an MRC fellowship.

Double-stranded DNA copies of the single-stranded genomic RNA of foot and mouth disease virus have been cloned into the Escherichia coli *plasmid pBR322. A restriction map of the viral genome was established and aligned with the biochemical map of foot and mouth disease virus. The coding sequence for structural protein VP1, the major antigen of the virus, was identified and inserted into a plasmid vector where the expression of this sequence is under control of the phage λ P$_L$ promoter. In an appropriate host the synthesis of antigenic polypeptide can be demonstrated by radioimmunoassay.*

FOOT AND MOUTH disease virus (FMDV) is a picornavirus which affects cloven-footed animals. Like other picornaviruses its genome consists of a single-stranded RNA molecule of about 8,000 bases. It is polyadenylated at its 3′ end, has a poly(C) tract close to the 5′ end and a protein covalently attached to its 5′ end. Although it does not have the usual eukaryotic mRNA cap it serves as a mRNA both *in vivo* and *in vitro*. Only the region between the poly(C) tract and the 3′ end of the RNA carries the coding sequence, with a single initiation point for translation close to the poly(C) tract (for reviews see refs 1, 2). FMDV virions contain primarily four capsid proteins, identified as VP1, VP2, VP3 and VP4 (terminology as in ref. 1 is used, VP1 corresponds to VP3 in ref. 2) which are synthesized as a common polypeptide precursor in the infected cell and map close to the 5′ end of the viral genome[3]. Of these proteins VP1 is of particular interest because it carries epitope(s) inducing neutralizing antibodies[4,5]. For this reason it probably contributes to the high antigenic variation of FMDV which results in 7 serotypes and more than 60 subtypes. This variability causes major problems in vaccination programmes and makes the virus interesting not only for academic but also for applied research.

Because of recent advances in DNA technology a double-stranded DNA copy of the viral RNA would be of advantage for further detailed analysis of the FMDV genome, and, in particular, of the regions coding for the structural proteins. Thus, the antigenic variability could be analysed on a molecular basis by restriction mapping and DNA sequencing. The synthesis of VP1 in a bacterial host would be of obvious interest; although this protein is a less potent immunogen than the intact virus, it can protect animals from infection, as has been shown for swine[6]. Here we report the isolation of cDNA clones covering 70% of the FMDV genome and present a restriction map for the genome of FMDV strain O$_1$K and the precise location of capsid protein VP1 within this map. We also show that the VP1 coding sequence is expressed in *E. coli*.

Physical and genetic map of FMDV, serotype O$_1$ Kaufbeuren

Single-stranded cDNA was synthesized from FMDV RNA using oligo(dT)$_{12-18}$ as a primer for AMV reverse transcriptase. This cDNA was rendered double stranded by *E. coli* DNA polymerase I in the presence of the four [α-^{32}P]-labelled deoxynucleoside triphosphates. The size of the double-stranded cDNA was determined by electrophoresis on a 1% agarose gel using appropriate markers. More than 40% of the cDNA synthesized in this way was between 4,500 and 8,000 base pairs long. As shown in Fig. 1 a major fraction of the cDNA was much

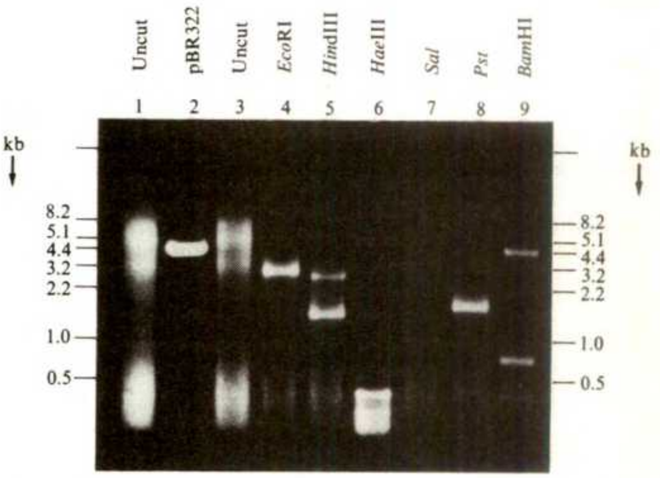

Fig. 1 Restriction analysis of FMDV cDNA. Strain O$_1$K was isolated in Kaufbeuren during an epizootic outbreak that occurred in southern Germany in 1966–67. The virus was cloned three times from single plaques and passaged about 50 times in cell cultures. The identity of the passaged virus was confirmed by complement binding assays with the original antibodies. For RNA isolation the virus was grown in BHK cell monolayers in several roller bottles. Viral RNA was prepared essentially as described by Grubman *et al.*[17]. Single-stranded cDNA was prepared by AMV reverse transcriptase (80 units) initiated by 0.1 unit (A_{260}) of pT$_{12-18}$ primer in 100 µl of 50 mM Tris-HCl *p*H 8.3, 50 mM KCl, 8 mM $MgCl_2$, 25 mM β-mercaptoethanol, dATP, dCTP, dGTP and dTTP each at 0.5 mM and 14 µg FMDV RNA having been pretreated with 2.5 mM CH_3 HgOH for 3 min at room temperature. After incubation at room temperature for 5 min and at 42 °C for 60 min, the mixture was boiled in a water bath for 3 min and quickly cooled to dissociate the cDNA–RNA hybrids. The cDNA strand was rendered double stranded by combining the above mixture with 100 µl of 0.2 M HEPES buffer *p*H 6.9, 90 mM KCl, 0.4 mM each of dATP, dCTP, dGTP and dTTP, 50 µCi each of the four ^{32}P-labelled deoxytriphosphates and 50 units DNA polymerase I, before incubation at 15 °C for 2 h. To stop the reaction, the mixture was extracted with phenol and passed through a Sephadex G-150 column. The double-stranded cDNA was further analysed by digestion with various restriction enzymes. cDNA (2×10^4 c.p.m.) was mixed with 7 µg of adenovirus 2 (Ad2) DNA and digested with the enzymes indicated in lanes 4–9. Fragments were analysed on a 1.0% agarose gel. Staining with ethidium bromide showed the position of the Ad2 DNA fragments which were used as internal markers and were also an indication for complete digestion. cDNA fragments were detected by autoradiography. Linearized pBR322 was added as a marker (lane 2). kb, Kilobase.

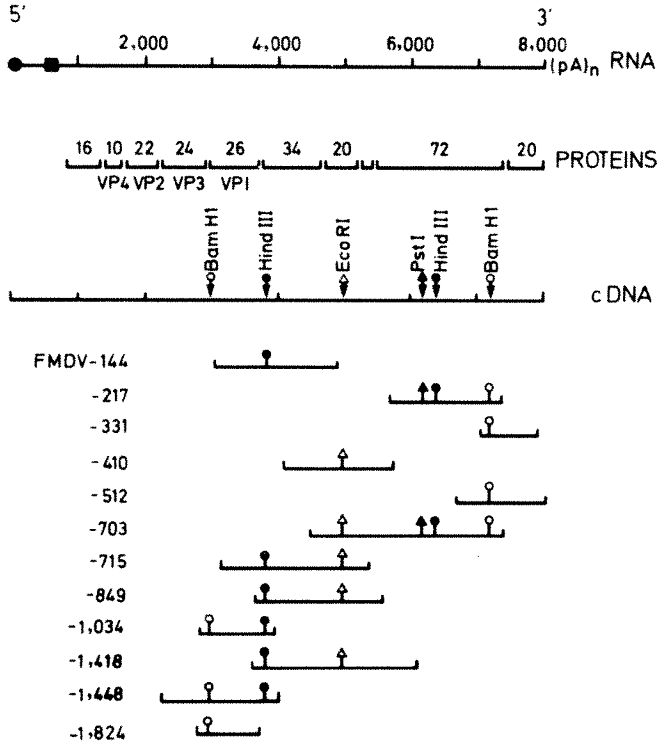

Fig. 2 Localization of cloned FMDV cDNA fragments. For convenience the size of the RNA is given as 8,000 bases instead of the 7,800 bases estimated by physical analysis[18] and the *Bam*HI restriction site is referred to as map position 3,000. The molecular weights ($\times 10^{-3}$) of the proteins are as indicated. VP1 to VP4 are the viral capsid proteins. Within the RNA molecule ■ indicates the internal poly(C) stretch close to the 5' end and ● indicates the viral genomic protein (VPg) covalently linked to the 5' end of the viral RNA. Plasmid pBR322 was digested completely with *Pst*I endonuclease. The mixture was extracted with 1 vol phenol and precipitated with 2.5 vol ethanol. Homopolymeric dG-tails were added using terminal deoxynucleotidyl transferase in a 50-µl reaction volume containing 1 µg of cleaved plasmid, 200 mM Na-K-cacodylate (pH 7.2), 1 mM $CoCl_2$, 1 mM β-mercaptoethanol, 200 µM dGTP and 12 units of enzyme. Incubation was for 30 min at 37 °C. Approximately 5 µg of double-stranded cDNA were elongated with dCTP residues by terminal deoxynucleotidyl transferase in a 50-µl reaction volume as above, but containing 100 µM dCTP and 15 units of enzyme. Incubation was for 5 min at 37 °C, and the reaction was stopped by freezing. For annealing, 20 ng dG-tailed *Pst*I-cleaved pBR322 vector and 50 ng dC-tailed double-stranded cDNA were mixed in 30 µl 1 × SSC buffer. The mixture was placed in a water bath at 69 °C and allowed to cool slowly overnight to 35 °C. The recombinant DNA mixture was then used to transform competent *E. coli* HB101 cells. The analysis of the plasmids from colonies showing Tet^r and Amp^s phenotype and the deduction of the cDNA restriction map from the experiment described in Fig. 1 is given in the text. The experiments were carried out in L3 B1 conditions in accordance with the German guidelines for recombinant DNA research.

shorter. This bimodal distribution may be explained by a high degree of secondary structure in certain parts of the RNA template. For further analysis the cDNA was digested with various restriction endonucleases (Fig. 1, lanes 4–9). Simple restriction patterns were obtained with restriction endonucleases *Eco*RI and *Pst*I or *Hin*dIII and *Bam*HI, which generated one or two restriction fragments, respectively.

A restriction map can be deduced using the size of these fragments and the relative intensity of these bands in a gel. 3'-Proximal cDNA sequences occur more often in the cDNA population and the corresponding bands are therefore more intense. Because the 5'-proximal cDNA sequences are heterogeneous in length no corresponding fragments can be detected. Of two fragments generated by *Hin*dIII the more intense smaller fragment must contain sequences closer to the 3' end of the FMDV genome. For the *Bam*HI digest the intensities of the two bands are about equal; however, because of the uniform labelling of the cDNA the 4-kilobase band comprises less molecules than the smaller (0.8 kilobase) band. In this way a restriction map of the FMDV genome was obtained and aligned relative to the 3' end of the RNA (Fig. 2). Approximate correlations between the different viral proteins and the viral genome were deduced from the order of translation of the different polypeptides and from their apparent molecular weights[7]. This correlation can now be used to predict the position of viral genes within specific restriction fragments of the FMDV genome. This prediction is, of course, approximate but as shown below it was successfully applied to find the coding region for VP1. The predicted position was, in fact, only 300 base pairs away from the position shown in Fig. 2 (between the *Bam*HI cut at map position 3,000 and the *Hin*dIII cut at map position 3,847).

Fig. 3 Exact correlation of the physical map of the FMDV genome with cloned cDNA sequences that code for VP1. The position of the VP1 gene, of cloned FMDV sequences and of unique restriction sites in the enlarged part of the genome are based on the nucleotide sequence of pFMDV-1034 (ref. 10). The nucleotide sequence at the 5' end of the VP1 gene and the deduced NH_2-terminal amino acid sequence for VP1 are presented in the second enlargement. Amino acids that agree with those determined experimentally[9] are underlined.

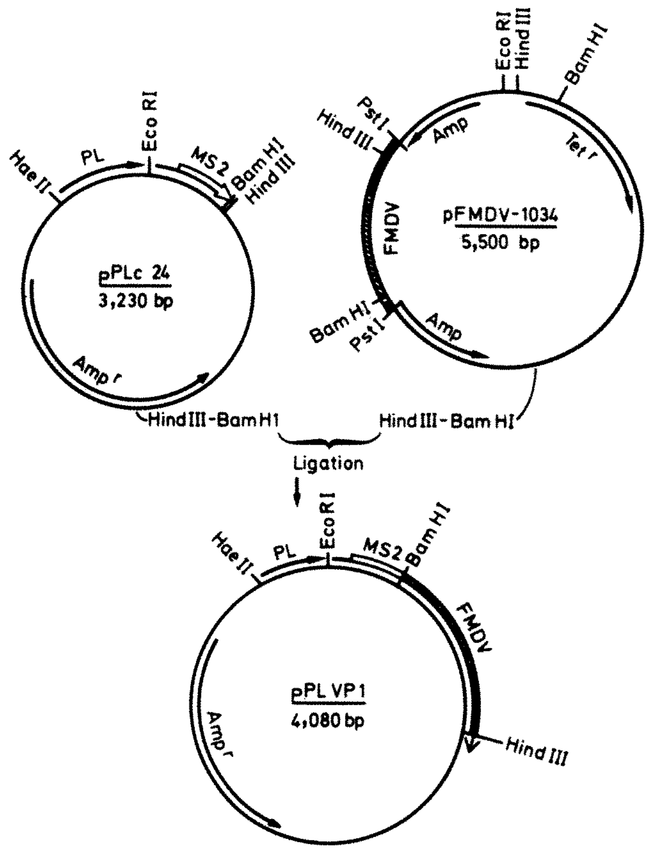

Fig. 4 Construction of plasmid pPL VP1. The schematic outline shows the vector plasmid pPL c24 and the donor plasmid pFMDV-1034. Amp, β-lactamase region coding for resistance to ampicillin; Tet, coding region for resistance to tetracycline; PL, λ P_L control element; MS2, DNA fragment derived from bacteriophage MS2 where the boxed part indicates the coding sequence for the first 99 amino acids of the MS2 polymerase; FMDV, insert derived from FMDV cDNA, the shadowed area shows the coding region for VP1. The predicted fusion polypeptide from the constructed plasmid pPL VP1 is indicated. Only restriction sites relevant for this construction are shown. The FMDV insert of pFMDV-1034 was isolated by electrophoresis on a 1% agarose gel after digestion of the plasmid with *Pst*I. The isolated FMDV fragment was digested with *Hin*dIII and *Bam*HI, the vector was sequentially digested with *Bam*HI and *Hin*dIII. 0.2 pmol of restricted vector were combined with 0.1 pmol of the restricted FMDV fragment in 50 µl ligation buffer (50 mM Tris-HCl *p*H 8.0, 10 mM Mg Cl_2, 50 mM NaCl, 0.2 mM EDTA, 1 mM ATP and 1 mM dithioerythritol) and incubated for 16 h at 15 °C after addition of T4 ligase. The most likely construction created in this way is pPL VP1. The *Bam*HI–*Hin*dIII fragment excised from pPL c24 is only 10 nucleotides long with 6 nucleotides overlapping and will not be efficiently reinserted. Enzymatic reactions were stopped by incubation at 65 °C for 10 min.

Cloning of FMDV cDNA into pBR322 and characterization of the hybrids

To insert the double-stranded cDNA molecules into plasmid pBR322, oligo(dC)-tails were added to their 3′ termini after treatment with nuclease S_1 (ref. 8). The dC-tailed DNA molecules were annealed to pBR322 DNA to which 3′ oligo(dG) sequences had been added after cleavage with *Pst*I. The annealed DNA was then used to transform competent cells of *E. coli* HB101. One thousand transformants which were ampicillin sensitive and tetracycline resistant were transferred to microtitre plates. Replicas of each plate were used for hybridization with ^{32}P-labelled fragmented viral RNA (average chain length 300 nucleotides). Colonies which displayed strong hybridization with the ^{32}P-labelled probe were selected for further analysis assuming that these contain large inserts.

Plasmids were isolated and the FMDV DNA inserts excised with *Pst*I. Surprisingly, none of the clones contained inserts longer than about 2,500 base pairs. Further analysis of the FMDV inserts by restriction mapping of the *Pst*I-cleaved DNA with *Eco*RI, *Bam*HI and *Hin*dIII showed that the cloned DNA did not all begin with overlapping sequences at the 3′ end as expected from the oligo(dT)-primed synthesis of the cDNA, but originated from various parts of the FMDV genome and covered about 75% of the 8,000 bases (Fig. 2). Predicted overlaps between various inserts were further confirmed by comparative structural analysis using restriction nucleases *Hae*III, *Hin*fI, *Hha*I, *Taq*I and *Ava*I (results not shown). These results also confirmed the physical map of the FMDV genome which was based originally on the use of only four restriction enzymes. In conjunction with the biochemical map of the viral proteins this predicts that several clones (for example FMDV-144 and FMDV-715) should contain nucleotide sequences which code for capsid protein VP1 (Fig. 2). The reasons for the unexpectedly small size of the FMDV cDNA inserts and their scattering throughout the genome are not understood. Before cloning, 40% of the cDNA molecules were >4,000 base pairs long starting from the 3′ end of the FMDV genome, as demonstrated by the sharpness of the digestion patterns with various restriction endonucleases (Fig. 1). Nevertheless, the average size of the cloned cDNA inserts was only about 1 kilobase, even when only cDNA molecules larger than 4 kilobases were used (isolated by preparative polyacrylamide gel electrophoresis, data not shown). This rules out the possibility that the result obtained was due to nonspecific degradation of the cDNA during its synthesis and suggests that oligo(dC)-tails were added internally by the terminal transferase at single-stranded nicks, which may have been introduced during the preparation of the cDNA.

In all clones analysed both terminal *Pst*I sites were conserved and analysis of overlapping cloned FMDV DNA showed complete agreement of the nucleotide sequence within the overlapping DNA part. This again suggests that the short size of the inserted FMDV DNA is not due to internal recombination or deletion.

Identification of DNA inserts coding for VP1

By comparison with the original biochemical map, clones FMDV-715 and FMDV-144 seemed to contain the coding sequence for viral protein VP1. Nucleotide sequences from the corresponding parts of the cloned cDNA were therefore determined and compared with the known sequence of the NH_2-terminal 40 amino acids of VP1[9]. A fit was obtained with the 5′-proximal end of the DNA insert of pFMDV-144, which contained a sequence capable of coding for amino acids 22–40 of protein VP1 (Fig. 3). This indicated that the VP1 gene maps about 300 nucleotides to the left of the position estimated from our original map. Additional clones were therefore selected which also contained the missing part of the VP1 gene (see below). Of these, the insert from pFMDV-1034 was analysed in detail and its nucleotide sequence determined[10]. It showed that the insert from pFMDV-1034 extends 126 nucleotides into the 5′ direction beyond the end of clone pFMDV-144. After the first

Fig. 5 Junction sequences at the borders of the inserted FMDV DNA in plasmid pPl VP1, as predicted by the construction outlined in Fig. 4. The nucleotide sequence at the *Bam*HI site was confirmed by DNA sequencing. The corresponding amino acid sequence was deduced from the DNA sequence.

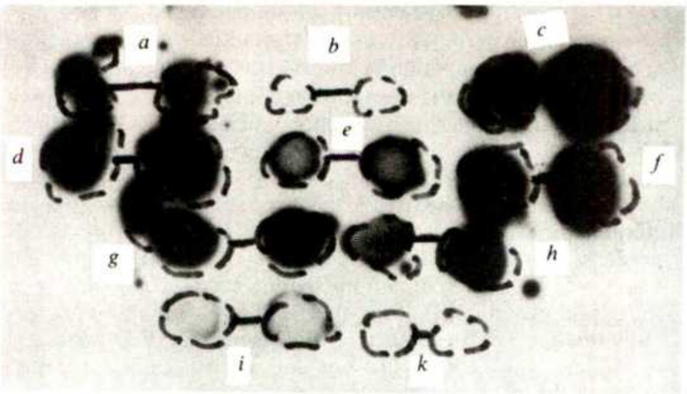

Fig. 6 Autoradiograph showing the detection of VP1-specific material in bacterial extracts. Colonies of *E. coli* K12ΔH1 (K12 M72 Lac_{am} ΔtrpEA2 strep^{r}[λC1 857 N_{am7} N_{am53} ΔH1 bio^{-}])[14] transformed by pPl VP1-1 to pPl VP1-7 or by pBR322 and pPl c24 as controls were grown at 27 °C and served as inoculum for liquid cultures (100 ml, L-broth). Cultures were grown up to 6×10^8 cells ml^{-1} at 27 °C and then the temperature was shifted and kept for 5 h at 42 °C. After chloroform treatment the bacteria were collected by centrifugation, resuspended in 1 ml phosphate-buffered saline (PBS) and sonicated for 1 min in an ice bath. The bacterial debris were washed with 0.5 ml PBS and both supernatants were combined. 5 μl of these extracts were applied in duplicate onto polyvinyl disks coated with anti-O_1K IgG prepared from hyperimmune serum of guinea pigs. The disks were incubated for 4 h at 37 °C and washed as described elsewhere[15] except that 0.05% NP40 was added to the washing solution. Finally, the disks were incubated overnight at 4 °C with ^{125}I-labelled anti-VP1 (4×10^6 c.p.m. per μg; 5×10^6 c.p.m. per disk, preabsorbed with 0.5 ml extract from K12 ΔHI/pPL c24). After thorough washing the disks were autoradiographed. *a* and *d–i*, extract prepared from *E. coli* K12ΔH1 carrying plasmid pPl VP1-1 to pPL VP1-7, respectively. *b*, *k*, Extract from K12ΔH1/pPL c24 and K12ΔH1/pBR322 as negative controls. *c*, FMDV virus (2 μg) as positive control.

61 nucleotides the sequence is in agreement with the N′-terminal amino acid sequence of VP1 (the sequence relevant to this discussion is shown in Fig. 3). This sequence is followed up to the end of pFMDV-1034 (map position 4,010) by a continuous translation reading frame and thus codes for more than 350 amino acids of FMDV-specific polypeptide which is well above the estimated size of VP1[1,2,11]. Except for the difference of one nucleotide, identical sequences were obtained from corresponding segments of the independently isolated clones FMDV-144 and FMDV-715, which start at map positions 3,041 and 3,122, respectively (Fig. 3). Both the identity of the common nucleotide sequence between independent isolates and the presence of a continuous open reading frame indicate that this part of the FMDV genome was cloned intact and that it contains the whole coding sequence for VP1. This conclusion is further supported by the results obtained for expression of this sequence in *E. coli* (see below).

Specific screening for genes coding for viral proteins

Having localized the gene for VP1 within a specific part of the FMDV genome, the whole library can now be screened specifically for DNA inserts carrying the coding sequence for viral proteins. The *Pst*I–*Hin*dIII fragment of pFMDV-144, which carries most of the coding sequence for VP1, was used as a probe to select other clones having inserts covering the same part of the FMDV genome. From the total library of 1,000 clones, 16 displayed strong hybridization and were analysed further by *Bam*HI restriction mapping and size determination of the resulting fragments. The presence of a *Bam*HI restriction site within the insert and the size of the insert make it possible to identify clones which carry the coding sequence not only for VP1 but also for all or a portion of the nucleotide sequence of VP2 and VP3. Clones selected in this way were identified as FMDV-1034, FMDV-1448 and FMDV-1824 (Fig. 2). In an analogous screening process the *Bam*HI–*Hin*dIII fragment of pFMDV-217 was used to probe for sequences originating from the 3′ end of the genome. Analysis of the hybridization data confirmed that the localization of the clones shown in Fig. 2 was correct. No clone hybridized to both parts of the genome, which again indicates that there were no recombinant DNA molecules carrying the entire FMDV genome.

Construction of plasmids expressing VP1 in *E. coli* cells

To express the viral protein VP1 in a bacterial host we chose an expression vector carrying the strong leftward promoter of bacteriophage λ the activity of which can be controlled by using host strains that carry the gene for a temperature-sensitive λ repressor (*c*I *ts*). This vector (pPL c24, Fig. 4, ref. 12) has been used successfully to express the gene for human fibroblast interferon[13]. It carries a unique restriction site for *Bam*HI at amino acid 99 of the MS2 replicase gene and a unique site for *Hin*dIII 10 nucleotides downstream. Using these two sites, the *Bam*HI–*Hin*dIII fragment of pFMDV-1034 can be inserted in the vector such that only one orientation of insertion is possible and the information for the MS2 gene will be in phase with the coding sequence of FMDV starting at amino acid 9 of coat protein VP1 (Figs 3, 4). Thus, the MS2 sequences can be used to promote polypeptide synthesis of the coat protein VP1, which as a processing product does not have its own initiation signals. A fusion polypeptide of 396 amino acids should be synthesized carrying the N-terminal 99 amino acids of MS2 replicase, 284 amino acids of FMDV and 13 amino acids coded for by the vector. The junction sequences between the MS2 replicase gene and the FMDV DNA at the *Bam*HI site and between the FMDV DNA and the vector DNA at the *Hin*dIII site are shown in Fig. 5.

Hybrid plasmids were constructed as outlined in Fig. 4 and transformed into an *E. coli* C600 r_{k}^{-} m_{k}^{-} (λ) host. Plasmids were isolated from seven colonies which showed a positive response by hybridization to a labelled FMDV probe and analysed for expression. For this purpose the plasmids were retransformed into an *E. coli* K12 ΔHI host[14], where expression from the P_{L} promoter can be controlled by temperature. Plasmids pPL c24 and pBR322 were included as controls.

From each transformation isolates were assayed for VP1-specific antigenic determinants in bacterial extracts (Fig. 6), essentially as described by Broome and Gilbert[15]. Positive results were obtained only with transformants carrying the hybrid plasmids but not with those carrying the vector plasmid pPL c24 (Fig. 6*b*) or pBR322 (Fig. 6*k*). Varying intensities of the positive signals may be due to variation in the preparation of extracts as the inserted plasmids should be the same in the different isolates.

The specificity of the antigenic material in the bacterial extracts was further demonstrated in a series of additional experiments which will be reported in detail elsewhere. An indirect enzyme-linked immunosorbent inhibition assay[16] using mouse anti-VP1 serum confirmed the results reported above. In the radioimmunoassay different sets of experiments showed that the antigenic material produced in the bacterial cell competes efficiently with ^{125}I-labelled FMDV, and that it did not react with labelled mouse anti-VP1 antibodies if these were exposed to FMDV before the test. A 60-fold dilution of the bacterial extract used in Fig. 6*d* was still positive when tested for VP1 in the radioimmunoassay. This indicates that at least 1,000 molecules of antigenic polypeptide are synthesized per cell. Extracts prepared from an *E. coli* C600 r_{k}^{-} m_{k}^{-}(λ) host carrying the plasmid pPL VP1 gave a negative result in the radioimmunoassay, indicating that the synthesis of antigenic material is under control of the P_{L} promoter. Finally, expression experiments in minicells showed that the protein displaying specific antigenicity has the size of the predicted fusion polypeptide.

Taken together, these data suggest that viral protein VP1 can be synthesized in an antigenically active state in *E. coli* cells, and thus may provide a new way of producing a vaccine without the risk of accidental infection by incompletely inactivated virus. The genes for VP1 of other serotypes are of equal interest and should be made available by the same techniques used in the present work. Comparison of the nucleotide sequences specific to the VP1 coding regions might give some insight into the molecular mechanism of antigenic variability in FMDV.

We thank Dr M. Mussgay for his interest and support, E. Bürgelt and M. Kauzmann for technical assistance, and Dr E. Domingo for helpful discussion.

Generation of F_1 hybrid cytotoxic T lymphocytes specific for self H–2

Keiichiro Nakano, Ichiro Nakamura & Gustavo Cudkowicz

Departments of Pathology and Microbiology, School of Medicine, State University of New York at Buffalo, Buffalo, New York 14214

Cytotoxic T lymphocytes specific for self H–2 antigens are generated by murine F_1 hybrid (H–2 heterozygous) spleen cells cultured with irradiated parental (H–2 homozygous) splenocytes. The effectors bind to heterozygous and homozygous cells bearing the appropriate H–2 alleles but only lyse homozygous targets. Autoreactivity for membrane-bound molecules of normal cells may be a mechanism for regulating cellular interactions.

THYMUS-DERIVED lymphocytes are able to recognize autologous membrane-bound molecules coded for by the major histocompatibility complex (MHC). In the mouse, such recognition of self is the basis for the restriction of cell-mediated immune responses against viruses[1], haptens[2–4] and minor histocompatibility antigens[5] by H-2K, H-2D, H-2L and H-2I molecules. Moreover, it is through the recognition of self H-2I molecules that macrophage–lymphocyte interactions lead to immune responses by T and B lymphocytes[6,7]. In spite of the pervasiveness of self MHC recognition in immunology (see a recent discussion by Dausset and Contú[8]), mature effector cells or immunoglobulins specific for, rather than restricted by, self MHC molecules are generally not demonstrable. Regulatory mechanisms presumably prevent or control precursor lymphocyte differentiation and maturation into effectors that would entail autoimmune disorders. However, autoreactivity may be a double-edged sword: if directed against relevant cell-surface molecules such as the MHC products, anti-self effectors may serve to modulate cellular activities and maintain, instead of disrupt, homeostasis. During *in vitro* studies on the induction of F_1 hybrid anti-parent cell-mediated immunity, we have been able to demonstrate the existence of cytotoxic T lymphocytes (CTLs) specifically sensitized against self H–2 molecules. These T lymphocytes were unique in that they were capable of binding to target cells carrying the appropriate H–2 genes in single (heterozygous) or double (homozygous) dose. Most interestingly, the autoreactive CTLs were capable of lysing the homozygous but not the heterozygous targets.

Induction of F_1 anti-parent CTLs

F_1 anti-parent cytotoxic lymphocytes were generated in (C57BL/6×DBA/2)F_1 anti-C57BL/6 (abbreviated B6D2F_1 anti-B6) mixed spleen-cell cultures and tested for cytolytic activity by the release of radioactive ^{51}Cr from prelabelled target cells[9–12]. F_1 hybrid lymphocytes bearing the Thy-1 surface antigen[11], and thus of the T-lymphocyte class, became strongly cytotoxic for thioglycollate-induced peritoneal exudate cells (PECs) of the stimulating parental strain but not for syngeneic F_1 target PECs or for cells of the second parental strain (Fig. 1*a*). The susceptibility of F_1, DBA/2 and B6 targets to immune cytolysis was compared by raising allogeneic CTLs of appropriate specificity and measuring cytolysis simultaneously (Fig. 1*b*, *c*). As all the target cells were specifically lysed by appropriate allogeneic CTLs, the exclusive lysis of B6 PECs by F_1 anti-parent CTLs probably reflects their immunological specificity. Target determinants detected on PECs were also expressed on parental lymphoblasts stimulated by mitogens and on parental lymphoma cells[10,12].

F_1 spleen cells cultured for 5 days without parental stimulators failed to generate specific anti-parent CTLs even though the culture medium contained prescreened fetal calf serum. Low levels of cytotoxic activity were sometimes detectable among such F_1 cells cultured in the presence of fetal calf serum (for example, 10–15% specific lysis), but in these cases cytolysis exhibited no preference for PECs of either parental type and was polyclonal in nature. Thus the induction of specific anti-parent CTLs was strictly contingent on co-culture of responder splenocytes with irradiated stimulator cells.

F_1 anti-parent cytotoxic responses are not limited to the particular strain combination of B6D2F_1 and B6[10,13–15]. CTL specificity was always determined by the strain of the parental cells—B6D2F_1 spleen cells generate anti-B6 or anti-DBA/2 CTLs depending on whether B6 or DBA/2 cells were the stimulators[10]. Similarly, (B6×C3H)F_1 CTLs specific for either B6 or C3H targets can be elicited by using B6 or C3H stimulator cells[14].

The generation of F_1 anti-parent CTLs occurred in conditions identical to those of the conventional, antigen-dependent, allogeneic mixed leukocyte reaction. As the F_1 mice were the offspring of crosses between inbred strain parents, F_1 anti-parent immune responsiveness could be attributed to the exclusive expression of certain alloantigens on homozygous parental cells. Such an interpretation contradicts the immunogenetic laws of transplantation and of immunity to histocompatibility antigens[16,17]. According to these empirical generalizations, the expression of membrane-bound alloantigens eliciting cell-mediated immunity is co-dominant and, thus, not limited to homozygous parental cells. Irradiation of parental

0028–0836/81/070559–05$01.00

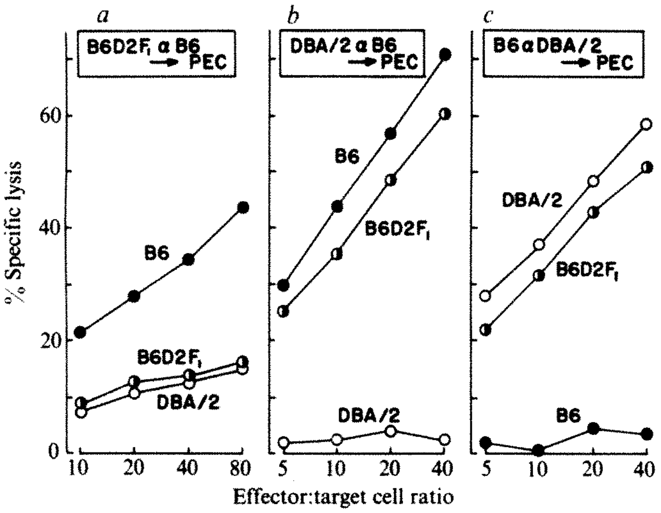

Fig. 1 Direct cytotoxicity of F_1 hybrid anti-parent (*a*) and allogeneic (*b*, *c*) CTLs induced *in vitro*. Primary 5-day mixed-splenocyte cultures of responder and irradiated (2,000 rad of ^{137}Cs γ rays) stimulator cells were set up as described[10,12,14]. The stimulator:responder ratio was 1:1 for F_1/parent and 1:10 for allogeneic cell mixtures; the number of responder cells was held constant at 3.5×10^6 per culture. Cultured spleen cells were tested for cytotoxic activity in 4-h chromium release assays on PECs stimulated by thioglycollate and prelabelled with radioactive ^{51}Cr at the indicated effector:target cell ratios[12,14]. The strains of responder and stimulator cell donors are given in the rectangle at the top of each panel; those of target PEC donors are indicated next to the lines relating cytolysis to the effector:target cell ratio. Per cent specific lysis was calculated according to the formula:

$$\% \text{ Specific lysis} = \frac{\text{experimental} - \text{spontaneous}}{\text{maximum} - \text{spontaneous}} \times 100$$

Spontaneous release was the radioactivity released by target cells in the presence of cultured but nonstimulated spleen cells. Spontaneous release was 15–20% of the maximum release, that is, the radioactivity released by target cells frozen and thawed four times. Experimental release was the radioactivity released by target cells in the presence of cultured, stimulated cells. Standard errors of the mean per cent specific lysis of four replicate samples were consistently below 10% of the mean values. Note that B6D2F$_1$ and DBA/2 PEC targets were lysed to a very limited extent by B6D2F$_1$ anti-B6 CTLs. In contrast, target cells of the same preparations were fully susceptible to lysis by allogeneic CTLs of appropriate specificity.

stimulator cells could have altered membrane structures so as to render them more immunogenic or to express new determinants, but this is unlikely as F_1 anti-parent CTLs can be elicited by nonirradiated, mitomycin C-treated stimulator cells (ref. 15 and our unpublished data) and the CTLs are not specific for irradiated target cells. Generation of autoreactive CTLs in F_1 anti-parent mixed cultures is an alternative explanation. The exclusive lysis of parental targets would then be attributed to the density or other property of membrane epitopes that may distinguish homozygous parental from heterozygous F_1 cells. Although this second interpretation of F_1 anti-parent cytotoxicity is not consistent with immunological theories postulating the elimination of autoreactive clones of lymphocytes at an early stage of development[18,19], the data below show it to be valid.

F_1 hybrid anti-parent CTLs are specific for H-2-controlled molecules

The genetic control of target determinants was investigated by replacing B6 targets (H-2^b) with PECs of various H-2 types (Table 1). If B6D2F$_1$ anti-B6 CTLs were specific for H-2 determinants, any PECs of H-2^b type should be lysed irrespective of the strain of origin, whereas PECs of H-2^a, H-2^d or H-2^k type should not be lysed even if donor mice shared the genetic backgrounds with strains B6 or C57BL/10 (abbreviated B10). The anti-parent CTLs lysed B6, B10 and C3H.B10 PECs, all H-2^b (group 1), but not PECs of strain A, B10.A (H-2^a), DBA/2, B10.D2 (H-2^d) and C3H (H-2^k) mice (group 2). PECs carrying the antigens of recombinant H-2 haplotypes involving chromosomal exchanges between H-2^b and H-2^a, or H-2^b and H-2^d, were lysed only when the b allele was present in the D region (group 3). The genetic background and the presence of the b allele in the K, I-A and I-B regions was irrelevant for target cell lysis as revealed by PECs of B10.A(5R) mice. PECs of F_1 hybrid mice with one copy of the original and one of the recombinant H-2 chromosomes were also tested as targets (groups 4 and 5)—D^b-homozygous PECs were the only F_1 target cells lysed. For all other PECs of F_1 hybrid mice, the values of specific lysis did not exceed background.

In conclusion, the lytic activity of B6D2F$_1$ anti-B6 CTLs was specific for D^b molecules, as indicated by the recombinant analysis of Table 1 and by additional studies with strains dissociating the control of target antigens from genes on both sides of H-2D, that is, from the S region on the centromeric and the Tla region on the telomeric sides of the chromosome[20]. The lack of reactivity of B6D2F$_1$ anti-B6 CTLs with cells of the H-2^a, H-2^d and H-2^k haplotypes suggests that determinants unique to the D^b molecules served as the target antigens. PECs of H-2^q, H-2^s and H-2^u types were also not lysed by F_1 CTLs raised against B6, and antigens of fetal calf serum did not take part in the lytic phase of this response[20].

F_1 hybrid anti-parent CTLs are autoreactive

The reactivity of B6D2F$_1$ anti-B6 CTLs generated in primary mixed spleen-cell cultures was further analysed by competitive inhibition experiments. The lysis of radiolabelled (hot) B6 PECs by F_1 CTLs was tested in the presence of added unlabelled (cold) PECs taken from mice of various inbred strains and F_1 crosses

Table 1 Genetics of target determinants for the lytic activity of B6D2F$_1$ anti-B6 CTLs

F_1 anti-parent CTLs were induced in mixed spleen-cell cultures and tested for cytolytic activity as indicated in the Fig. 1 legend. Target cells were radiolabelled PECs. Alleles at various regions of H-2 are given for the inbred strains used according to recent listings[49,50]. The data of this table are a composite of several experiments. Note that only H-2D^b-homozygous cells were effectively lysed (range of specific lysis 23–36%). All other targets were not effectively lysed: the range of 4–14% specific lysis is regarded as background. These low values varied between experiments and were dependent on the batch of fetal calf serum used during culture. Background lysis did not exhibit any identifiable specificity.

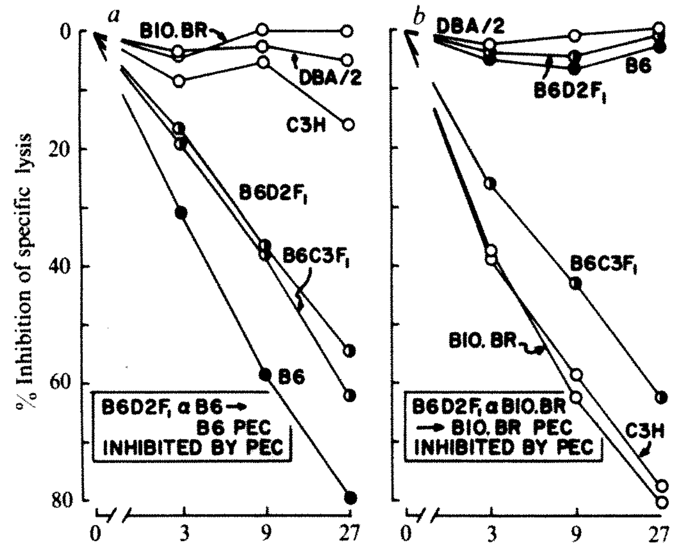

Fig. 2 Competitive inhibition of F_1 hybrid anti-parent (*a*) and F_1 anti-allogeneic (*b*) cell-mediated lympholysis by cold PECs. CTLs were raised in primary mixed spleen-cell cultures and assayed on PEC targets, as described in Fig. 1 legend. The strains of responder, stimulator and target cell donors are given in the rectangle of each panel. The effector : target cell ratio was 40 : 1 in F_1 anti-parent and 20 : 1 in F_1 anti-allogeneic cytotoxicity assays. In the absence of inhibitor PECs, specific lysis of radiolabelled parental B6 targets was 20.5%; that of allogeneic B10.BR(H-2^k) targets was 51.2%. Graded numbers of unlabelled inhibitor PECs were incubated with CTLs for 15–30 min before addition of radiolabelled target PECs. Thus, the number of inhibitor cells was the only variable in the assay mixture. The strains of inhibitor cell donors are given next to the line relating inhibition of lysis to the inhibitor : target cell ratio. Per cent inhibition of specific lysis was calculated according to the formula:

$$\%\ \text{Inhibition of specific lysis} = \left(1 - \frac{\%\ \text{specific lysis in the presence of inhibitors}}{\%\ \text{specific lysis in the absence of inhibitors}}\right) \times 100$$

Note that parental but not allogeneic target cell lysis was inhibited by $B6D2F_1$ PECs syngeneic with the effector cells in both tests. $B6C3F_1$ cells inhibited the lysis of parental targets because of the H-2^b haplotype, and that of allogeneic targets because of the H-2^k haplotype. See Table 1 for the H-2 haplotypes of inbred and F_1 mice used.

(Fig. 2). If the F_1 CTLs were specific for parental antigens not expressed on heterozygous cells, only H-2^b-homozygous, cold PECs should have been inhibitory. However, H-2^b-heterozygous $B6D2F_1$ and $B6C3F_1$, as well as homozygous B6, cold PECs were all able to compete with the hot B6 targets for the F_1 CTLs (Fig. 2*a*). PECs of C3H, B10.BR (H-2^k) and DBA/2 (H-2^d) mice, not bearing the D^b gene product, failed to inhibit target cell lysis, as expected. Heterozygous F_1 PECs were less efficient than homozygous B6 cells in inhibiting F_1 anti-parent cytolysis, presumably due to different gene dosage. The intrinsic ability of cold PECs to inhibit competitively and specifically the lytic activity of CTLs was verified by raising $B6D2F_1$ anti-allogeneic CTLs and conducting simultaneous inhibition assays for allogeneic cytolysis with given cold PEC preparations (Fig. 2*b*). The lytic activity of $B6D2F_1$ anti-allogeneic CTLs was unaffected by the presence of the same syngeneic, cold PECs that inhibited $B6D2F_1$ anti-parental cytotoxicity. Thus, F_1 anti-parent but not F_1 anti-allogeneic CTLs are autoreactive according to competitive syngeneic inhibition tests. A highly unusual feature of the autoreactive CTLs is the ability to bind specifically syngeneic PECs (Fig. 2) without apparently causing lysis (Fig. 1). It is this feature that operationally distinguishes autoreactive CTLs from H-2-restricted effectors specific for foreign antigens. These CTLs, though unable to kill syngeneic targets, are regarded as autoreactive because they specifically bind to target H-2 molecules expressed on their own surface as well as on their precursors.

Inhibition of F_1 anti-parent CTLs was not contingent on the use of PECs as inhibitor cells. Identical results were obtained in experiments in which H-2^b-homozygous, H-2$^{b/d}$-heterozygous and H-2^d-homozygous embryonic fibroblasts served as inhibitor cells instead of PECs (Fig. 3). This experiment was critical for concluding that F_1 anti-parent CTLs are autoreactive. Fibroblasts, unlike lymphocytes, lack receptors for target-cell alloantigens and therefore could not inhibit the lysis of radiolabelled PECs by binding to and masking antigenic sites. Blocking of cytolysis, as opposed to competition for CTLs, was not excluded in experiments with cold PECs which contain assorted lymphoid and nonlymphoid cell types. In addition, fibroblasts are unlikely to express idiotypic determinants and, thus, the data are not consistent with the possibility that F_1 responder lymphocytes engaged in anti-idiotypic cytotoxic responses restricted by H-2.

Genetic mapping of self determinants recognized by F_1 anti-parent CTLs

PECs from inbred and F_1 hybrid mice bearing H-2^b recombinant haplotypes (used in the genetic mapping of target determinants for direct lysis (Table 1)) were tested for the ability to inhibit competitively lysis of parental B6 targets by $B6D2F_1$ anti-B6 CTLs (Fig. 4). All homozygous and heterozygous cells that were D^b-positive inhibited cytolysis, whereas cells with other alleles in the D region, or with the b allele in the K, I-A and I-B regions, failed to inhibit (Fig. 4*a*). The inbred and F_1 cells of HTG, B10.A(2R) and B10.A(4R) origin or parentage were critical in demonstrating that one or two copies of D^b genes were necessary and sufficient for inhibition (see Table 1 for haplotype constitution). All of the critical cells used in this experiment could inhibit allogeneic CTLs raised against either D^b or K^b antigens (Fig. 4*b*, *c*). These controls persuaded us that the specificity of F_1 anti-parent CTLs, rather than possible variations in PEC preparations, determined the outcome of the assay. As the genetic mapping of target antigens for direct lysis (Table 1) agrees fully with that for competitive binding of homozygous

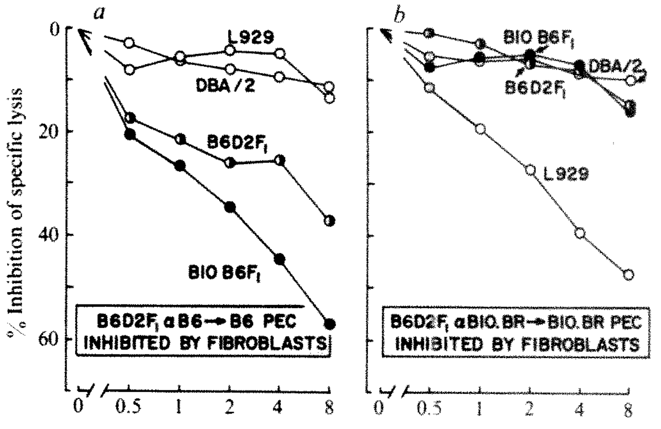

Fig. 3 Competitive inhibition of F_1 hybrid anti-parent (*a*) and F_1 anti-allogeneic (*b*) cell-mediated lympholysis by cold embryonic fibroblasts. CTLs were raised in primary mixed spleen-cell cultures and assayed on PEC targets as described in Figs 1 and 2 legends. The strains of responder, stimulator and target-cell donors are given in the rectangle of each panel. In the absence of inhibitor cells, specific lysis of radiolabelled parental B6 targets was 24.9%; that of allogeneic B10.BR(H-2^k) targets was 66.1%. Inhibition tests of cytolysis were carried out as described in Fig. 2 legend except for replacing PECs with cultured embryonic fibroblasts or transformed L929 fibroblasts. The strains of inhibitor cell donors are given next to the lines relating inhibition of lysis to the inhibitor : target cell ratio. $B10B6F_1$ stands for $(B10 \times B6)F_1$ hybrids (homozygous H-2^b). Primary monolayer cultures of fibroblasts were set up from near-term embryos and maintained for four to six serial passages before use. L929 fibroblasts are of C3H origin (H-2^k). Note the similarity between results of inhibition tests with PECs (Fig. 2) and with fibroblasts.

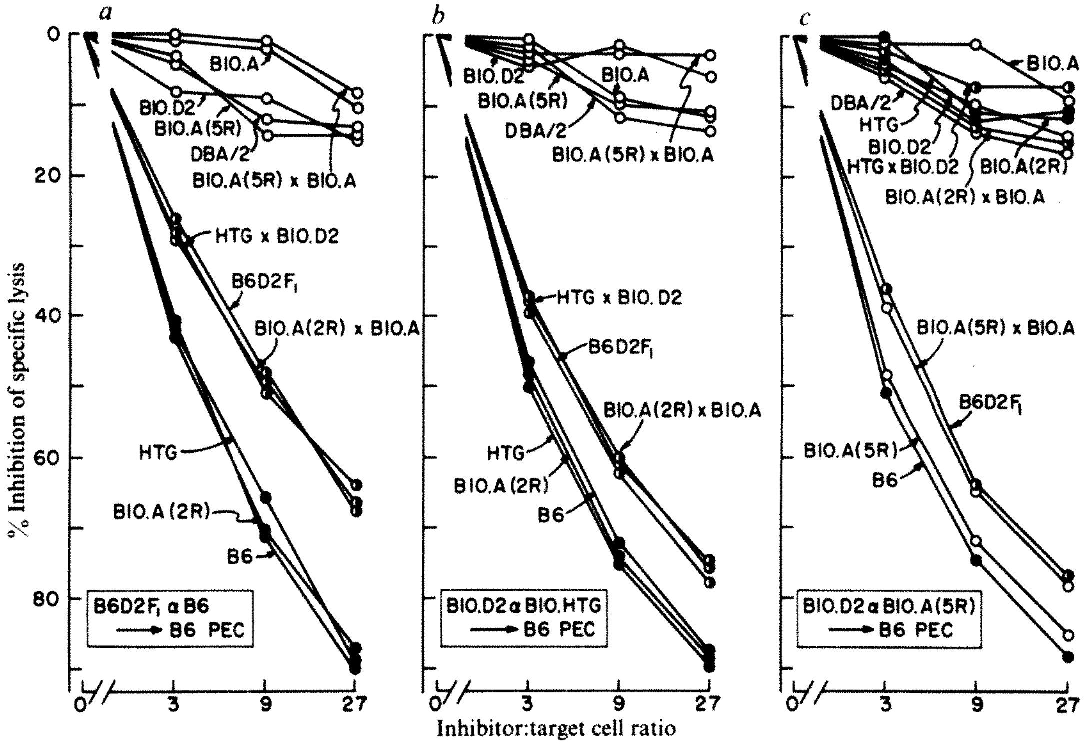

Fig. 4 Genetics of target determinants for the binding activity of B6D2F$_1$ anti-B6 CTLs in competitive inhibition tests. F$_1$ anti-parent and allogeneic CTLs were raised in primary mixed spleen-cell cultures and assayed on PEC targets, as described in Figs 1 and 2 legends. The strains of responder-, stimulator- and target-cell donors are given in the rectangle of each panel. In the absence of inhibition, specific lysis of radiolabelled parental B6 targets by F$_1$ CTLs was 23.7% (*a*); specific lysis of the same targets by allogeneic anti-H-2D^b (*b*) and anti-H-2K^b (*c*) CTLs was 40.2% and 33.1%, respectively. Inhibition tests of cytolysis were carried out as described in Fig. 2 legend. The strains of inhibitor PEC donors are given next to the inhibition lines; H-2 haplotypes of the mice used are indicated in Table 1. Note that one copy of the D^b allele was necessary and sufficient for [B10.A(2R)×B10.A]F$_1$ and (HTG×B10.D2)F$_1$ PECs to inhibit cytolysis by B6D2F$_1$ CTLs (*a*). Similar results were obtained with [B10.A(4R)×B10.A]F$_1$ and B10.A(4R) PECs (not shown because of crowding). Note also the verification of the competence and specificity of D^b+K^b−, D^b+K^b+, D^b−K^b+ and D^b−K^b− PECs for inhibiting allogeneic cytolysis directed against either D^b (*b*) or K^b (*c*) alloantigens.

and heterozygous PECs (Fig. 4), we conclude that the reactivity of B6D2F$_1$ anti-B6 CTLs is directed to self antigens controlled by H-2D^b. Studies with mixed splenocyte cultures of other F$_1$/parental strain combinations indicate that this type of autoreactivity is not exceptional—F$_1$ CTLs raised against parental H-2^d or H-2^k cells are specific for self antigens controlled by H-2D^d, H-2L^d (ref. 21) and H-2K^k (ref. 14), respectively. Such CTLs also bind to homozygous and heterozygous PECs, but only lyse the former (I. N., J. F. Warner and G.C. unpublished data). To our knowledge, there is no precedent for lysis-negative, inhibition-positive target cells in specific cell-mediated immune responses.

Requirements for induction of anti-self H-2 immune responses

This and other publications[9-15,20-22] and our unpublished studies show that effector T lymphocytes specific for self H-2 products can readily and consistently be generated *in vitro* from spleen cells of conventional, untreated, adult F$_1$ hybrid mice. The target structures for such CTLs are expressed on normal and transformed lymphoid cells[9-15], fibroblasts[22] and peritoneal exudate cells[12,14]. Most important, nonstimulated peritoneal cells freshly explanted and maintained in medium free of fetal calf serum served as targets, indicating that normal cells do express the target structures for autoreactive CTLs[20].

The major genetic requirement was the H-2 heterozygosity of responder cells to be cultured with homozygous stimulator cells. In the conditions used, autoreactive CTLs were not obtained in primary cultures of H-2-homozygous splenocytes with and without irradiated syngeneic or allogeneic cells. Autoreactive F$_1$ CTLs were specific for molecules controlled by one end of the non-recombinant H-2 complex even though heterozygosity extended to both ends[14,15,20,21]. F$_1$ spleen cells are competent, however, to generate more than one major population of CTLs—B6D2F$_1$ anti-DBA/2 CTLs reactive with D-end products include at least two independent subpopulations, one specific for D^d and the other for L^d molecules[21]. Moreover, the stimulation of F$_1$ splenocytes with homozygous cells bearing an appropriate H-2 recombinant haplotype may result in the independent generation of CTL clones specific for products of both ends of H-2, for example, D^b and K^k (ref. 14).

The particular conditions in which autoreactive CTLs were raised may account for, first, the requirement of responder-cell heterozygosity, and second, the CTL properties of strict stimulator-directed specificity and of inability to lyse heterozygous target cells. Major phenotypic differences between the homozygous and heterozygous cells are due to the effect of gene dosage. Although H-2 gene products are co-dominantly expressed on heterozygous cells[23], the products of both alleles may not necessarily be expressed in equivalent amount or fashion[24]. Moreover, interallelic and intergenic 'hybrid or interaction determinants' exist for murine I-region products[25,26] and for erythrocyte antigens of rabbits[27] and pigeons[28]. It is, therefore, conceivable that allelic interactions at the genetic and phenotypic levels result in quantitative and/or qualitative differences in expression of H-2 molecules on the surface of heterozygous and homozygous cells. Such differences could explain why homozygous cells provide optimal immunogenic stimuli for the induction of autoreactive F$_1$ CTLs, and why the binding of CTLs to heterozygous targets fails to trigger lytic events. However, noncytolytic F$_1$ cells of the effector preparation may exert autoinhibition and the results would be the same—lysis of heterozygous targets would be inhibited more effectively than that of homozygous targets.

It has been shown previously that irradiated parental spleen cells depleted of T lymphocytes[12] or of phagocytic cells adherent to plastic or Sephadex G-10 (ref. 29) cannot function as stimulators of F$_1$ anti-parent responses. Parental phagocytic-adherent cells expressing I-region antigens are the most effective antigen-presenting cells in this system (ref. 29 and unpublished data of W. W. Freimuth and G.C.). Parental T lymphocytes, which by themselves stimulate rather weakly, may provide a triggering signal through back stimulation and release of lymphokines[12]. The effectiveness of purified, phagocytic-adherent stimulator cells may be attributed to presentation of self H-2 molecules to CTL precursors, coupled with the induction of syngeneic mixed-leukocyte reactions[30-32] and release of cytokines or other factors. Thus the generation of autoreactive CTLs involves at least two steps: (1) activation of F_1 CTL precursors by nonspecific diffusible mediators, and (2) selection and differentiation of CTL clones driven by self immunogen.

Autochthonous or spontaneous *in vitro* generation of anti-self H–2 CTLs by lymphoid cells of inbred or F_1 mice has been described by several investigators[32–36]. Deliberate stimulation was either not applied or was provided for by irradiated syngeneic spleen cells. In the context of the suggested model, allogeneic effect factor[32,33] and fetal calf serum[34–36] may have provided directly or indirectly the activating stimuli. Autologous or syngeneic cells present in the culture may have been the source of immunogen. In the absence of potent helper factors, or in conditions less favourable than those of mixed F_1/parent spleen-cell cultures, the generation of autoreactive CTLs is likely to be erratic and part of a broader, polyclonal lymphocyte activation[37–39]; such CTLs may be restricted by, rather than directed against, self H–2. In an interesting model of spontaneous generation of CTLs[36], the age of F_1 mice donating lymphoid cells was a critical variable, and the expression of target determinants on parental and syngeneic F_1 lymphoblasts was transient after stimulation with mitogen. Endogenous viral antigens that become expressed on stimulated lymphocytes[40–42] may have been recognized by these CTLs in the context of self H–2 determinants.

The induction of F_1 anti-parent CTLs has its closest parallel in the production of anti-self H–2 antibodies by F_1 hybrid mice immunized with cells of a parental Abelson virus-induced lymphoma[43]. The antibodies were specific for H–2D and H–2K antigens expressed on normal and neoplastic cells of H–2 homozygous and heterozygous mice. The successful induction of autoreactive B-lymphocyte effectors specific for self H–2 antigens apparently depended on the heterozygosity of responder mice, homozygosity of immunizing cells and probably on the diffusible mediators that virus-infected lymphoma cells release or induce. Hybrid resistance to parental grafts of normal or malignant haematopoietic cells[9,44–46] may represent yet another response to self H–2 determinants mediated by effectors of the natural killer (NK) type[47,48]. Like the autoreactive T- and B-lymphocyte responses, this F_1 host resistance involves recognition of, and reactivity against, the products of H–2-associated genes of homozygous parental target cells. However, no evidence has been obtained for cytotoxic or other activity (for example, cytostatic) of NK-like effectors against syngeneic targets.

We thank Vita Milisauskas for cultured embryonic fibroblasts. K.N. was on leave from the Department of Medicine and Physical Therapy, University of Tokyo, Japan. This work was supported by NIH grants AM-13969 and CA-12844, and American Cancer Society grant IM-212.

Production of anti-self H–2 antibodies by hybrid mice immune to a viral tumour

Rex Risser & David J. Grunwald

McArdle Laboratory for Cancer Research, University of Wisconsin, Madison, Wisconsin 53706

During the course of immunization of hybrid mice (genotype $H\text{–}2^{b/k}$*) with a parental Abelson virus-induced lymphoma (genotype* $H\text{–}2^{b/b}$*), antibodies were produced to the* $H\text{–}2K^b$ *or* $H\text{–}2D^b$ *antigens of the immunizing cells. Such 'anti-self H–2' antibodies demonstrate the existence of autoreactive B-cell clones in hybrid mice, and pose intriguing questions for the nature of self-tolerance.*

THE success or failure of tissue grafts among inbred mice has been found to conform to certain empirically derived laws, one being that grafts from an inbred homozygous parent are accepted by hybrid offspring made between the donor strain and another inbred strain[1,2]. A corollary of this law is that hybrids do not generate cell-mediated or humoral immune responses to the parental graft, that is, they are tolerant to grafts of parental tissues[3–5]. The major histocompatibility complex (MHC) of the

0028–0836/81/070563–06$01.00

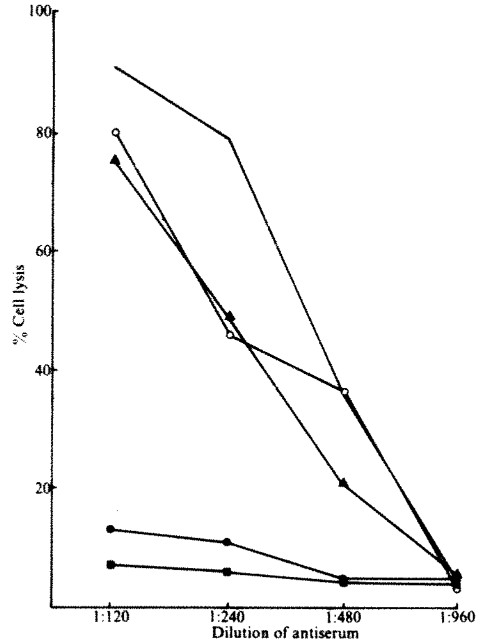

Fig. 1 Absorption of (C3H × B6)F_1 anti-B6T1 (S41 no. 2) antiserum with normal spleen cells from *H-2* congeneic mice. Cytotoxicity tests were performed on B6T1 cells as described[15] using preselected rabbit serum (dilution 1:7) as a complement source. Absorption experiments were performed as described elsewhere[15] by incubating 5×10^7 nucleated spleen cells with 120 μl of antiserum (dilution 1:120). Cells used for absorption: —, none; ●, B6 ($H\text{-}2^b$); ■, B10 ($H\text{-}2^b$); ○, B10.BR ($H\text{-}2^k$), and ▲, B6.C-H-2^d ($H\text{-}2^d$). Absorption with $H\text{-}2^b$ cells removed cytotoxic antibodies, whereas absorption with congeneic $H\text{-}2^d$ or $H\text{-}2^k$ cells did not.

mouse, *H-2*, controls these cell interactions, partly by specifying the genetically dominant expression of polymorphic transplantation antigens at the surfaces of all somatic cells[1,2,6].

Exceptions to the law of hybrid acceptance of parental grafts were noted in early tumour transplantation studies[7,8] and have also been observed in spleen and bone marrow cell transfers in certain strain combinations[9,10]. In the latter case it has been proposed that these exceptions reflect the expression of antigens by homozygous but not heterozygous mice[10]. A locus for such haematopoietic histocompatibility or Hh antigens displayed on parental cells and recognized by F_1 mice has been mapped to chromosome 17 of the mouse in the *H-2D* region[11]. The search for *in vitro* correlates of hybrid histocompatibility led to the discovery of induced and spontaneous F_1 anti-parent cytotoxic T-lymphocyte responses[12], the determinants of which also map to *H-2D* or, in some instances, to *H-2K*[13]. Because the recognition of a variety of antigens by cytotoxic T lymphocytes has been shown to require *H-2K* or *H-2D* identity on target and effector cells[14], it is unclear whether these F_1 anti-parent cytotoxic T-lymphocyte responses reflect responses to some additional antigen (perhaps Hh or viral) whose recognition is *H-2* restricted or true anti-MHC autoreactivity.

During the course of immunizations of various hybrid mice with a parental transplanted lymphoma induced by the Abelson murine leukaemia virus, we observed a serological correlate of hybrid rejection of parental tumour cells. Here we characterize this serological response and demonstrate that it is directed to the H-2K and H-2D molecules of the parental cells, although such products can also be found on cells of the responding hybrid.

A high titre of cytotoxic antibodies was produced when [C3H/HeJ × C57BL/6(B6)]F_1 mice were hyperimmunized with the transplanted B6 Abelson virus lymphoma B6T1[15]. Antiserum from one such hyperimmune mouse (S41 no. 2) was cytotoxic for the immunizing cell with a mid-point titre of 1:320. However, when antiviral antibodies were removed from the antiserum by absorption with tissue culture cells (non-$H\text{-}2^b$) producing virus, cytotoxic antibodies remained that reacted with the immunizing lymphoma cell. When the serum was absorbed a second time with bone marrow cells from each of the seven BALB/c × B6 recombinant inbred strains of Bailey[16], cells from strains carrying the $H\text{-}2^b$ allele of B6 removed cytotoxic reactivity for B6T1 but cells from the strains carrying $H\text{-}2^d$ of the BALB/c allele did not (data not shown). These results suggested that at least one antibody present in antiserum from mouse S41 no. 2 detected a cell-surface antigen on B6T1 that was shared with normal spleen cells carrying the $H\text{-}2^b$ allele. To confirm that such antibodies detected antigens controlled by the $H\text{-}2^b$ haplotype, unabsorbed antiserum was diluted 1:120 then absorbed once with spleen cells from uninfected B6, C57BL/10 (B10), congeneic B6.C-H-2^d or congeneic B10.BR ($H\text{-}2^{k/k}$) mice and tested in cytotoxic tests with B6T1 target cells. The results of this experiment, shown in Fig. 1, demonstrated that the major antigens detected on B6T1 cells in cytotoxic tests with this antiserum were also expressed on normal spleen cells of B6 or B10 mice but not on spleen cells of $H\text{-}2^d$ or $H\text{-}2^k$ congeneic partner strains.

If such antibodies were directed to the H-2 determinants expressed on normal cells, then they would be expected to lyse normal spleen cells from H-2^b-carrying mice. This antiserum lysed 95% of spleen cells from B6, B10, 129 and (C3H × B6)F_1 mice but did not lyse spleen cells from C3H/HeJ, B10.BR, B10.A or B6.C-H-2^d mice, a result that clearly demonstrated the reactivity of this serum for determinants specified by the $H\text{-}2^b$ haplotype[17] (Fig. 2).

Response of hybrid mice to immunization with B6T1

The unusual nature of the reactivities found in the preceding antiserum prompted us to examine several other hybrid mice for production of anti-self H-2 antibodies. To do this we screened for antibodies that lyse 95% of spleen cells from B6 or B10 mice but show low (0–25%) lysis of spleen cells from B6.C-H-2^d or B10.D2n($H\text{-}2^d$) mice in direct cytotoxic tests with these cells. The results of this survey (Table 1) indicated that several hybrid mice which survived hyperimmunization produced cytotoxic

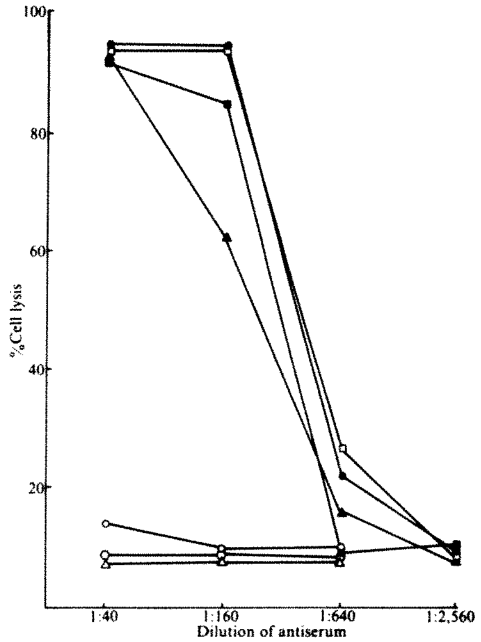

Fig. 2 Direct cytotoxic tests with (C3H × B6)F_1 anti-B6T1 (S41 no. 2) antiserum were performed as described[15] on spleen cells of: ●, B6; □, B10; ▲, 129 ($H\text{-}2^b$); ■, (C3H × B6)F_1 ($H\text{-}2^{k/b}$); ○, B10.BR; △, B6.C-H-2^d; and ○, C3H ($H\text{-}2^k$) mice using preselected rabbit serum (dilution 1:15) as a complement source. Normal spleen cells of mice bearing only the $H\text{-}2^b$ haplotype were lysed by this antiserum.

Table 1 Immunization and antibody response of hybrid mice

Mouse	Immunogen	No. mice immunized	No. surviving 10^8 cells	No. producing αH–2^b/No. screened
(C3H × B6)F_1 10–13 months	—	—	—	0/11
(BALB/c × B6)F_1 15 months	—	—	—	0/6
(C3H × B6)F_1	B6 bone marrow	10	10	0/10
B6	B6T1	113	15	0/15
(C3H × B6)F_1	B6T1	16	5	3/5
(C57BR × B6)F_1	B6T1	11	3	1/3
(BALB/c × B6)F_1	B6T1	15	2	1/2
(SEA × B6)F_1	B6T1	11	1	0/1

Female mice 8–12 weeks old were inoculated subcutaneously with 10^2 B6T1 cells, and tumours that developed were allowed to regress before a second intraperitoneal challenge of 10^2 cells was given. In alternate weeks mice were immunized with 10-fold increasing dose of cells until a plateau of 10^8 cells per mouse was achieved, and this immunization dose was maintained for the life of the animal. The initial immunization with bone marrow cells was 10^6 cells. Mice were bled individually 10 days after immunization, and antiserum, diluted 1 : 20, was screened for cytotoxic activity on B6 and B6.C–H–2^d, or B10 and B10.D2n spleen cells. Mice were considered positive for H–2^b antibody if their sera lysed 95% of spleen cells from the H–2^b strain. No antiserum sample lysed >30% of spleen cells from the respective congeneic (B6.C–H–2^d or B10.D2n) strains.

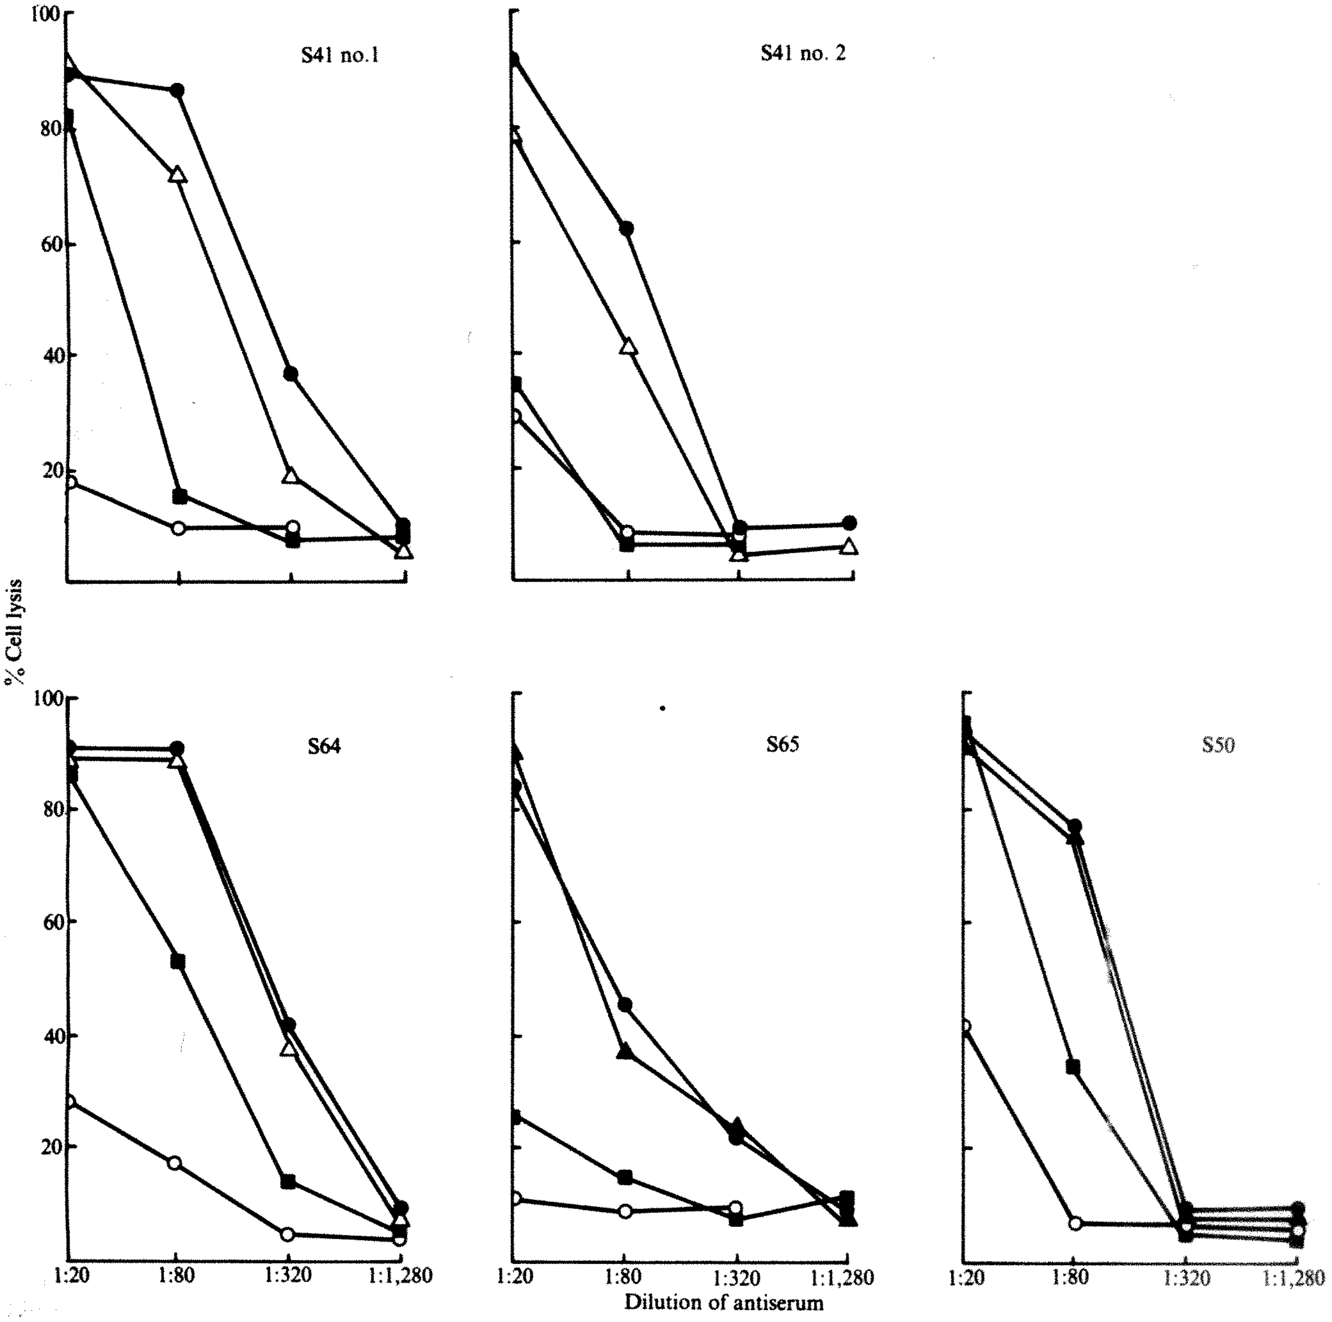

Fig. 3 Genetic mapping of antigens recognized by anti-self H–2 antisera. Antisera were assayed in direct cytotoxic tests on: ●, B10; △ and ▲, B10.A(5R) (*H–2K^b^, D^d^*); ■, B10.A(2R) (*H–2K^k^, D^b^*); and ○, B10.A (*H–2K^k^, D^d^*) cells as described elsewhere[15] using preselected rabbit serum (dilution 1 : 15) as a complement source. All five hybrid sera which contained anti-H–2^b antibodies recognized H–$2K^b$ antigens, and three of these sera (S41 no. 1, S64, S50) also recognized H–$2D^b$ antigens.

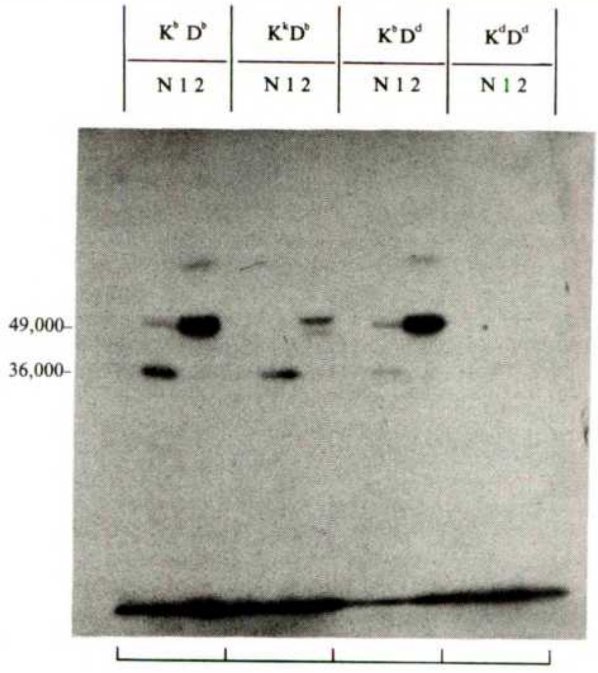

Fig. 4 Reactivity of antisera from hybrid mice with parental H–2K^b and/or H–2D^b molecules. 3×10^7 spleen cells from B10, B10.A(2R), B10.A(5R) and B10.D2n mice in 1 ml phosphate-buffered saline (PBS) were radiolabelled with 2 mCi Na^{125}I by the lactoperoxidase method[31,32]. Cells were washed with PBS, resuspended in 0.8 ml hypotonic buffer (10 mM Tris-HCl, *p*H 7.4, 10 mM NaCl, 1.5 mM $MgCl_2$, 1% Trasylol [protease inhibitor, FBA]) and lysed by the addition of 0.2 ml lysis buffer (50 mM $NaHPO_4$, *p*H 7.2, 4.5% NaCl, 5% Triton X-100, 2.5% sodium deoxycholate, 0.5% SDS)[33]. Lysates were centrifuged at 1,500*g* for 20 min to remove nuclei. Each lysate was then mixed with 3 ml of a 10% suspension of formalin-fixed *Staphylococcus aureus* bacteria (Cowan I strain)[34] and centrifuged at 120,000*g* for 90 min. This procedure removed all iodinated immunoglobulin molecules capable of binding the protein A-bearing bacteria. 10 μl of each antiserum was incubated with 2×10^6 c.p.m. of each lysate and immune complexes were collected by the addition of 200 μl of the *S. aureus* suspension. The immunoprecipitates were washed four times in RIPA buffer[35] (10 mM Tris-HCl, *p*H 7.2, 150 mM NaCl, 1% sodium deoxycholate, 1% Triton X-100, 0.1% SDS, 1% Trasylol), solubilized by heating to 100 °C for 5 min in sample buffer (0.0625 M Tris-HCl, *p*H 6.8, 10% glycerol, 5% 2-mercaptoethanol, 3% SDS, 0.001% bromophenol blue) and electrophoresed through a discontinuous 10% SDS-polyacrylamide slab gel according to the method of Laemmli[36]. For visualization of protein markers, gels were fixed and stained in 0.05% Coomassie brilliant blue in a solution containing ethanol/acetic acid/water (5 : 1 : 5) and destained in 7.5% acetic acid/5% ethanol. Dried gels were exposed to Kodak X-Omat R film in the presence of an intensifying screen. K^bD^b, K^kD^b, K^bD^d and K^dD^d refer to the *H–2* genotypes of the spleen cells from the B10, B10.A(2R), B10.A(5R) and B10.D2n strains, respectively. Tracks labelled N, 1 and 2 refer to the antisera used: N, normal mouse serum; 1, (C3H × B6)F_1 anti-B6T1, S41 no. 2; and 2, (BALB/c × B6)F_1 anti-B6T1, S50.

anti-H–2^b antibodies. As the data in Table 1 indicate, most of the mice challenged with this tumour do not survive, thus insufficient numbers were available to determine whether the production of anti-self H–2 antibodies was detrimental to the health of the animals. We can say, however, that the five hybrid mice which produced anti-H–2^b antibodies survived at least six challenges with 10^8 B6T1 cells, and one mouse, a (C57BR × B6)F_1, lived 15 months (20 challenges of 10^8 B6T1 cells) after its initial anti-H–2^b response was detected. This mouse (S65) was killed because it seemed to be lymphomatous. Autopsy revealed a massive lymphoma involving the mesenteric lymph node, liver and thymus, and histological examination also revealed glomerulonephritis. Washed cells from the tumour were lysed in cytotoxicity tests with conventional anti-H–2^b and anti-H–2^k antisera as well as the anti-self H–2 antiserum of that mouse, thus the lymphoma was of recipient and not immunizing cell origin. It remains to be determined whether the tumour, which was of recipient genotype, arose as a consequence of virus infection or autoimmune reactions.

Sera from 11 aged non-immune (C3H × B6)F_1 or six aged non-immune (BALB × B6)F_1 mice did not show appreciable reactivity (≤15% lysis) for B6 spleen cells, nor did antisera from 10 (C3H × B6)F_1 mice hyperimmunized with B6 bone marrow cells show reactivity for H–2^b spleen cells. Furthermore, antisera from 15 B6 mice hyperimmunized with the same B6T1 lymphoma cells did not have significant cytotoxic activity for B6 spleen cells, although all of these antisera contained antibody cytotoxic for B6 Moloney murine leukaemia virus (MuLV) leukaemias (recognition of the Friend–Moloney–Rauscher antigen[18]), and several contained antibody specifically cytotoxic for B6 Abelson lymphomas (recognition of the Abelson lymphoma antigen[15]).

Genetic mapping of determinants recognized by anti-self H–2 antibodies

Antisera from each of the five mice that produced anti-H–2^b antibodies were tested for direct cytotoxic activity on spleen cells of B10, B10.A, B10.A(2R) and B10.A(5R) mice (Fig. 3). All antisera reacted well with B10 and B10.A(5R) cells as >95% of spleen cells were lysed with titration mid-points of 1 : 160–1 : 640. Two antisera also reacted well with B10.A(2R) cells, and one antiserum (S64) reacted weakly with B10.A(2R) (95% lysis with a titration mid-point of 1 : 40). None of the antisera lysed more than 30% of spleen cells from B10.A. These results indicate that antigens controlled by the *H–2K–IA–IB* or *H–2K–IA–IB* plus *H–2D* subregions of the *H–2^b* but not *H–2^d* nor *H–2^k* haplotypes are recognized by these anti-self H–2 antisera. The lack of reactivity with cells of the *H–2^d* or *H–2^k* haplotypes excludes many public specificities of *H–2^b* haplotype from these antisera. We have also tested spleen cells of SWR (*H–2^q*), RIII/2J (*H–2^r*), PL (*H–2^u*) and B10.M (*H–2^f*) mice for sensitivity to lysis by these antisera, because these haplotypes also share public specificities[17] with *H–2^b*. As none of these spleen cells was lysed to an appreciable extent by anti-self H–2 antisera, we conclude that the major reactivity of these antisera is directed to the private specificities controlled by *H–2^b*.

Molecular identity of species recognized by anti-self H–2 antisera

To identify the molecule(s) on spleen cells that was recognized by these antisera, cells from B10, B10.A(2R), B10.A(5R) and B10.D2n were radiolabelled by the ^{125}I-lactoperoxidase technique, lysates prepared and immunoprecipitated with anti-self H–2 antiserum or normal mouse serum. Immunoprecipitates were electrophoresed through polyacrylamide gels containing SDS, and the results analysed autoradiographically. Each of the antisera showed strong reactivity with molecules of molecular weights (MW) ~49,000 and ≤13,000 (the dye front) on B10 or B10.A(5R) cells (Fig. 4). One antiserum, which reacted well in cytotoxic tests with B10.A(2R) cells, showed strong precipitating activity for molecules of MW 49,000 and ≤13,000 on these cells, whereas another antiserum (S64) that had a lower cytotoxic titre (1 : 40) on B10.A(2R) cells precipitated less material of these molecular weights. Reactivity for molecules of MW 37,000 was also noted with B10 and B10.A(5R) cells. No reactivity was observed with any molecule on B10.D2n cells.

Because the major molecules precipitated by these antisera co-migrate with the H–2K or H–2D heavy chains[19], we sought to confirm that the major protein recognized by anti-self H–2 sera was the *H–2K*^{b} product. We did this by removing the H–2K^b molecule from lysates by immunoprecipitation with conventional antisera, and then determining if molecules recognized by anti-self H–2 sera remained in the lysates. The results of this 'preclearing' experiment, presented in Fig. 5, demonstrate that preclearing of B6 radiolabelled lysates with conventional anti-H–2K–IA–IB^b antisera removed the major molecules reactive with anti-self H–2 sera, whereas preclearing with normal mouse serum (Fig. 5) or conventional anti-H–2^k (data not shown) did not. Therefore we conclude that the major species recognized by the antiserum of mouse S64 [(C3H×B6)F$_1$ anti-B6T1] on normal B6 spleen cells is the molecule carrying the H–2K^b transplantation antigens. Similar experiments have confirmed the identity of the principal molecules recognized by other anti-self H–2 antisera as being the *H–2K*^{b} product.

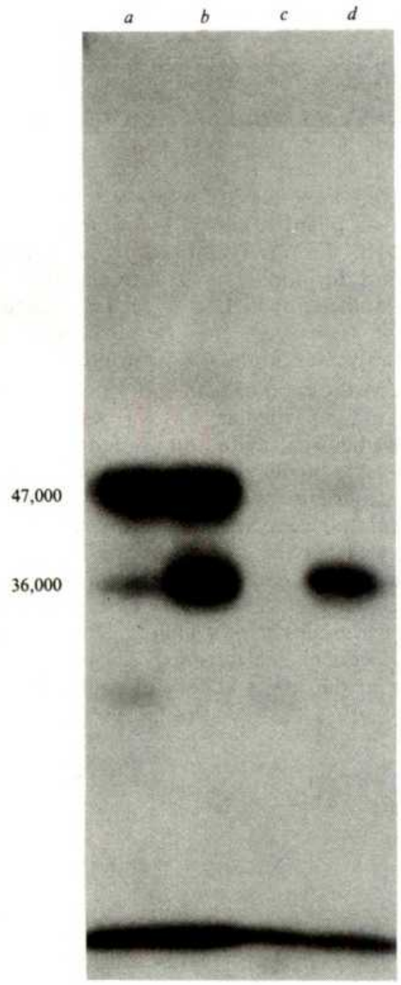

Fig. 5 Hybrid anti-self H–2 antisera and conventional anti-H–2K^b antisera recognize the same molecules. A single-cell suspension of B6 spleen cells was prepared and iodinated by the lactoperoxidase method. The cells were lysed and precleared with 3 ml of a 10% suspension of *S. aureus* bacteria as described in Fig. 4 legend. The lysate was then divided into two equal parts. One aliquot (lanes *a*, *b*) was incubated with 25 µl of normal mouse serum and the other (lanes *c*, *d*) was incubated with 25 µl of conventional anti-H–2K^b serum [(A×B10.D2)F$_1$ anti-B10.A(5R)]. The immune complexes were removed by the addition of 600 µl of the bacterial suspension followed by centrifugation. The supernatant of each reaction was further subdivided into two equal portions and incubated with 25 µl of anti-H–2K^b antiserum (lanes *a*, *c*) or 25 µl of (C3H×B6)F$_1$ antiserum (lanes *b*, *d*). These immunoprecipitation reactions were analysed by SDS-polyacrylamide gel electrophoresis as described in Fig. 4 legend.

Discussion

We have demonstrated that hybrid mice can generate a brisk humoral immune response to the major histocompatibility antigens presented on a parental virally induced leukaemia, although the hybrid mice also express those same histocompatibility antigens on their somatic cells. These results establish unambiguously the existence of autoreactive anti-MHC B-cell clones in hybrid mice. Earlier studies showed that not all immunizations of hybrid mice with parental tumours elicit anti-self H–2 antibodies. The Moloney cell-surface antigen (MCSA)[20], the X.1 antigen[21], and the Meth A antigen[22] were each detected by antisera from F$_1$ mice immunized with parental tumour cells, and no anti-self H–2 antibodies were detected in those sera. Anomalous anti-H–2 reactions are not without precedent, however, as demonstrated by the recent description of anti-H–2^k cytotoxic antibodies in the sera of mutant BALB/c mice immunized with normal BALB/c lymphoid cells[23].

The phenomenon of hybrid humoral response to parental antigens is reminiscent of the phenomenon of hybrid resistance to parental tumour grafts[10]. Two major features distinguish the humoral response described here from the *in vivo* phenomenon of F$_1$ rejection of parental bone marrow grafts or tumour grafts. First, the antigens detected on B6 cells by hybrid resistance map to the *H–2D* region, whereas those detected by anti-self H–2 antibodies map to the *H–2K* and *H–2D* regions. Second, the antigens detected in this serological study are expressed on heterozygous cells, whereas those detected in graft rejection do not seem to be. Furthermore, we did not detect anti-H–2^b antibody in (C3H×B6)F$_1$ hybrid mice immunized with B6 bone marrow, a strain combination that displays hybrid resistance[11].

Recent work on the induction of F$_1$ anti-parent cytotoxic T-lymphocyte responses by co-cultivation of F$_1$ spleen cells with homozygous parental cells[24,25], by treatment with allogeneic effect factor[26], or spontaneously[24,25] provide considerable evidence for the existence of autoreactive cytotoxic T-cells in the generation of cellular immune responses. Although the antigens recognized by F$_1$ anti-parent cytotoxic T-lymphocytes mapped to *H–2K* or *H–2D*, this apparent autoreactivity may reflect an H–2 compatibility requirement in conjunction with some other, perhaps endogenous viral, antigen and not cytotoxic function directed to the MHC product itself. Our present serological observations have no such ambiguity, and clearly demonstrate the possibility of humoral immune functions directed to self MHC products.

Ample evidence supports the physical and functional association of *H–2* products with oncornavirus glycoproteins[27–30], and it may be that the H–2 molecules of the tumour are recognized as foreign only in conjunction with unusual viral determinants. The failure to obtain anti-self H–2 antibodies from B6 mice immunized with this tumour might reflect the need for a proper immune response gene to recognize the unusual viral determinant. Note, however, that B6 mice are quite capable of responding to several viral antigens expressed on these cells[15]. Moreover, when anti-self responses were observed in hybrid mice, such anti-self H–2 antibodies were the major cytotoxic activities of the serum as demonstrated by absorption tests.

The observation here that normal bone marrow immunization did not elicit anti-self H–2 antibodies and the failure of earlier workers to observe such antibodies[20,21] in F$_1$ antiviral tumour immunizations may indicate that the anti-self response is only triggered by some novel, non-viral property of this tumour cell. Considered in that context, the failure of homozygous B6 mice to produce anti-self H–2 antibodies raises two questions regarding this response. First, whose antibodies are reactive with the H–2^b molecules, those of C3H or B6? Second, which genes must be heterozygous for this response to occur? It is possible, although unlikely, that self-reactive antibodies are absent from the repertoire of immunoglobulin genes of an inbred strain. More intriguing however, is the possibility that autoreactivity is itself generated by MHC heterozygosity. The resolution of the questions posed by the observation of anti-self H–2 antibodies will be of importance in the study of the generation and regulation of the immune response.

γ-Ray observations of Cygnus X-3 at energies of 10^{12}eV

S. Danaher, D. J. Fegan & N. A. Porter

Physics Department, University College, Dublin, Ireland

T. C. Weekes

Mount Hopkins Observatory, Harvard-Smithsonian Center for Astrophysics, Amado, Arizona 85640

The Crimean Observatory group have detected γ rays from the direction of the X-ray source Cyg X-3 (refs 1–5): rays of energy 10^{12}eV were observed using the atmospheric Cerenkov technique. Measurements with satellite-borne instruments in the 10^8 eV region have shown effects from Cyg X-3 in one case[6], but not in another[7]. Similarly, γ rays have been seen in some balloon flights[8], but not in those of McKechnie *et al.*[9] nor of White *et al.*[10]. A study using the atmospheric Cerenkov technique at 10^{11} eV showed no effect[11], though it has been shown to be compatible with the Crimean result[4]. We report here observations taken at Mount Hopkins Observatory, Arizona (altitude 2.3 km) in April, May and June 1980 using a similar system to that of Stepanian *et al.*[3], which seem to confirm, at least qualitatively, the Crimean results.

The Crimean group found a periodic signal with the same 4.8-h period as the X rays, and having two peaks: a narrow main one centred at 0.18 periods after X-ray minimum, and a broader interpulse at 0.7–0.8 periods after X-ray minimum. They have also reported a sporadic non-periodic effect. Recently (Stepanian, personal communication) they have found that the interpulse peak dominates over the main one.

In the present series of observations two mirrors of diameter 1.5 m were used, with a 5-cm photomultiplier and aperture stop at the focus of each, giving a full field of view of 2.0°. Coincidences were taken between the two detectors with a resolving time of 7 ns, and were recorded on magnetic tape together with pulses from the single detectors, and random coincidences. Current controlled servo lamps kept the background light constant. Observations were made in drift scans lasting 30 min each: 10 min before the source entered the field (OFF), 10 min in the field (ON), and a final 10 min outside the field (OFF). A scan was rejected if (1) the OFF parts of the scan divided into 120 10-s intervals failed a Poisson homogeneity test at the 1% level, (2) the two OFF observations differed by more than two Poisson standard deviations, or (3) if in any 10-s interval, the count rate was sufficiently high to give a 4σ departure from the mean. Of 139 scans on Cyg X-3, 95 were acceptable. These were taken at various phases on the 4.8-h period.

Figure 1 shows the ratio of ON/OFF rates plotted in 10 bins corresponding to the particular phases of X-ray emission. Standard errors have been calculated experimentally, for each phase bin and are ~14% higher than the Poisson values, consistent with previous experience with the Cerenkov technique. Phases have been calculated using Stepanian's constants and formulae. The ratios are clearly close to unity except at the interval from 0.7 to 0.8, which has a 3.5σ deviation from unity. The number of counts involved are: ON 799, OFF 662 before and 668 after transit. Three drift scans were available. Random coincidences and single rates were normal during the scans. The apparent flux corresponding to the effect at the interpulse is $\sim 1.5 \times 10^{-10}$

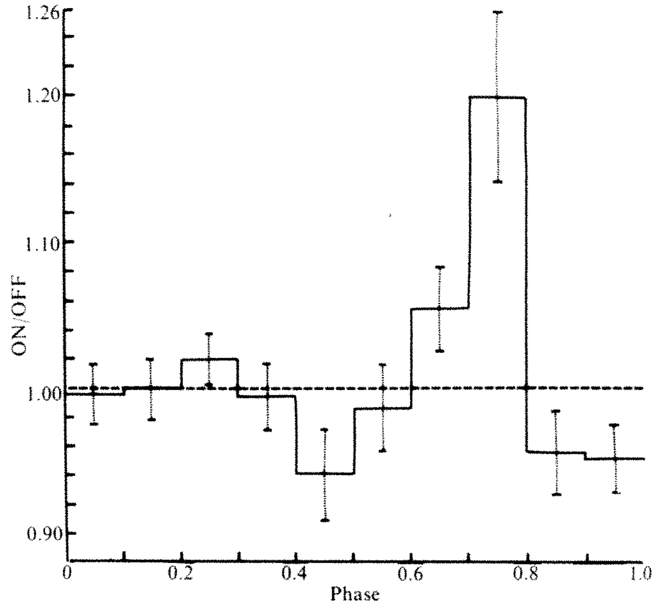

Fig. 1 Phase histogram of γ-ray emission from Cyg X-3.

photons cm^{-2} s^{-1} in good agreement with the value of 9×10^{-11} photons cm^{-2} s^{-1} quoted in ref. 4, and the threshold energy is $\sim 2\times10^{12}$eV, similar to that of the Crimean group.

While there is some slight uncertainty in the period and period derivative for Cyg X-3, (refs 12, 13), our phases are directly comparable with the Crimean results as we have used the same constants. We therefore seem to have confirmed, at least qualitatively, their observations. Note that the phase of the peak in our results corresponds to maximum emission for lower energy γ rays[6] and for X rays[14]. If the Cerenkow measurements are accepted as indicating a flux of high energy γ rays, they favour models which require a young pulsar[15]. A periodic analysis of the high-energy data may reveal the predicted 4–20 ms rotation.

We thank Dr A. A. Stepanian for communicating results before publication, the National Board for Science and Technology of Ireland, and the Smithsonian Scholarly Studies Fund, for partial support.

Effect of a surrounding star cluster on a magnetoid

Martin Lugg

Department of Physics, University College of Wales, Penglais,
Aberystwyth SY23 3BZ, UK

Magnetoids—supermassive rotating highly magnetic stars—have long been considered[1–4] as models of the power sources of active galactic nuclei, but previous studies have taken no account of interaction with neighbouring matter. We now show that interaction with a star cluster (of a kind likely to exist near the nucleus of a galaxy) will disrupt the main body of a nuclear magnetoid forming a dense core which is liable to explosion and/or gravitational collapse. The lifetime of such a magnetoid is estimated at 10^4 yr, too short to explain the activity of quasars and Seyfert galaxies (which might, nevertheless, be accounted for by residual black holes).

A magnetoid is assumed to form from gas falling into the central potential well of a galaxy and collapsing until a quasi-equilibrium state is reached, with radiation pressure, centrifugal and magnetic forces balancing gravity. Subsequent evolution involves a slow contraction during which gravitational potential energy is converted to rotational energy, which is then lost through equatorial mass shedding and magnetic-dipole radiation. Typical magnetoid parameters required to explain highly active nuclei are a mass $M\sim10^8M_\odot$ and a radius $R\sim10^{16}$ cm, giving a mean density $\bar\rho_m\sim10^{-8}$ g cm^{-3}.

Previous investigations have considered the magnetoid mainly as an isolated body, with little attention being paid to its surroundings, in particular the dense star cluster contained in the centre of the parent galaxy. Our Galaxy, for example, has a stellar core of density $\sim10^7M_\odot\,\mathrm{pc}^{-3}$ out to $\gtrsim0.1$ pc (ref. 5), values which should at least be matched in more active nuclei. Such a star cluster will have a dramatic effect on a recently formed magnetoid.

Here we assume the star cluster has an isotropic velocity distribution so that the collision frequency of stars with the magnetoid is $f=n_*\sigma V_0$, where n_* is the number density of stars, V_0 is their velocity dispersion and $\sigma(=\pi r_0^2)$ is the collision cross-section; r_0 is the impact parameter at which an incoming star will just graze the magnetoid. We take as typical a cluster of size $r_c\sim1$ pc containing $n_*\sim10^7$ stars pc^{-3} of average mass $m_*\sim1M_\odot$ surrounding a magnetoid of mass $10^8M_\odot$; then $V_0\simeq(GM/r_c)^{1/2}\simeq6\times10^7$ cm s^{-1} and the collision frequency

$$f\simeq200\,M_8^{1/2}R_{16}\quad\mathrm{yr}^{-1}\tag{1}$$

with M_8 being the magnetoids mass in units of $10^8M_\odot$ and R_{16} its radius in units of 10^{16} cm. A colliding star on its passage through the magnetoid will experience a drag force of

$$F_*=m_*\dot V_*\simeq\rho_m\pi r_*^2v_*^2\tag{2}$$

r_*, v_* are the radius and velocity of the star respectively. We take the magnetoid to be modelled by a polytrope of index 3, as usual for supermassive stars, and use the density function $\rho_m(r)$ computed by Monaghan and Roxburgh[6]. This model gives a central condensation, $\rho_c/\bar\rho_m=54.2$, thinning to a large diffuse envelope with $\rho_m<\rho_c/100$ for $r>0.58R$. Equation (2) can be written in the form

$$\frac{\mathrm{d}E_*}{\mathrm{d}s}=\frac{-2\pi}{m_*}\rho_m(s,x)E_*r_*^2\tag{3}$$

where s is the distance a star has travelled in the magnetoid, and x is the impact parameter. Using a polynomial fit to $\rho_m(s,x)$ equation (3) was integrated to obtain the energy lost by a star in one passage of the magnetoid, ΔE_*, as a function of impact parameter. The percentage energy loss reached a maximum of 15% for a star passing through the centre of the magnetoid.

The equation for ΔE_* was then integrated over x, assuming that the stars collide evenly over the magnetoid cross-section. This gave the average percentage energy loss per collision as 0.96%. The energy loss $\Delta E_*(x)$ equals the average $\langle\Delta E_*\rangle$ at $x=0.43R$ so 18% of the stars lose more than 1% of their impact energy in one collision. With an impact energy $E_i\simeq GMm_*/R$ the average energy loss per collision is

$$\langle\Delta E_*\rangle=2.6\times10^{49}M_8^2R_{16}^{-3}(r_*/r_\odot)^2\quad\mathrm{erg}\tag{4}$$

spread over a crossing time of $\lesssim1$ yr. This energy is deposited in the magnetoid at a rate given by equations (1) and (4) as

$$L_*=f\langle\Delta E_*\rangle\simeq3.7\times10^{44}M_8^{5/2}R_{16}^{-2}(r_*/r_\odot)^2\quad\mathrm{erg\,s^{-1}}\tag{5}$$

which is small compared with the magnetoid's thermal luminosity, L_{th}. For a supermassive star radiation pressure dominates gas pressure and the thermal luminosity is given by the Eddington critical luminosity, L_{Edd}, at which radiation pressure and gravity balance,

$$L_{\mathrm{th}}=L_{\mathrm{Edd}}=1.3\times10^{46}M_8\quad\mathrm{erg\,s^{-1}}\tag{6}$$

Since $\langle\Delta E_*\rangle\simeq10^{-2}E_i$ a star requires an average of ~100 collisions before its orbit lies entirely within the magnetoid. However, $\langle\Delta E_*\rangle$ is much greater than the star's original kinetic energy in the cluster, $E_0=\frac{1}{2}m_*V_0^2\simeq2.5\times10^{48}$ erg, so that after one collision a star becomes bound to the magnetoid and collides on every subsequent orbit to become captured after ~100 orbits or $\sim10^4$ yr.

The initial capture rate of $\gtrsim100$ stars yr^{-1} can only be maintained while there are stars in low angular momentum orbits; when these orbits become depleted the subsequent capture rate depends on the rate of refilling them by angular momentum diffusion in the cluster. The orbits get refilled in a

0028-0836/81/070569-02$01.00

time not much shorter than the relaxation time scale, $t_r \simeq V_0^3/G^2 m_*^2 n_* \log(N/2) \simeq 10^9$ yr (ref. 7), required to randomize the orbits completely. This is much greater than the 10^4 yr required to capture a star, so once the low angular momentum orbits have been emptied the capture rate drops sharply. The collision cross-section of the magnetoid, $\sigma = \pi r_0^2 = 2\pi GMR/V_0^2 \simeq 3.5 \times 10^{-2}\,\mathrm{pc}^2$, so for an isotropic cluster of radius ~1 pc the magnetoid will capture an estimated fraction 1/100 of the cluster, or $\sim 10^5$ stars, before the capture rate drops.

We now consider the effect of these captured stars on the magnetoid as they continue to lose energy and sink towards the magnetoid's centre. Ablation of a stellar envelope occurs when $\rho_m(r) V_*^2 > \rho_e V_{esc}$ (ref. 9), where ρ_e is density of the stellar envelope and V_{esc} the escape velocity from the star, that is when

$$\rho_e < 1.7 \times 10^{-3} (V_*/V_i)^2 (\rho_m(r)/\rho_c)(M_*/M_\odot)^{-1}(r_*/r_\odot) \quad \mathrm{g\,cm^{-3}} \tag{7}$$

where V_i is the impact velocity of a star with the magnetoid, about $10^9\,\mathrm{cm\,s^{-1}}$. A solar-type star passing through the centre of the magnetoid, thus loses the part of its envelope rarer than $1.7 \times 10^{-3}\,\mathrm{g\,cm^{-3}}$, which is the outer 0.1 $r_\odot$, or $10^{-4} M_\odot$. A red giant[8] of $1.3 M_\odot$, however, would be stripped down to around one-sixth of its original radius and one-third of its original mass. The detailed picture will depend on how evolved the galactic nucleus is at the time of magnetoid formation, but in any case dwarf and sub-dwarf stars will outnumber giants, and ablation is not likely to be important except near the centre of the magnetoid. In a counter-effect, as the dwarf stars slow down they will accrete mass from the magnetoid envelope at a rate[9]

$$A \sim \frac{2\pi (G m_*)^2 \rho_m}{V_*^3} \sim 10^{-5} (m_*/m_\odot)^2 (V_*/10^8\,\mathrm{cm\,s^{-1}})^{-3} M_\odot \quad \mathrm{yr^{-1}} \tag{8}$$

and carry it further into the magnetoid, though this is negligible for $V_* \gtrsim 10^7\,\mathrm{cm\,s^{-1}}$.

Another possible effect will be fragmentation of the gas in the magnetoid due to the differential gravitational pull of the stars. This can occur when the average density in the form of stars, $\bar{\rho}_*$, exceeds the gas density, $\bar{\rho}_m$, in a certain region[10]; that is, when 10^5 solar-type stars are confined within a radius r_c from the magnetoid's centre where $r_c = 2.6 \times 10^{14} M_8^{-1/3} R_{16}$ cm. To reach this state a star has to lose 96% of the energy it had when initially captured, a process taking only $\sim 10^3$ yr.

Finally the stars will be colliding with each other at a rate $f_c \simeq 2\pi N n_* r_*^2 V$. For 10^5 stars confined within a radius r_c, $V \simeq 10^8 (r_c/10^{15}\,\mathrm{cm})^{-1/2}\,\mathrm{cm\,s^{-1}}$, so $f_c \simeq 200\ (r_c/10^{15}\,\mathrm{cm})^{-7/2}\,\mathrm{yr^{-1}}$. The energy released ($\sim 10^{48}$ erg per collision) will tend to disrupt the magnetoid and aid fragmentation, while the debris will help to slow down other incoming stars.

The net effect of these processes is to concentrate mass, in the form of a dense core of coalescing stars and gas, in the centre of the magnetoid. For a star cluster initially having an isotropic velocity distribution this core will have insufficient angular momentum to prevent it collapsing to normal stellar densities and beyond. Collapse may be stopped by a nuclear explosion if the core has a mass $\lesssim 1.5 \times 10^5 M_\odot$ (ref. 11), otherwise the core collapses to a black hole.

It thus seems inevitable that a magnetoid (or any other form of supermassive star) formed in an ordinary galactic nucleus will be disrupted in a time $\sim 10^4$ yr by the processes described, to leave a dense star cluster (the higher angular momentum part of the original cluster) surrounding a black hole of either $\sim 10^5$–$10^6 M_\odot$ if no core explosion occurred, or $\sim 10^2$–$10^3 M_\odot$ as a remnant of an explosion. Such a black hole will then grow and be able to power an active galactic nucleus[12] for the $> 10^6$ yr required for Seyfert galaxies and quasars.

I thank Drs J. Frank and D. F. Falla for helpful discussions, and acknowledge receipt of a Research Studentship from the SRC.

Atmospheric transport of soil dust from Africa to South America

J. M. Prospero, R. A. Glaccum & R. T. Nees

Rosenstiel School of Marine and Atmospheric Science, University of Miami, 4600 Rickenbacker Causeway, Miami, Florida 33149

The arid and desert regions of North Africa are a prolific source of atmospheric dust. This dust is, for example, responsible for the 'red snows' reported in the Alps and Pyrenees[1] and for dust falls further north in Europe[2–6], but these phenomena are infrequent and sporadic. By contrast, the transport of mineral dust into the tropical North Atlantic is common and often produces a widespread dense haze[7]. Investigations in the past 15 yr[8–11] have shown that, in the summer months[12,13], the distribution of dust is related to macro and micro-meteorological circumstances, that the dust often reaches altitudes of 5–7 km and that it may be spread over several hundreds of kilometres in latitude and extend to the Caribbean Sea and the south-east United States. We report here the results from an aerosol sampling station at Cayenne, French Guiana, which indicate that large quantities of soil dust are being carried out of North Africa and across the Atlantic during the winter months as well but at this time of year the transport is primarily to South America.

A seasonal meteorological control on African dust transport can be inferred from a 15-yr mineral aerosol study[10] carried out on Barbados, West Indies (13°10′N, 59°30′W). There is a pronounced annual cycle in dust concentration with the maximum occurring during the summer; monthly mean winter concentrations are 10–100 times lower. The seasonal cycle in dust concentration at Barbados is apparently not due to any cessation of dust transport out of Africa during the winter months—the dust haze along the west coast of Africa occurs more frequently in winter than in the summer[14]. However, the winter haze distribution is shifted about 10° to the south of the

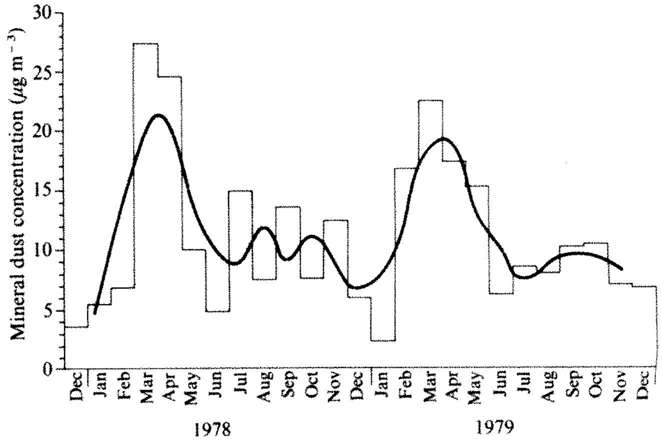

Fig. 1 Monthly arithmetic mean mineral dust concentration in the surface-level air at Cayenne, French Guiana. The heavy line is the three month moving average. The means are computed from nominal 24-h daily samples.

Table 1 Mineral composition of soil aerosols

summer distribution. Thus, this seasonal cycle at Barbados could be due to the seasonal southward shift of the large-scale circulation patterns over Africa and the tropical Atlantic. The continued dust activity in Africa during the winter and the consequent haze distribution suggested that the principal dust transport trajectories might be found in the latitudes south of that of Barbados. To test this hypothesis, we established an aerosol sampling station in Cayenne, French Guiana (4°50'N, 52°22'W) in December 1977; the station has been in continuous operation ever since then.
